Although melatonin is a hormone, it is marketed as a dietary supplement—not as a drug. As a result, melatonin is not regulated by the FDA and has not been reviewed for safety and efficacy. Because melatonin is not regulated, commercial preparations may contain impurities and may not have the exact amount of melatonin advertised on the label (typically 0.3, 1.5, or 3 mg). Melatonin is the only hormone that can be purchased without a prescription. It is available in health-food stores, vitamin shops, and even airport newsstands.

Several small, short-term trials suggest that melatonin can promote sleep. For example, doses of 0.3 to 1 mg taken 1 to 2 hours before bedtime hastened onset of sleep and the time to REM sleep, without reducing total time in REM sleep. At a slightly higher dose (2 mg of a controlled-release formulation 2 hours before bedtime), melatonin hastened sleep onset by 14 minutes and decreased total time awake during the night by 24 minutes. When taken in huge doses (80 to 100 mg) at noon, melatonin can cause daytime fatigue. In blind insomniacs, taking melatonin for 3 weeks normalized the melatonin production cycle and relieved insomnia. Because small doses may fail to elevate melatonin levels throughout the night, maintenance of sleep may be best with larger doses or with sustained-release formulations.

Benefits of melatonin in jet lag are in doubt. Two older studies suggest that melatonin can help. In one, the severity and duration of jet lag were reduced by taking 5 mg of melatonin once daily for 3 days before the flight and for 3 days after. In the other, subjective feelings of fatigue were reduced by taking 8 mg at 10:00 PM on the evening of the flight and for 3 days after. However, these results were not supported by a large, double-blind trial reported in 1999. This trial involved 257 Norwegian physicians flying home from New York. They were randomly assigned to one of four regimens: placebo, 0.5 mg of melatonin at bedtime, 5 mg at bedtime, or 0.5 mg taken at bedtime on the first night and then progressively earlier each day after. Dosing started on the day of their flight and continued for 5 days after. The result? Melatonin had no effect: Symptoms of jet lag in all three treatment groups were the same as those in the placebo group.

When used short term in low doses (eg, under 2 mg), melatonin has not caused observable adverse effects. In contrast, short-term use of large doses has caused hangover, headache,

nightmares, hypothermia, and transient depression. In one case, reversible psychosis occurred with a huge daytime dose. Possible adverse effects of long-term use are unknown.

In conclusion, melatonin is the miracle that awaits definitive proof. Although benefits in jet lag seem unlikely, small studies on insomnia *have* been encouraging. However, large-scale, long-term, carefully controlled trials are needed to prove that melatonin is truly safe and effective for insomnia, and to establish optimal dosages and dosing schedules.

35.3.3 Pharmacokinetics.

Absorption is rapid and nearly complete, although food can reduce both the rate and extent of absorption. Despite generally good absorption, the absolute bioavailability of ramelteon is very low—only 1.8%, owing to extensive first-pass metabolism, primarily by hepatic CYP1A2 (the 1A2 isozyme of cytochrome P450). Much of each dose is converted to an active metabolite, designated M-II, that contributes to therapeutic effects. The half-lives of the parent drug and active metabolite average 2 to 5 hours. In patients with hepatic impairment, elimination is delayed and drug levels can rise. Renal impairment does not affect drug levels.

35.3.4 Adverse Effects.

Ramelteon is very well tolerated. In clinical trials, the incidence of adverse effects was nearly identical to that of placebo. The most common side effects are somnolence (5% vs. 3% with placebo), dizziness (5% vs. 3%), and fatigue (4% vs. 2%). According to the FDA, ramelteon may share the ability of benzodiazepines to cause sleep driving and other sleep-related complex behaviors.

Ramelteon can increase levels of prolactin and reduce levels of testosterone. As a result, the drug has the potential to cause amenorrhea, galactorrhea, reduced libido, and fertility problems. If these occur, the prescriber should be consulted.

35.3.5 Physical Dependence and Abuse.

There is no evidence that taking ramelteon leads to physical dependence or abuse. As a result, ramelteon is the first FDA-approved sleep remedy that is not regulated under the Controlled Substances Act.

35.3.6 Drug Interactions.

Fluvoxamine [Luvox], a strong inhibitor of CYP1A2, can increase levels of ramelteon more than 50-fold. Accordingly, the combination should be avoided. Weaker inhibitors of CYP1A2 should be used with caution. Alcohol can intensify sedation, and hence should be avoided.

35.3.7 Precautions.

Ramelteon should be used with caution by patients with moderate hepatic impairment, and should be avoided by those with severe impairment. Because ramelteon promotes sedation, patients should be advised to avoid dangerous activities, such as operating a motor vehicle or heavy machinery.

35.3.8 Use in Pregnancy and Breast-Feeding.

Very high doses (197 times the human dose) are teratogenic in rats. Effects during human pregnancy have not been studied. Until more is known, prudence dictates avoiding the drug during pregnancy (or at least using it with caution). Ramelteon is not recommended for use by nursing mothers.

35.3.9 Preparations, Dosage, and Administration.

Ramelteon [Rozerem] is available in 8-mg tablets. The usual dosage is 8 mg taken 30 minutes before bedtime. Because food reduces absorption, ramelteon should not be taken with or immediately after a high-fat meal.

35.4 BARBITURATES

The barbiturates (pronounced bahr-bi-tewr'-ates or bahr-bitch'-oo-rates) have been available for more than 100 years. These drugs cause relatively nonselective depression of CNS function and are the prototypes of the general CNS depressants. Because they depress multiple aspects of CNS function, barbiturates can be used for daytime sedation, induction of sleep, suppression of seizures, and general anesthesia. Barbiturates cause tolerance and dependence, have a high abuse potential, and are subject to multiple drug interactions. Moreover, barbiturates are powerful respiratory depressants that can be fatal in overdose. Because of these undesirable properties, barbiturates are used much less than in the past, having been replaced by newer and safer drugs—primarily the benzodiazepines and benzodiazepine-like drugs (eg, zolpidem). However, although their use has declined greatly, barbiturates still have important applications in seizure control and anesthesia. Moreover, barbiturates are valuable from an instructional point of view: By understanding these prototypic agents, we gain an understanding of the general CNS depressants as a group, along with an appreciation of why barbiturates are no longer used for anxiety and insomnia.

35.4.1 Classification

The barbiturates can be grouped into three classes based on duration of action: (1) ultrashort-acting agents, (2) short to intermediate-acting agents, and (3) long-acting agents. As indicated in

[Table 34-3](#), the duration of action of these drugs is inversely related to their lipid solubility. Barbiturates with the highest lipid solubility have the shortest duration of action. Conversely, barbiturates with the lowest lipid solubility have the longest duration.

Duration of action influences the clinical applications of barbiturates. The ultrashort-acting agents (eg, thiopental) are used for induction of anesthesia. The short to intermediate-acting agents (eg, secobarbital) are used as sedatives and hypnotics. The long-acting agents (eg, phenobarbital) are used primarily as antiseizure drugs.

35.4.2 Mechanism of Action

Like benzodiazepines, barbiturates bind to the GABA receptor–chloride channel complex (see [Fig. 34-1](#)). By doing so, these drugs can (1) enhance the inhibitory actions of GABA and (2) directly mimic the actions of GABA.

Since barbiturates can directly mimic GABA, there is no ceiling to the degree of CNS depression they can produce. Hence, in contrast to the benzodiazepines, these drugs can readily cause death by overdose. Although barbiturates can cause general depression of the CNS, they show some selectivity for depressing the *reticular activating system* (RAS), a neuronal network that helps regulate the sleep-wakefulness cycle. By depressing the RAS, barbiturates produce sedation and sleep.

35.4.3 Pharmacologic Effects

35.4.3.1 CNS Depression.

Most effects of barbiturates—both therapeutic and adverse—result from generalized depression of CNS function. With increasing dosage, responses progress from sedation to sleep to general anesthesia.

Most barbiturates can be considered nonselective CNS depressants. The main exception is phenobarbital, a drug used to control seizures. Seizure control is achieved at doses that have minimal effects on other aspects of CNS function.

35.4.3.2 Cardiovascular Effects.

At hypnotic doses, barbiturates produce modest reductions in blood pressure and heart rate. In contrast, toxic doses can cause profound hypotension and shock. How? At high doses, barbiturates depress the myocardium and vascular smooth muscle—as well as all other electrically excitable tissues.

35.4.3.3 Induction of Hepatic Drug-Metabolizing Enzymes.

Barbiturates stimulate synthesis of hepatic microsomal enzymes, the principal drug-metabolizing enzymes of the liver. As a result, barbiturates can accelerate their own metabolism and the metabolism of many other drugs.

Barbiturates stimulate drug metabolism by promoting the synthesis of porphyrin ([Fig. 34-2](#)). Porphyrin is then converted into heme, which in turn is incorporated into cytochrome P450, a key component of the hepatic drug-metabolizing system.

35.4.4 Tolerance and Physical Dependence

35.4.4.1 Tolerance.

Tolerance is defined as reduced drug responsiveness that develops over the course of repeated drug use. When barbiturates are taken regularly, tolerance develops to many—but not all—of their CNS effects. Specifically, tolerance develops to sedative and hypnotic effects and to other effects that underlie barbiturate abuse. However, even with chronic use, *very little tolerance develops to toxic effects*.

In the tolerant user, doses must be increased to produce the same intensity of response that could formerly be achieved with smaller doses. Hence, individuals who take barbiturates for prolonged periods—be it for therapy or recreation—require steadily increasing doses to achieve the effects they desire.

Figure 34-2 Induction of hepatic microsomal enzymes by barbiturates. By increasing synthesis of porphyrin, barbiturates increase production of cytochrome P450, a key component of the hepatic drug-metabolizing system.

TABLE 34-3 Characteristics of Barbiturate Subgroups

Barbiturate Subgroups	Representative Drug	Lipid Solubility	Time Course		Applications
			Onset (min)	Duration (hr)	
Ultrashort-acting	Thiopental	High	0.5	0.2	Induction of anesthesia; treatment of seizures
Short- to intermediate-acting	Secobarbital	Moderate	10–15	3–4	Treatment of insomnia
Long-acting	Phenobarbital	Low	60 or less	10–12	Treatment of seizures

375

376

Figure 34-3 Development of tolerance to the toxic and subjective effects of barbiturates. With prolonged barbiturate use, tolerance develops. However, less tolerance develops to toxic effects than to desired effects. Consequently, as duration of use increases, the difference between the dose producing desirable effects and the dose producing toxicity becomes progressively smaller, thereby increasing the risk of serious harm.

It is important to note that *very little tolerance develops to respiratory depression*. Because tolerance to respiratory depression is minimal, and because tolerance does develop to therapeutic effects, with continued treatment, the lethal (respiratory-depressant) dose remains relatively constant while the therapeutic dose climbs higher and higher ([Fig. 34-3](#)). As tolerance to therapeutic effects increases, the therapeutic dose grows steadily closer to the lethal dose—a situation that is clearly hazardous.

As a rule, tolerance to one general CNS depressant bestows tolerance to all other general CNS depressants. Hence, there is cross-tolerance among barbiturates, alcohol, benzodiazepines, general anesthetics, chloral hydrate, and a number of other agents. Tolerance to barbiturates and the other general CNS depressants does *not* produce significant cross-tolerance with opioids (eg, morphine).

35.4.4.2 Physical Dependence.

Prolonged use of barbiturates results in physical dependence, a state in which continued use is required to avoid an abstinence syndrome. Physical dependence results from adaptive neurochemical changes that occur in response to chronic drug exposure.

Individuals who are physically dependent on barbiturates exhibit cross-dependence with other general CNS depressants. Because of cross-dependence, a person physically dependent on barbiturates can prevent withdrawal symptoms by taking any other general CNS depressant (eg, alcohol, benzodiazepines). As a rule, cross-dependence exists among all of the general CNS depressants. However, there is no significant cross-dependence with opioids.

The general CNS depressant abstinence syndrome can be severe. Contrary to popular understanding, abrupt withdrawal from general CNS depressants is more dangerous than withdrawal from opioids. Although withdrawal from opioids is certainly unpleasant, the risk of serious injury is low. In contrast, the abstinence syndrome associated with general CNS depressants can be fatal.

The following description illustrates how dangerous withdrawal from general CNS depressants can be. Early reactions include weakness, restlessness, insomnia, hyperthermia, orthostatic hypotension, confusion, and disorientation. By the third day, major convulsive episodes may develop. Approximately 75% of patients experience psychotic delirium (a state similar to alcoholic delirium tremens). In extreme cases, these symptoms may be followed by exhaustion, cardiovascular collapse, and death. The entire abstinence syndrome evolves over approximately 8 days. The intensity of symptoms can be greatly reduced by withdrawing general CNS depressants slowly.

A long-acting barbiturate (eg, phenobarbital) may be administered to facilitate the withdrawal process. Because of cross-dependence, phenobarbital can substitute for other CNS depressants, and can thereby suppress symptoms of withdrawal. Because phenobarbital leaves the body slowly, treatment permits a gradual transition from a drug-dependent state to a drug-free state. When phenobarbital is given to aid withdrawal, its dosage should be reduced gradually over 10 days to 3 weeks.

It is important to note that physical dependence should not be equated with addiction. Addiction is defined as a behavior pattern characterized by continued drug use despite physical, psychologic, or social harm. Although physical dependence can contribute to this behavior pattern, physical dependence, by itself, will neither cause nor sustain addictive behavior. The distinction between addiction and physical dependence is discussed further in [Chapter 37](#) (Drug Abuse I: Basic Considerations).

35.4.5 Pharmacokinetics

Lipid solubility has a significant impact on the pharmacokinetic properties of individual barbiturates. As noted, barbiturates of high lipid solubility have a rapid onset and brief duration. Onset is rapid because lipid solubility allows these drugs to penetrate the blood-brain barrier with ease, thereby reaching sites of action quickly. As they undergo uptake by tissues other than the brain, levels in plasma fall, creating a concentration gradient favoring movement from the brain back into the blood. As a result, highly lipid-soluble barbiturates undergo rapid redistribution from the brain back into the blood and then into other tissues. This redistribution terminates CNS effects.

In comparison to the highly lipid-soluble agents, barbiturates of lower lipid solubility have effects of relatively slow onset but prolonged duration. Onset is delayed because low lipid solubility impedes passage across the blood-brain barrier. Effects are prolonged because termination is dependent on renal excretion and hepatic metabolism—processes that are slower than simple redistribution from the brain to other tissues.

With the exception of the highly lipid-soluble agents, all of the barbiturates have long half-lives. These half-lives are so long, in fact, that significant amounts remain in plasma more than 24 hours after giving a single dose. This persistence has two clinical consequences: First, when barbiturates are taken at night to promote sleep, residual drug may cause sedation the following day. Second, since barbiturates are not eliminated entirely in 24 hours, daily administration produces accumulation. As a result, the brain undergoes continuous exposure to progressively higher levels of drug—a phenomenon that promotes tolerance.

35.4.6 Therapeutic Uses

35.4.6.1 Seizure Disorders.

Two barbiturates—phenobarbital and mephobarbital—are employed to treat seizure disorders (see [Chapter 24](#)). These drugs suppress seizures at doses that are essentially nonsedative.

35.4.6.2 Induction of Anesthesia.

Thiopental and other highly lipid-soluble barbiturates are given to induce general anesthesia (see [Chapter 27](#)). Unconsciousness develops within seconds of IV injection.

35.4.6.3 Insomnia.

By depressing the CNS, barbiturates can promote sleep. However, because they can cause multiple undesired effects, barbiturates have been replaced by benzodiazepines and related drugs as treatments of choice for insomnia.

35.4.6.4 Other Uses.

Barbiturates have been used to treat acute manic states and delirium. In children, they can decrease restlessness secondary to colic, pylorospasm, and whooping cough. In addition, they can help reduce anxiety in children prior to minor dental and medical procedures. Excessive excitation from overdose with CNS stimulants (eg, amphetamine, theophylline, ephedrine) can be decreased with barbiturates. They can also be employed for emergency treatment of convulsions caused by tetanus, eclampsia, and epilepsy. When administered in anesthetic doses, barbiturates can help reduce mortality from head injury; deep anesthesia reduces the brain's requirements for oxygen and glucose and thereby helps preserve CNS function. However, until anesthetic levels are achieved, barbiturates *increase* sensitivity to pain, and hence should not be used until pain is under control.

35.4.7 Adverse Effects

35.4.7.1 Respiratory Depression.

Barbiturates reduce ventilation by two mechanisms: (1) depression of brainstem neurogenic respiratory drive and (2) depression of chemoreceptive mechanisms that control respiratory drive. Doses only 3 times greater than those needed to induce sleep can cause complete suppression of the neurogenic respiratory drive. With severe overdose, barbiturates can cause apnea and death.

For most patients, the degree of respiratory depression produced at therapeutic doses is not significant. However, in elderly patients and those with respiratory disease, therapeutic doses can compromise respiration substantially. Combining a barbiturate with another CNS depressant intensifies respiratory depression.

35.4.7.2 Suicide.

Barbiturates have a low therapeutic index. Accordingly, overdose can readily cause death. Because of their toxicity, the barbiturates are frequently employed as vehicles for suicide, and hence should not be dispensed to patients with suicidal tendencies.

376

35.4.7.3 Abuse.

377

Barbiturates produce subjective effects that many individuals find desirable. As a result, they are popular drugs of abuse. The barbiturates that are most prone to abuse are those in the short to intermediate-acting group (eg, secobarbital). Individual barbiturates within the group are classified under Schedule II or III of the Controlled Substances Act, reflecting their high potential for abuse. Although barbiturates are frequently abused in nonmedical settings, they are rarely abused during medical use.

35.4.7.4 Use in Pregnancy.

Barbiturates readily cross the placenta and can injure the developing fetus. Women of child-bearing age should be informed about the potential for fetal harm and warned against becoming pregnant. Use of barbiturates during the third trimester may cause drug dependence in the infant.

35.4.7.5 Exacerbation of Intermittent Porphyria.

Barbiturates can intensify attacks of acute intermittent porphyria, a condition brought on by excessive synthesis of porphyrin. Symptoms include nausea, vomiting, abdominal colic, neuromuscular disturbances, and disturbed behavior. Barbiturates exacerbate porphyria by stimulating porphyrin synthesis (see [Fig. 34-2](#)). Because they intensify porphyria, barbiturates are absolutely contraindicated for individuals with a history of the disorder.

35.4.7.6 Hangover.

Barbiturates have long half-lives, and therefore can produce residual effects (hangover) when taken for insomnia. Hangover can manifest as sedation, impaired judgment, and reduced motor skills. Patients should be forewarned that their ability to perform complex tasks, both manual

and intellectual, may be significantly decreased the day after taking a barbiturate to induce sleep.

35.4.7.7 Paradoxical Excitement.

In some patients, especially the elderly and debilitated, barbiturates may cause excitation. The mechanism of this paradoxical response is unknown.

35.4.7.8 Hyperalgesia.

Barbiturates can intensify sensitivity to pain. In addition, they may cause pain directly. These drugs have caused muscle pain, joint pain, and pain along nerves.

35.4.8 Drug Interactions

35.4.8.1 CNS Depressants.

Drugs with CNS-depressant properties (eg, barbiturates, benzodiazepines, alcohol, opioids, antihistamines) intensify each other's effects. If these agents are combined, fatal CNS depression can result. Accordingly, patients should be warned emphatically against combining barbiturates with alcohol and other drugs that can depress CNS function.

35.4.8.2 Interactions Resulting from Induction of Drug-Metabolizing Enzymes.

As discussed above, barbiturates stimulate synthesis of hepatic drug-metabolizing enzymes, thereby accelerating metabolism of other drugs. Increased metabolism is of particular concern with *warfarin* (an anticoagulant), *oral contraceptives*, and *phenytoin* (an antiseizure agent). When these drugs are taken concurrently with a barbiturate, their dosages should be increased.

Following barbiturate withdrawal, rates of drug metabolism gradually decline to baseline values. Several weeks are required for this to occur. Drug dosages that had been increased to account for augmented metabolism must now be reduced to their prebarbiturate amount.

35.4.9 Acute Toxicity

Acute intoxication with barbiturates is a medical emergency; left untreated, overdose can be fatal. Poisoning is often the result of attempted suicide, although it can also occur by accident (usually in children and drug abusers). Since acute toxicity from barbiturates and other general CNS depressants is very similar, the discussion below applies to all of these drugs.

35.4.9.1 Symptoms.

Acute overdose produces a classic triad of symptoms: *respiratory depression*, *coma*, and *pinpoint pupils*. (Pupils may later dilate as hypoxia caused by respiratory depression sets in.) The three classic symptoms are frequently accompanied by *hypotension* and *hypothermia*. Death is likely to be the result of pulmonary complications and renal failure.

35.4.9.2 Treatment.

Proper management requires an intensive care unit. With vigorous treatment, most patients recover fully.

Treatment has two main objectives: (1) removal of barbiturate from the body and (2) maintenance of an adequate oxygen supply to the brain. Oxygenation can be maintained by keeping the airway patent and giving oxygen.

Several measures can promote barbiturate removal. Unabsorbed drug can be removed from the stomach (using gastric lavage) and from the intestine (using a saline cathartic). Drug that has already been absorbed can be removed with hemodialysis. For phenobarbital and other barbiturates that are excreted intact in the urine, forced diuresis and alkalinization of urine may facilitate their renal excretion.

Steps should be taken to prevent hypotension and loss of body heat. Blood pressure can be supported with fluid replacement and dopamine. Body heat can be maintained with blankets and warming devices.

Barbiturate poisoning has no specific antidote. CNS stimulants should definitely *not* be employed. Not only are stimulants ineffective, they are dangerous: Their use in barbiturate poisoning has been associated with a significant increase in mortality. Naloxone, a drug that can reverse poisoning by opioids, is *not* effective against poisoning by barbiturates.

35.4.10 Administration

35.4.10.1 Oral.

Oral administration is employed for daytime sedation and to treat insomnia. Patients should be warned not to increase their dosage or discontinue treatment without consulting the prescriber. Dosages should be reduced for elderly patients. When terminating therapy, the dosage should be gradually tapered.

35.4.10.2 Intravenous.

Intravenous administration is reserved for general anesthesia and emergency treatment of convulsions. Injections should be made slowly to minimize respiratory depression and hypotension. Blood pressure, pulses, and respiration should be monitored, and facilities for resuscitation should be available. The patient should be under continuous observation. Extravasation may result in local necrosis, hence care must be taken to ensure that extravasation does not occur. Solutions that are cloudy or contain a precipitate should not be used. Intra-arterial injection should be avoided, owing to a risk of gangrene secondary to prolonged arteriospasm.

35.4.10.3 Intramuscular.

Barbiturate solutions are highly alkaline and can cause pain and necrosis when injected IM. Consequently, IM injection is generally avoided. Injection in the vicinity of peripheral nerves can cause irreversible neurologic injury.

35.5 MISCELLANEOUS SEDATIVE-HYPNOTICS

35.5.1 Basic Pharmacologic Profile

The three drugs discussed in this section are nonselective CNS depressants, with actions much like those of the barbiturates. At therapeutic doses, they can cause substantial drowsiness, and hence patients should avoid driving and other hazardous activities. Combining these drugs with other CNS depressants (eg, alcohol, barbiturates, benzodiazepines, opioids, antihistamines) can produce profound depression of CNS function, and hence must be avoided. Prolonged use can produce tolerance and physical dependence. Consequently, these agents should be reserved for short-term therapy. In patients who have been treated long term, termination should be done gradually to minimize the withdrawal reaction. The nonselective CNS depressants can produce subjective effects that individuals prone to drug abuse consider desirable. As a result, the agents discussed here are classified under Schedule IV of the Controlled Substances Act.

In general, acute overdose resembles poisoning with barbiturates. Characteristic signs are respiratory depression, coma, miosis, and hypotension. Management is the same as with barbiturate poisoning. Because overdose can cause potentially fatal respiratory depression, these drugs should not be given to patients suspected of suicidal tendencies.

Nonselective CNS depressants should be avoided during pregnancy and lactation. Some of these agents may cause birth defects, especially if taken during the first trimester. In addition, if these drugs are taken late in pregnancy, the infant may be born drug dependent. These drugs can

achieve concentrations in breast milk that are sufficient to cause lethargy in the infant. Accordingly, nursing mothers should not use them.

35.5.2 Chloral Hydrate

Chloral hydrate [Aquachloral Supporettes, Somnote] is a general CNS depressant with properties similar to those of the barbiturates. This agent is a prodrug that undergoes rapid conversion to its active form in the liver. The drug's principal application is induction of sleep. However, tolerance to hypnotic effects develops quickly, and withdrawal is associated with sleep disruption and nightmares.

Chloral hydrate is supplied in capsules (500 mg), a syrup (50 and 100 mg/mL), and suppositories (324 and 648 mg). Patients should be instructed to swallow the capsules intact, without crushing or chewing. The syrup should be diluted with water, fruit juice, or ginger ale. With oral administration, epigastric distress, nausea, and flatulence are common.

The recommended dosage is 0.5 to 1 gm 30 minutes before bedtime. However, doses in this range are frequently too low to induce sleep. To elicit an adequate response, as much as 2 gm may be needed.

Chloral hydrate is subject to abuse and is classified as a Schedule IV drug. Abuse is similar to that seen in alcoholism. Prolonged consumption of chloral hydrate results in substantial tolerance and physical dependence. As a result, chloral hydrate addicts may ingest extremely large amounts of the drug. Abrupt withdrawal can cause delirium and seizures. Left untreated, the abstinence syndrome can be fatal.

377

35.5.3 Meprobamate

378

Meprobamate [Miltown] has pharmacologic properties that lie between those of barbiturates and benzodiazepines. As a CNS depressant, meprobamate is more selective than barbiturates but less selective than benzodiazepines. Meprobamate induces hepatic drug-metabolizing enzymes and can exacerbate intermittent porphyria. Its only indication is short-term management of anxiety. However, it is rarely used today. Meprobamate is available in 200- and 400-mg tablets. The usual adult dosage is 1.2 to 1.6 gm/day in three or four divided doses. Meprobamate is a Schedule IV drug.

35.5.4 Paraldehyde

Paraldehyde [Paral] is a general CNS depressant indicated for insomnia and management of alcoholic delirium tremens. The drug is employed almost exclusively in hospitals and institutions. Use by outpatients is rare.

Poisoning with paraldehyde is different from poisoning with other CNS depressants. In addition to causing respiratory depression and hypotension, paraldehyde causes prominent metabolic acidosis. Symptoms of toxicity include rapid, labored breathing; bleeding gastritis; toxic hepatitis; nephrosis; pulmonary hemorrhage; and edema. An oral dose of 25 mL can be fatal.

Solutions of paraldehyde decompose rapidly to acetic acid. Preparations that smell strongly of acetic acid (ie, that smell like vinegar) should be discarded. Since decomposition occurs rapidly, containers that have been open for more than 24 hours should not be used.

Administration may be oral or rectal (as a retention enema). Oral paraldehyde has an unpleasant taste and irritates the throat and stomach. The usual oral dosage for adults is 4 to 8 mL diluted in milk or iced fruit juice to improve palatability. Paraldehyde is a Schedule IV drug.

35.6 MANAGEMENT OF TRANSIENT INSOMNIA

Insomnia can be defined as an inability to sleep well. Some people have difficulty falling asleep, some have difficulty maintaining sleep, some are troubled by early morning awakening, and some have sleep that is not refreshing. Insomnia is transient for some people and chronic for others. In any given year, about 30% of Americans experience short-term insomnia, and about 10% experience chronic insomnia. In the United States, the direct costs of insomnia total about \$13.9 billion a year—a figure that includes the costs of testing, prescriber visits, and hypnotic drugs.

As a result of sleep loss, insomniacs experience daytime drowsiness along with impairment of mood, memory, coordination, and the ability to concentrate and make decisions. Chronic insomnia is a major risk factor for automotive and industrial accidents, marital and social problems, major depression, coronary heart disease, and metabolic and endocrine dysregulation.

Loss of sleep is often the result of a medical condition. Psychiatric disorders often disturb sleep, and pain can keep anyone awake. Sleep is frequently lost owing to concern regarding impending surgery and other procedures.

At one time or another, nearly everyone suffers from situational insomnia. Worry about exams may keep students awake. Job-related pressures may deprive workers of sleep. Deadlines may keep authors awake. Unfamiliar surroundings may keep travelers awake. Major life stressors (bereavement, divorce, loss of job) frequently disrupt sleep. Other factors, such as uncomfortable bedding, excessive noise, and bright light, can deprive us of sound sleep.

35.6.1 Sleep Phases

The sleeping state has two primary phases: *rapid-eye-movement* (REM) sleep and *non-rapid-eye-movement* (NREM) sleep. NREM sleep is further divided into four stages, labeled I, II, III, and IV. Sleep is relatively light in stages I and II, and deep in stages III and IV. REM sleep is the phase when most recallable dreams occur. In a typical night, we go through four to six REM periods. Males often experience penile erection during REM sleep, a curious phenomenon unrelated to dream content. The percentage of time spent in each sleep phase is as follows:

- Stage I: 5%
- Stage II: 50%–60%
- Stages III and IV: 10%–20%
- REM: 20%–25%

35.6.2 Basic Principles of Management

35.6.2.1 Cause-Specific Therapy

Treatment is highly dependent on the cause of insomnia. Accordingly, if therapy is to succeed, the underlying reason for sleep loss must be determined. To make this assessment, a thorough history is required.

When the cause of insomnia is a known medical disorder, primary therapy should be directed at the underlying illness; hypnotics should be employed only as adjuncts. For example, if pain is the reason for lack of sleep, analgesics should be prescribed. If insomnia is secondary to major depression, antidepressants are the appropriate treatment. If anxiety is the cause of insomnia, the patient should be given an anxiolytic.

35.6.2.2 Nondrug Therapy

For many insomniacs, nondrug measures may be all that is needed to promote sleep. For some individuals, avoidance of naps and adherence to a regular sleep schedule is sufficient. For others, decreased consumption of caffeine-containing beverages (eg, coffee, tea, cola drinks) may fix the problem. Still others may benefit from restful activity as bedtime nears. If environmental factors are responsible for lack of sleep, the patient should be taught how to correct them or compensate for them. All patients should be counseled about sleep fitness (also known as sleep hygiene). Rules for sleep fitness are summarized in [Table 34-4](#).

A recent study found that *cognitive behavioral therapy* is *superior* to drug therapy (with zopiclone) for short-term and long-term management of chronic insomnia in older adults. The cognitive and behavioral interventions employed were sleep restriction, control of bedroom environment, cognitive therapy, progressive relaxation, and education about sleep hygiene.

35.6.2.3 Therapy with Hypnotic Drugs

Hypnotics should be used only when insomnia cannot be managed by other means. Hence, before resorting to drugs, we should implement nondrug measures, and we should treat any pathology that may underlie inadequate sleep.

Drug therapy of transient insomnia should be short term (just 2 to 3 weeks). The patient should be reassessed on a regular basis to determine if drug therapy is still needed.

Escalation of dosage should be avoided. A need for increased dosage suggests development of tolerance. If hypnotic effects are lost in the course of treatment, it is preferable to interrupt therapy rather than elevate dosage. Interruption will allow tolerance to decline, thereby restoring responsiveness to treatment.

378

TABLE 34-4 Rules for Sleep Fitness

- Establish a regular time to go to bed and a regular time to rise. This will help reset your biologic clock.
- Sleep only as long as needed to feel refreshed. Too much time in bed causes fragmented and shallow sleep. In contrast, restricting time in bed helps consolidate and deepen sleep.
- Insulate your bedroom against light and sounds that disturb your sleep (eg, install carpeting and insulated curtains).
- Keep your bedroom temperature moderate. High temperature may disturb sleep.
- Exercise daily, but not later than 7:00 PM. Regular exercise helps deepen sleep.
- Avoid daytime naps. Staying awake during the day helps you sleep at night.
- Avoid caffeine, especially in the evening.
- Avoid consuming too much fluid in the evening so as to minimize nighttime trips to the bathroom.
- Avoid alcohol in the evening. Although alcohol can help you fall asleep, it causes sleep to be fragmented.
- Avoid tobacco; it disturbs sleep (and shortens your life, too).
- Try having a light snack near bedtime, since hunger can disturb sleep—but don't eat heavily.
- Relax before bedtime with soft music, mild stretching, yoga, or pleasurable reading.
- Leave your problems outside the bedroom. Reserve time earlier in the evening to work on problems and to plan tomorrow's activities.
- Reserve your bedroom for sleeping (and sex). This will help condition your brain to see the bedroom as a place where sleep happens. Don't eat, read, or watch TV in bed.
- If you don't fall asleep within 20 minutes or so, get up and do something relaxing (eg, read, listen to music, watch TV), and then return to bed when you feel drowsy. Repeat as often as required.
- Don't look at the clock if you wake up during the night. If necessary, turn its face away from the bed.

In certain patients, hypnotics must be employed with special caution. Patients who snore heavily and those with respiratory disorders have reduced respiratory reserve, which can be further compromised by the respiratory-depressant actions of hypnotics. Hypnotic agents are generally contraindicated for use during pregnancy; these drugs have the potential to cause fetal harm, and their use is never an absolute necessity.

Patients taking hypnotics should be forewarned that residual CNS depression may persist the next day. Although CNS depression may not be pronounced, it may still compromise intellectual or physical performance.

When hypnotics are employed, care must be taken to prevent *drug-dependency insomnia*, a condition that can lead to inappropriate prolongation of therapy. Drug-dependency insomnia is a particular problem with older hypnotics (eg, barbiturates), and develops as follows: (1) Insomnia motivates treatment with hypnotics. (2) With continuous drug use, low-level physical dependence develops. (3) Upon cessation of treatment, a mild withdrawal syndrome occurs and disrupts sleep. (4) Failing to recognize that the inability to sleep is a manifestation of drug withdrawal, the patient becomes convinced that insomnia has returned and resumes drug use. (5) Continued drug use leads to heightened physical dependence, making it even more difficult to withdraw medication without producing another episode of drug-dependency insomnia. To minimize drug-dependency insomnia, hypnotics should be employed judiciously. That is, they should be used in the lowest effective dosage for the shortest time required.

35.6.3 Major Drugs Used for Treatment

Transient insomnia can be treated with prescription drugs, nonprescription drugs, and alternative medicines. Among the prescription drugs, benzodiazepines and the benzodiazepine-like drugs (zolpidem, zaleplon, and eszopiclone) are drugs of first choice. Older sedative-hypnotics, such as barbiturates and chloral hydrate, are rarely used today. Nonprescription drugs and alternative medicines are much less effective than the first-choice drugs, and hence should be reserved for people whose insomnia is mild.

As shown in [Table 34-5](#), hypnotic drugs differ with respect to onset and duration of action, and hence differ in their applications. Drugs with a rapid onset (eg, zolpidem) are good for patients who have difficulty falling asleep, whereas drugs with a long duration (eg, estazolam) are good for patients who have difficulty maintaining sleep. Drugs like flurazepam, which have both a rapid onset and long duration, are good for patients with both types of sleep problems.

35.6.3.1 Benzodiazepines

Benzodiazepines are drugs of first choice for short-term treatment of insomnia. These agents are safe and effective and lack the undesirable properties that typify barbiturates and other older hypnotics. Benzodiazepines have a low abuse potential, cause minimal tolerance and physical dependence, present a minimal risk of suicide, and undergo few interactions with other drugs. Only five benzodiazepines are marketed specifically for use as hypnotics (see [Table 34-5](#)). However, any benzodiazepine with a short to intermediate onset could be employed.

Benzodiazepines have multiple desirable effects on sleep: they decrease the latency to sleep onset, decrease the number of awakenings, and increase total sleeping time. In addition, they impart a sense of deep and refreshing sleep. With most benzodiazepines, tolerance to hypnotic actions develops slowly, allowing them to be used nightly for several weeks without a noticeable loss in hypnotic effects. Furthermore, with most benzodiazepines, treatment does not significantly reduce the amount of time spent in REM sleep, and withdrawal is not associated with significant rebound insomnia.

Two agents—*triazolam* [Halcion] and *flurazepam* [Dalmane]—can be considered prototypes of the benzodiazepines used to promote sleep. Triazolam has a rapid onset and short duration, making it a good choice for patients who have difficulty falling asleep (as compared with difficulty maintaining sleep). Flurazepam has a delayed onset and more prolonged duration, making it an effective agent for patients who have difficulty maintaining sleep. However, because flurazepam has a relatively long half-life, the drug is likely to cause daytime drowsiness, and hence is not used widely today. Triazolam has a much shorter half-life than flurazepam, which is both good news and bad news. The good news is that, because it leaves the body rapidly, triazolam does not cause daytime sedation. The bad news is that, because triazolam is rapidly cleared, treatment is associated with two problems: (1) tolerance to hypnotic effects can develop quickly—in 11 to 18 days, which is much faster than with other benzodiazepines; and (2) triazolam causes more rebound insomnia than other benzodiazepines.

379

380

TABLE 34-5 Major Drugs for Insomnia

Drug	Time Course		Use in Insomnia*		Bedtime Dosage (mg)	
	Onset (min)	Duration	DFA	DMS	Nonelderly	Elderly
Benzodiazepines						
Triazolam [Halcion]	15–30	Short	✓		0.125–0.25	0.13
Flurazepam† (generic only)	30–60	Long	✓	✓	30	7.5
Quazepam† [Doral]	20–45	Long	✓	✓	15	7.5
Estazolam (generic only)	15–60	Intermediate		✓	1–2	0.5–1
Temazepam [Restoril]	45–60	Intermediate		✓	15–30	7.5–15
Benzodiazepine-like Drugs						
Eszopiclone [Lunesta]	30	Intermediate	✓	✓	2–3	1–2
Zolpidem						
Immediate release [Ambien]	30	Short	✓		10	5
Extended release [Ambien CR]	30	Intermediate	✓	✓	12.5	6.25
Zaleplon [Sonata]	15–30	Ultrashort	✓		10–20	5
Melatonin Receptor Agonist						
Ramelteon [Rozerem]	30	Short	✓		8	

* DFA = difficulty falling asleep, DMS = difficulty maintaining sleep.

† Because of its long duration, this drug is not generally recommended.

35.6.3.2 Benzodiazepine-like Drugs: Zolpidem, Zaleplon, and Eszopiclone

Zolpidem [Ambien], zaleplon [Sonata], and eszopiclone [Lunesta] are drugs of first choice for insomnia. In fact, one of these drugs—zolpidem—is prescribed more often than any other hypnotic. All three drugs have the same mechanism as the benzodiazepines—and all three are as effective as the benzodiazepines, and may be safer for long-term use. Furthermore, whereas benzodiazepines are contraindicated during pregnancy, the benzodiazepine-like drugs are not (although use during pregnancy should be discouraged). All three drugs have a rapid onset, and hence can help people with difficulty *falling* asleep. Also, with zolpidem and eszopiclone, effects persist long enough to help people who have difficulty *staying* asleep. In contrast, effects of zaleplon fade too rapidly to help people with trouble staying asleep. However, zaleplon is

great for people who wake up in the middle of the night. Why? Owing to its ultrashort duration, zaleplon can be taken a few hours before arising and still not cause drowsiness during the day. Of the three drugs, only eszopiclone has been *proved* effective for long-term use. However, even though long-term studies for zaleplon and zolpidem are lacking, it seems likely that they too would retain efficacy when taken long term.

35.6.3.3 Ramelteon

Ramelteon [Rozerem] is a melatonin agonist approved for long-term therapy of insomnia. The drug has a rapid onset and short duration, and hence is good for inducing sleep, but not maintaining sleep. Ramelteon does not cause tolerance or dependence, and is not regulated as a controlled substance.

35.6.4 Other Hypnotics

35.6.4.1 Trazodone

Trazodone [Desyrel] is an atypical antidepressant with strong sedative actions. The drug can decrease sleep latency and prolong sleep duration, and does not cause tolerance or physical dependence. Trazodone is especially useful for treating insomnia resulting from use of antidepressants that cause significant CNS stimulation (eg, fluoxetine [Prozac], bupropion [Wellbutrin]). Principal adverse effects are daytime grogginess and postural hypotension. (Hypotension results from alpha-adrenergic blockade.) The basic pharmacology of trazodone is presented in [Chapter 32](#).

35.6.4.2 Antihistamines

Two antihistamines—diphenhydramine [Nytol, Sominex, others] and doxylamine [Unisom]—are FDA-approved for use as “sleep aids,” and can be purchased without a prescription. These drugs are less effective than benzodiazepines and benzodiazepine-like drugs, and tolerance develops quickly (in 1 to 2 weeks). Daytime drowsiness and anticholinergic effects (eg, dry mouth, blurred vision, urinary hesitancy, constipation) are common.

35.6.4.3 Alternative Medicines

Of the alternative medicines employed to promote sleep, only two—valerian root (*Valeriana officinalis*) and melatonin—appear moderately effective. Several others—chamomile, passionflower, lemon balm, and lavender—have very mild sedative effects, and proof of benefits in insomnia is lacking. Valerian can help people fall asleep, but does not help them maintain sleep. Furthermore, hypnotic effects take a week or more to develop, and hence

valerian is no good for acute therapy. Valerian root is discussed further in [Chapter 107](#) (Dietary Supplements).

380

381

35.6.4.3.1

KEY POINTS

- Drugs used to treat anxiety are called antianxiety agents, anxiolytics, or tranquilizers.
- Drugs that promote sleep are called hypnotics.
- Barbiturates and other general CNS depressants are undesirable in that they can cause fatal respiratory depression, have a high potential for abuse, cause significant tolerance and physical dependence, and often induce hepatic drug-metabolizing enzymes.
- Benzodiazepines are preferred to barbiturates and other general CNS depressants because they are much safer, have a low abuse potential, cause less tolerance and dependence, and don't induce drug-metabolizing enzymes.
- Although benzodiazepines can cause physical dependence, the withdrawal syndrome is usually mild (except in patients who have undergone prolonged, high-dose therapy).
- To minimize withdrawal symptoms, benzodiazepines should be discontinued gradually, over several weeks or even months.
- Benzodiazepines cause minimal respiratory depression when used alone, but can cause profound respiratory depression when combined with other CNS depressants (eg, opioids, barbiturates, alcohol).
- Benzodiazepines produce their effects by enhancing the actions of GABA, the principal inhibitory neurotransmitter in the CNS.
- Although benzodiazepines undergo extensive metabolism, in most cases the metabolites are pharmacologically active. As a result, responses produced by administering a particular benzodiazepine often persist long after the parent drug has disappeared from the blood.
- All of the benzodiazepines have essentially equivalent pharmacologic actions; hence, selection among them is based in large part on differences in time course.
- The principal indications for benzodiazepines are anxiety, insomnia, and seizure disorders.

- The principal adverse effects of benzodiazepines are daytime sedation and anterograde amnesia.
- Rarely, patients taking benzodiazepines to promote sleep carry out sleep driving and other complex behaviors, and then have no memory of their actions.
- Flumazenil, a benzodiazepine receptor antagonist, can be used to treat benzodiazepine overdose.
- Like the benzodiazepines, the benzodiazepine-like drugs—zaleplon [Sonata], eszopiclone [Lunesta], and zolpidem [Ambien, Tovalt]—produce their effects by enhancing the actions of GABA.
- When insomnia has a treatable cause (eg, pain, depression, schizophrenia), primary therapy should be directed at the underlying illness; hypnotics should be used only as adjuncts.
- Benzodiazepines and the benzodiazepine-like drugs (zolpidem, zaleplon, eszopiclone) are drugs of choice for insomnia.
- When benzodiazepines are used for transient insomnia, treatment should last only 2 to 3 weeks.

35.6.4.3.2

Summary of Major Nursing Implications*

35.6.4.3.2.1

BENZODIAZEPINES

Alprazolam

Chlordiazepoxide

Clorazepate

Diazepam

Estazolam

Flurazepam

Lorazepam

Oxazepam

Quazepam

Temazepam

Triazolam

The nursing implications summarized here apply to the sedative-hypnotic benzodiazepines and their use in insomnia.

35.6.4.3.2....

Preadministration Assessment

35.6.4.3.2....

Therapeutic Goal

Benzodiazepines are used to promote sleep, relieve symptoms of anxiety (see [Chapter 35](#)), suppress seizure disorders (see [Chapter 24](#)), relax muscle spasm (see [Chapter 25](#)), and ease withdrawal from alcohol (see [Chapter 38](#)). They are also used for preanesthetic medication and to induce general anesthesia (see [Chapter 27](#)).

35.6.4.3.2....

Baseline Data

Determine the nature of the sleep disturbance (prolonged latency, frequent awakenings, early morning awakening) and how long it has lasted. Assess for a possible underlying cause (eg, medical illness, psychiatric illness, use of caffeine and other stimulants, poor sleep hygiene, major life stressor).

35.6.4.3.2....

Identifying High-Risk Patients

Benzodiazepines are *contraindicated* during pregnancy and for patients who experience sleep apnea. Use with *caution* in patients with suicidal tendencies or a history of substance abuse.

35.6.4.3.2....	Implementation: Administration	
35.6.4.3.2....	Routes	
35.6.4.3.2....	Oral.	
	All benzodiazepines.	
35.6.4.3.2....	IM and IV.	
	Diazepam, chlordiazepoxide, and lorazepam.	
35.6.4.3.2....	Rectal.	
	Diazepam.	381
35.6.4.3.2....	Administration	382
35.6.4.3.2....	Oral.	
	Advise patients to administer benzodiazepines with food if gastric upset occurs. Instruct patients to swallow sustained-release formulations intact, without crushing or chewing.	
	Warn patients not to increase the dosage or discontinue treatment without consulting the prescriber.	
	To minimize physical dependence when treating insomnia, administer intermittently (three or four nights a week) and use the lowest effective dosage for the shortest duration required.	
	To minimize abstinence symptoms, taper the dosage gradually (over several weeks or even months).	
35.6.4.3.2....	Intravenous.	
	Perform IV injections with care. Life-threatening reactions (severe hypotension, respiratory arrest, cardiac arrest) have occurred, along with less serious reactions (venous thrombosis, phlebitis, vascular impairment). To reduce complications, follow these guidelines: (1) make injections slowly; (2) take care to avoid intra-arterial injection and extravasation; (3) if direct venous injection is impossible, inject into infusion tubing as close to the vein as possible; (4) follow the	

manufacturer's instructions regarding suitable diluents for preparing solutions; and (5) have facilities for resuscitation available.

35.6.4.3.2....

Implementation: Measures to Enhance Therapeutic Effects

Educate patients about sleep fitness (see [Table 34-4](#)). Reassure patients with situational insomnia that sleep patterns will normalize once the precipitating stressor has been eliminated. Ensure that correctable underlying causes of insomnia (psychiatric or medical illness, use of stimulant drugs) are being managed.

35.6.4.3.2....

Ongoing Evaluation and Interventions

35.6.4.3.2....

Evaluating Therapeutic Effects

Insomnia is usually self-limiting. Consequently, drug therapy is usually short term. Benzodiazepines should be discontinued periodically to determine if they are still required. If insomnia is long term, make a special effort to identify possible underlying causes (eg, psychiatric illness, medical illness, use of caffeine and other stimulants).

35.6.4.3.2....

Minimizing Adverse Effects

35.6.4.3.2....

CNS Depression.

Drowsiness may be present the next day when benzodiazepines are used for insomnia. **Warn patients about possible residual CNS depression and advise them to avoid hazardous activities (eg, driving) if daytime sedation is significant.**

35.6.4.3.2....

Sleep Driving and Other Complex Sleep-Related Behaviors.

Rarely, patients taking benzodiazepines to promote sleep may carry out complex behaviors (eg, sleep driving, eating, making phone calls), and then have no memory of the event. To reduce the risk of these events, dosage should be as low as possible, and alcohol and other CNS depressants should be avoided. **Inform patients about the possibility of complex sleep-related behaviors and instruct them to notify the prescriber if they occur.** If the patient reports driving while asleep, the benzodiazepine should be withdrawn (albeit slowly).

35.6.4.3.2....

Paradoxical Effects.

Inform patients about possible paradoxical reactions (rage, excitement, heightened anxiety), and instruct them to notify the prescriber if these occur. If the reaction is verified, benzodiazepines should be withdrawn.

35.6.4.3.2....

Physical Dependence.

With most benzodiazepines, significant physical dependence is rare. However, with one agent—alprazolam [Xanax, Niravam]—substantial dependence has been reported. With all benzodiazepines, development of dependence can be minimized by using the lowest effective dosage for the shortest time necessary and by using intermittent dosing when treating insomnia.

When dependence is mild, withdrawal can elicit insomnia and other symptoms that resemble anxiety. These must be distinguished from a return of the patient's original sleep disorder. **Warn patients about possible drug-dependency insomnia during or after benzodiazepine withdrawal.**

When dependence is severe, withdrawal reactions may be serious (panic, paranoia, delirium, hypertension, convulsions). To minimize symptoms, withdraw benzodiazepines slowly (over several weeks or months). **Warn patients against abrupt discontinuation of treatment.** After drug cessation, patients should be monitored for 3 weeks for signs of withdrawal or recurrence of original symptoms.

35.6.4.3.2....

Abuse.

The abuse potential of the benzodiazepines is low. However, some individuals do abuse them. Be alert to requests for increased dosage, since this may reflect an attempt at abuse. Benzodiazepines are classified under Schedule IV of the Controlled Substances Act and must be dispensed accordingly.

35.6.4.3.2....

Use in Pregnancy and Lactation.

Benzodiazepines may injure the developing fetus, especially during the first trimester. **Inform women of child-bearing age about the potential for fetal harm and warn them against becoming pregnant.** If pregnancy occurs, benzodiazepines should be withdrawn.

Benzodiazepines readily enter breast milk and may accumulate to toxic levels in the infant. **Warn mothers against breast-feeding.**

35.6.4.3.2....

Minimizing Adverse Interactions

35.6.4.3.2....

CNS Depressants.

Combined overdose with a benzodiazepine plus another CNS depressant can cause profound respiratory depression, coma, and death. **Warn patients against use of alcohol and all other CNS depressants (eg, opioids, barbiturates, antihistamines).**

* Patient education information is highlighted as **blue text**

³⁶CHAPTER 35 Management of Anxiety Disorders

Anxiety is an uncomfortable state that has both psychologic and physical components. The psychologic component can be characterized with terms such as *fear*, *apprehension*, *dread*, and *uneasiness*. The physical component manifests as tachycardia, palpitations, trembling, dry mouth, sweating, weakness, fatigue, and shortness of breath.

Anxiety is a nearly universal experience that often serves an adaptive function. When anxiety is moderate and situationally appropriate, therapy may not be needed or even desirable. In contrast, when anxiety is persistent and disabling, intervention is clearly indicated.

In the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV), primary anxiety disorders are divided into six major classes: generalized anxiety disorder, panic disorder, obsessive-compulsive disorder, phobic disorders, post-traumatic stress disorder, and acute stress disorder. Although each class is distinct, they all have one element in common: an unhealthy level of anxiety. In addition, with all classes, depression is frequently comorbid.

Anxiety disorders are among the most common psychiatric illnesses. In the United States, about 25% of people develop pathologic anxiety at some time in their lives. As a rule, the incidence is higher in women than in men.

Fortunately, anxiety disorders often respond well to treatment—either psychotherapy, drug therapy, or both. As indicated in [Table 35-1](#), two classes of drugs are used most: *benzodiazepines* and *selective serotonin reuptake inhibitors* (SSRIs). Benzodiazepines are used primarily for one condition: generalized anxiety disorder (GAD). In contrast, the SSRIs are now used for *all* anxiety disorders. It should be noted that, although SSRIs were developed as antidepressants, they are highly effective against anxiety—whether or not depression is present.

^{36.1}GENERALIZED ANXIETY DISORDER

^{36.1.1}Characteristics

Generalized anxiety disorder is a chronic condition characterized by uncontrollable worrying. Of all anxiety disorders, GAD is the least likely to remit. Most patients with GAD also have another psychiatric disorder, usually depression. GAD should not be confused with *situational anxiety*, which is a normal response to a stressful situation (eg, family problems, exams, financial difficulties); symptoms may be intense, but they are temporary.

383

384

TABLE 35-1 First-Line Drugs for Anxiety Disorders

Anxiety Disorder	Benzodiazepines	SSRIs	Others
Generalized Anxiety Disorder	Alprazolam	Paroxetine	Buspirone
	Chlordiazepoxide	Escitalopram	Venlafaxine
	Clorazepate		Duloxetine
	Diazepam		
	Lorazepam		
	Oxazepam		
Panic Disorder		Fluoxetine	
		Paroxetine	
		Sertraline	
Obsessive-Compulsive Disorder		Citalopram	
		Escitalopram	
		Paroxetine	
		Fluoxetine	
		Fluvoxamine	
Social Anxiety Disorder		Sertraline	
		Fluvoxamine	Venlafaxine
		Paroxetine	
Post-traumatic Stress Disorder		Sertraline	
		Paroxetine*	
		Sertraline*	

SSRIs = selective serotonin reuptake inhibitors.

* According to the Institute of Medicine of the National Academies, these drugs are not effective in PTSD, even though they are approved by the Food and Drug Administration for this disorder.

The hallmark of GAD is unrealistic or excessive anxiety about several events or activities (eg, work or school performance) that lasts 6 months or longer. Other psychologic manifestations include vigilance, tension, apprehension, poor concentration, and difficulty falling or staying

asleep. Somatic manifestations include trembling, muscle tension, restlessness, and signs of autonomic hyperactivity, such as palpitations, tachycardia, sweating, and cold clammy hands. Diagnostic criteria for GAD, as described in DSM-IV, are shown in [Table 35-2](#).

36.1.2 Treatment

GAD can be managed with nondrug therapy and with drugs. Nondrug approaches include supportive therapy, cognitive behavioral therapy, biofeedback, and relaxation training. These can help relieve symptoms and improve coping skills in anxiety-provoking situations. When symptoms are mild, nondrug therapy may be all that is needed. However, if symptoms are intensely uncomfortable or disabling, drugs are indicated. Current first-line choices are the benzodiazepines, buspirone, and four antidepressants: venlafaxine, paroxetine, escitalopram, and duloxetine. With the benzodiazepines, onset of relief is rapid. In contrast, with buspirone and the antidepressants, onset is delayed. Accordingly, benzodiazepines are preferred drugs for immediate stabilization, especially when anxiety is severe. However, for long-term management, buspirone and the antidepressants are preferred. Because GAD is a chronic disorder, initial drug therapy should be prolonged, lasting at least 2 to 6 months. Unfortunately, even after extended treatment, drug withdrawal frequently results in relapse. Hence, for many patients, drug therapy must continue indefinitely.

TABLE 35-2 DSM-IV-TR Diagnostic Criteria for GAD

<p>A. Excessive anxiety and worry about several events or activities (such as work or school performance) that occur more days than not for at least 6 months.</p> <p>B. The person finds the worry difficult to control.</p> <p>C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms present for more days than not for the past 6 months). <i>Note:</i> only one item is required in children.</p> <ul style="list-style-type: none">• Restlessness or feeling keyed up or on edge• Being easily fatigued• Difficulty concentrating or mind going blank• Irritability• Muscle tension• Sleep disturbance (difficulty falling asleep or staying asleep, or restlessness, unsatisfying sleep) <p>D. The focus of the anxiety and worry is not related to another psychiatric disorder.</p> <p>E. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.</p> <p>F. The disturbance is not due to the direct physiologic effects of a substance (eg, drug of abuse, medication) or a general medical condition (eg, hyperthyroidism) and does not occur exclusively during a mood disorder, psychotic disorder, or pervasive developmental disorder.</p>
<p>Modified from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. Washington, DC: American Psychiatric Press, 2000, with permission. Copyright © 2000 American Psychiatric Association.</p>

36.1.2.1 Benzodiazepines

Benzodiazepines are first-choice drugs for anxiety. As discussed in [Chapter 34](#), benefits derive from enhancing responses to gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter. Onset of effects is immediate, and the margin of safety is high. Principal side effects are sedation and psychomotor slowing. Patients should be warned about these effects and informed they will subside in 7 to 10 days. Because of their abuse potential, benzodiazepines should be used with caution in patients known to abuse alcohol or other psychoactive substances.

Long-term use of benzodiazepines carries a risk of physical dependence. Withdrawal symptoms include panic, paranoia, and delirium. These can be especially troubling for patients with GAD.

Furthermore, they can be confused with a return of pretreatment symptoms. Accordingly, clinicians must differentiate between a withdrawal reaction and relapse. To minimize withdrawal symptoms, benzodiazepines should be tapered gradually—over a period of several months. If relapse occurs, treatment should resume.

Of the 14 benzodiazepines available, 6 are approved for anxiety. The agents prescribed most often are alprazolam [Xanax, Xanax XR, Niravam] and lorazepam [Ativan]. However, there is no proof that any one benzodiazepine is clearly superior to the others. Hence, selection among them is largely a matter of prescriber preference. Dosages for anxiety are summarized in [Table 35-3](#).

The basic pharmacology of the benzodiazepines is discussed in [Chapter 34](#).

36.1.2.2 Buspirone

36.1.2.2.1 Actions and Therapeutic Use.

Buspirone [BuSpar] is an anxiolytic drug that differs significantly from the benzodiazepines. Most notably, buspirone is *not* a central nervous system (CNS) depressant. For treatment of anxiety, buspirone is as effective as the benzodiazepines and has three distinct advantages: It does not cause sedation, has no abuse potential, and does not intensify the effects of CNS depressants (benzodiazepines, alcohol, barbiturates, and related drugs). Its major disadvantage is that anxiolytic effects develop *slowly*: initial responses take a week to appear, and several more weeks must pass before responses peak. Because therapeutic effects are delayed, buspirone is not suitable for PRN use or for patients who need immediate relief. Since buspirone has no abuse potential, it may be especially appropriate for patients known to abuse alcohol and other drugs. Because it lacks depressant properties, buspirone is an attractive alternative to benzodiazepines in patients who require long-term therapy but cannot tolerate benzodiazepine-induced sedation and psychomotor slowing. Buspirone is labeled only for *short-term* treatment of anxiety. However, the drug has been taken for as long as a year with no reduction in benefit. Buspirone does not display cross-dependence with benzodiazepines.

Hence, when patients are switched from a benzodiazepine to buspirone, the benzodiazepine must be tapered slowly. Furthermore, since the effects of buspirone are delayed, buspirone should be initiated 2 to 4 weeks before beginning benzodiazepine withdrawal. In contrast to benzodiazepines, buspirone lacks sedative, muscle relaxant, and anticonvulsant actions—and hence cannot be used for insomnia, muscle spasm, or epilepsy.

384

385

TABLE 35-3 Dosages of Benzodiazepines Approved for Anxiety

Generic Name	Trade Name	Dosage	
		Initial	Usual Range (mg/day)
Alprazolam	Xanax, Niravam	0.25–0.5 mg 3 times/day	0.5–6
	Xanax XR	0.5–1 mg once/day	3–6
Chlordiazepoxide	Librium	—	15–100
Clorazepate	Tranxene	—	15–60
Diazepam	Valium	—	4–40
Lorazepam	Ativan	0.5–1 mg 3 times/day	2–6
Oxazepam	Serax	—	30–120

The mechanism by which buspirone relieves anxiety has not been established. The drug binds with high affinity to receptors for serotonin and with lower affinity to receptors for dopamine. Buspirone does not bind to receptors for GABA or benzodiazepines.

36.1.2.2.2

Pharmacokinetics.

Buspirone is well absorbed following oral administration but undergoes extensive metabolism on its first pass through the liver. Administration with food delays absorption but enhances bioavailability (by reducing first-pass metabolism). The drug is excreted in part by the kidneys, primarily as metabolites.

36.1.2.2.3

Adverse Effects.

Buspirone is generally well tolerated. The most common reactions are *dizziness*, *nausea*, *headache*, *nervousness*, *lightheadedness*, and *excitement*. The drug is nonsedating and does not interfere with daytime activities. Furthermore, it poses little or no risk of suicide; huge doses (375 mg/day) have been given to healthy volunteers with only moderate adverse effects (nausea, vomiting, dizziness, drowsiness, miosis).

36.1.2.2.4

Drug and Food Interactions.

Levels of buspirone can be greatly increased (5- to 13-fold) by *erythromycin* and *ketoconazole*. Levels can also be increased by *grapefruit juice*. Elevated levels may cause drowsiness and subjective effects (dysphoria, feeling “spacey”). Buspirone does not enhance the depressant effects of alcohol, barbiturates, and other general CNS depressants.

36.1.2.2.5 Tolerance, Dependence, and Abuse.

Buspirone has been used for up to a year without evidence of tolerance, physical dependence, or psychologic dependence. No withdrawal symptoms have been observed upon termination. There is no cross-tolerance or cross-dependence between buspirone and the sedative-hypnotics (eg, benzodiazepines, barbiturates). Buspirone appears to have no potential for abuse, and hence is not regulated under the Controlled Substances Act.

36.1.2.2.6 Preparations, Dosage, and Administration.

Buspirone tablets [BuSpar] are available in five strengths: 5, 7.5, 10, 15, and 30 mg. The initial dosage is 5 mg 3 times a day. Dosage may be increased to a maximum of 60 mg/day.

36.1.2.3 Antidepressants: Venlafaxine, Paroxetine, Escitalopram, and Duloxetine

At this time, only four antidepressants—venlafaxine [Effexor XR], paroxetine [Paxil], escitalopram [Lexapro], and duloxetine [Cymbalta]—are approved for GAD. Venlafaxine is an atypical antidepressant; paroxetine and escitalopram are SSRIs, and duloxetine is a serotonin/norepinephrine reuptake inhibitor (SNRI). All four drugs are especially well suited for patients who have depression in addition to GAD. However, they are also effective even when depression is absent. As with buspirone, anxiolytic effects develop slowly: Initial responses can be seen in a week, but optimal responses require several more weeks to develop. Because relief is delayed, the antidepressants cannot be used PRN. Compared with benzodiazepines, the antidepressants do a better job of decreasing cognitive and psychic symptoms of anxiety, but are not as good at decreasing somatic symptoms. In contrast to the benzodiazepines, antidepressants have no potential for abuse. However, abrupt discontinuation *can* produce withdrawal symptoms.

Venlafaxine was the first antidepressant approved for GAD. The drug has been proved effective for both short-term and long-term use. The most common side effect is nausea, which develops in 37% of patients. Fortunately, nausea subsides despite continued treatment. Other common reactions include headache, anorexia, nervousness, sweating, daytime somnolence, and insomnia. In addition, venlafaxine can cause hypertension, although this is unlikely at the doses used in GAD. Combining venlafaxine with a monoamine oxidase inhibitor can result in serious toxicity, and hence must be avoided. Venlafaxine is available in two formulations: standard tablets [Effexor] and extended-release capsules [Effexor XR]. Only the extended-release formulation is approved for GAD. The initial dosage is 37.5 mg once a day, and the maintenance range is 75 to 225 mg once a day.

Paroxetine and *escitalopram* are the only SSRIs approved for GAD. These drugs are as effective as the benzodiazepines, but less well tolerated. For paroxetine, the initial dosage is 20 mg once a day in the morning. Dosage can be gradually increased to a maintenance range of 20 to 50 mg/day. For escitalopram, dosing begins at 10 mg once daily and can be increased to 20 mg once daily after a week. Treatment beyond 8 weeks has not been studied.

Duloxetine is the only SNRI approved for GAD. The usual dosage, both initial and maintenance, is 60 mg once a day.

The basic pharmacology of venlafaxine, paroxetine, escitalopram, and duloxetine is discussed in [Chapter 32](#).

385

36.2 PANIC DISORDER

386

36.2.1 Characteristics

Panic disorder is characterized by recurrent, intensely uncomfortable episodes known as *panic attacks*. As defined in DSM-IV, panic attacks have a sudden onset, reach peak intensity within 10 minutes, and have four or more of the following symptoms:

- Palpitations, pounding heart, racing heartbeat
- Chest pain or discomfort
- Sensation of shortness of breath or smothering
- Feeling of choking
- Dizziness, lightheadedness
- Nausea or abdominal discomfort
- Derealization (feelings of unreality) or depersonalization (feeling detached from oneself)
- Fear of losing control or going crazy
- Fear of dying
- Tingling or numbness in the hands
- Flushes or chills

Symptoms typically dissipate within 30 minutes. Many patients go to an emergency department because they think they are having a heart attack. Some patients experience panic attacks daily;

others have only one or two a month. Panic disorder is a common condition that affects 1.6% of Americans at some time in their lives. The incidence in women is 2 to 3 times the incidence in men. Onset of panic disorder usually occurs in the late teens or early 20s.

Perhaps 50% of patients who get panic disorder also experience *agoraphobia*, a condition characterized by anxiety about being in places or situations from which escape might be difficult or embarrassing, or in which help might be unavailable in the event that a panic attack should occur. Agoraphobia leads to avoidance of certain places (eg, elevators, bridges, tunnels, movie theaters) and situations (eg, being outside the home alone; being in a crowd; standing on line; driving in traffic; traveling by bus, train, or plane). In extreme cases, agoraphobics may never set foot outside the home. Because of avoidance behavior, agoraphobia can severely limit occupational and social options.

What's the underlying cause of panic attacks? We don't know. However, malfunction of the brain's "alarm system" is suspected. This malfunction may result from abnormalities in noradrenergic systems, serotonergic systems, and/or benzodiazepine receptors. Genetic vulnerability also may play a role.

36.2.2 Treatment

Between 70% and 90% of patients with panic disorder respond well to treatment. Two modalities may be employed: drug therapy and cognitive behavioral therapy (CBT). Combining drug therapy with CBT is more effective than either modality alone. As a rule, patients experience rapid and significant improvement. Drug therapy helps suppress panic attacks, while CBT helps patients become more comfortable with situations and places they've been avoiding. Additional benefit can be derived from avoiding caffeine and sympathomimetics (which can trigger panic attacks), avoiding sleep deprivation (which can predispose to panic attacks), and doing regular aerobic exercise (which can reduce anxiety).

Drug therapy should continue at least 6 to 9 months. Stopping sooner is associated with a high rate of relapse.

36.2.2.1 Antidepressants

Panic disorder responds well to all three major classes of antidepressants: SSRIs, tricyclic antidepressants (TCAs), and monoamine oxidase inhibitors (MAOIs). With all three, full benefits take 6 to 12 weeks to develop. Owing to better tolerability, SSRIs are preferred to TCAs and MAOIs. The basic pharmacology of the antidepressants is discussed in [Chapter 32](#).

36.2.2.1.1 Selective Serotonin Reuptake Inhibitors.

The SSRIs are first-line drugs for panic disorder. At this time, only three SSRIs—fluoxetine [Prozac], paroxetine [Paxil], and sertraline [Zoloft]—are approved for this condition. However, the other SSRIs appear just as effective. The SSRIs decrease the frequency and intensity of attacks, anticipatory anxiety, and avoidance behavior. Furthermore, they decrease panic attacks regardless of whether the patient is actually depressed. However, if the patient does have coexisting depression, antidepressants will benefit the depression and panic disorder simultaneously. Common side effects include nausea, headache, insomnia, and sexual dysfunction. Weight gain is also a problem. In addition, SSRIs can *increase* anxiety early in treatment. To minimize exacerbation of anxiety, dosage should be low initially and then gradually increased. For paroxetine, the initial dosage is 10 mg/day, and the target range is 20 to 40 mg/day. For fluoxetine, the initial dosage is 10 mg/day, and the usual maintenance dosage is 20 mg/day. For sertraline, the initial dosage is 25 mg/day, and the target range is 50 to 200 mg/day.

36.2.2.1.2 Tricyclic Antidepressants.

The TCAs (eg, imipramine [Tofranil], clomipramine [Anafranil]) are second-line drugs for panic disorder. They should be used only after a trial with at least one SSRI has failed. Although TCAs are as effective as SSRIs, they are not as well tolerated. The most common side effects are sedation, orthostatic hypotension, and anticholinergic effects: dry mouth, blurred vision, urinary retention, constipation, and tachycardia. Of greater concern, TCAs can cause fatal dysrhythmias if taken in overdose. As with the SSRIs, dosage should be low initially and then gradually increased. For clomipramine, the initial dosage is 25 mg/day, and the target range is 50 to 200 mg/day. For imipramine, the initial dosage is 10 mg/day, and the target range is 100 to 300 mg/day.

36.2.2.1.3 Monoamine Oxidase Inhibitors.

Although MAOIs (eg, phenelzine) are very effective in panic disorder, they are difficult to use. MAOIs can cause significant side effects, including orthostatic hypotension, weight gain, and sexual dysfunction. In addition, they can cause hypertensive crisis if the patient takes certain drugs or consumes foods rich in tyramine. Because of these drawbacks, MAOIs are considered last-line drugs for panic disorder.

36.2.2.1.4 Benzodiazepines.

Although benzodiazepines are effective in panic disorder, they are now considered second-line drugs. Why? Because, unlike the SSRIs, benzodiazepines pose a risk of abuse, dependence, and rapid re-emergence of symptoms after discontinuation. Of the available benzodiazepines, the agents used most often are alprazolam [Xanax, Xanax XR, Niravam], clonazepam [Klonopin], and lorazepam [Ativan]. All three provide rapid and effective protection against panic attacks. These drugs also reduce anticipatory anxiety and phobic avoidance. In contrast to antidepressants, which take weeks or even months to work, benzodiazepines often provide relief with the first few doses. Accordingly, benzodiazepines can be especially useful as initial therapy while responses to antidepressants are developing. The principal side effect of the benzodiazepines is sedation, but some tolerance develops in 7 to 10 days. As noted, benzodiazepines can cause physical dependence, which can make withdrawal extremely hard for some patients. The difficulty is that withdrawal produces intense anxiety, which people with panic disorder may find intolerable. To minimize withdrawal symptoms, benzodiazepines should be withdrawn very slowly—over a period of several months. In addition, withdrawal symptoms can be reduced by concurrent treatment with an SSRI. The basic pharmacology of the benzodiazepines is discussed in [Chapter 34](#).

386

36.3 OBSESSIVE-COMPULSIVE DISORDER

387

36.3.1 Characteristics

Obsessive-compulsive disorder (OCD) is a potentially disabling condition characterized by persistent obsessions and compulsions that cause marked distress, consume at least 1 hour a day, and significantly interfere with daily living. An *obsession* is defined as a recurrent, persistent thought, impulse, or mental image that is unwanted and distressing, and comes involuntarily to mind despite attempts to ignore or suppress it. Common obsessions include fear of contamination (eg, acquiring a disease by touching another person), aggressive impulses (eg, harming a family member), a need for orderliness or symmetry (eg, personal bathroom items must be arranged in a precise way), and repeated doubts (eg, did I unplug the iron?). A *compulsion* is a ritualized behavior or mental act that the patient is driven to perform in response to his or her obsessions. In the patient's mind, carrying out the compulsion is essential to prevent some horrible event from occurring (eg, death of a loved one). If performing the compulsion is suppressed or postponed, the patient experiences increased anxiety. Common compulsions include hand washing, mental counting, arranging objects symmetrically, and hoarding. Patients usually understand that their compulsive behavior is excessive and senseless, but nonetheless are unable to stop. Diagnostic criteria for OCD, as described in DSM-IV, are presented in [Table 35-4](#).

36.3.2 Treatment

Patients with OCD respond to drugs and behavioral therapy. Optimal treatment consists of both.

Behavioral therapy is probably more important in OCD than in any other psychiatric disorder. In the technique employed, patients are exposed to sources of their fears, while being encouraged to refrain from acting out their compulsive rituals. When no dire consequences come to pass, despite the absence of “protective” rituals, patients are able to gradually give up their compulsive behavior. Although this form of therapy causes great anxiety, the success rate is high.

Five drugs are approved for OCD: four SSRIs and one TCA (clomipramine). All five enhance serotonergic transmission. The SSRIs are better tolerated than clomipramine, and hence are preferred.

36.3.2.1 Selective Serotonin Reuptake Inhibitors

The SSRIs are first-line drugs for OCD. Only four SSRIs—fluoxetine [Prozac], fluvoxamine [Luvox], sertraline [Zoloft], and paroxetine [Paxil]—are approved for OCD. However, the remaining two—citalopram [Celexa] and escitalopram [Lexapro]—are also effective. All six reduce symptoms by enhancing serotonergic transmission. They all are equally effective, although individual patients may respond better to one than to another. With all six, beneficial effects develop slowly, taking several months to become maximal. Common side effects include nausea, headache, insomnia, and sexual dysfunction. Weight gain can also occur. Despite this array of side effects, SSRIs are safer than clomipramine and better tolerated. Dosages are as follows:

- *Citalopram*—20 mg once daily initially, increased to a maximum of 60 mg/day
- *Escitalopram*—10 mg once daily initially; a maximum dosage has not been established
- *Fluoxetine*—20 mg in the morning initially, increased to a maximum of 80 mg/day

TABLE 35-4 DSM-IV-TR Diagnostic Criteria for Obsessive-Compulsive Disorder

<p>A. The presence of either obsessions or compulsions:</p> <p><i>Obsessions</i></p> <ol style="list-style-type: none"> 1. Recurrent and persistent thoughts, impulses, or images that are experienced at some time during the disturbance as intrusive and senseless and that cause marked anxiety and distress. 2. The thoughts, impulses, or images are not simply excessive worries about real-life problems. 3. The person attempts to ignore or suppress the thoughts, impulses, or images, or to neutralize them with some other thought or action. 4. The person recognizes that the obsessions are a product of his or her own mind. <p><i>Compulsions</i></p> <ol style="list-style-type: none"> 1. Repetitive behaviors (eg, hand washing, putting objects in order) or mental acts (eg, praying, counting, repeating words silently) that the person feels driven to perform in response to an obsession or according to rigid rules. 2. The behaviors or mental acts are performed to prevent or reduce distress or to prevent some dreaded event; however, these behaviors or mental acts either have no realistic connection with what they are designed to neutralize or prevent, or are clearly excessive. <p>B. At some time during the disorder, the person recognizes that the obsessions or compulsions are excessive or unreasonable. (This does not apply to children.)</p> <p>C. The obsessions or compulsions cause marked distress, are time consuming (take more than 1 hour a day), or significantly interfere with normal routines, occupational or academic functioning, or usual social activities or relationships.</p> <p>D. The symptoms are not related to another psychiatric disorder, and are not caused by a substance, medication, or general medical illness.</p> <p>Adapted from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. Washington, DC: American Psychiatric Press, 2000, with permission. Copyright © 2000 American Psychiatric Association.</p>
--

387

388

- *Fluvoxamine*—50 mg at bedtime initially, increased to a maximum of 300 mg/day
- *Paroxetine*—20 mg in the morning initially, increased to a maximum of 60 mg/day
- *Sertraline*—50 mg once a day initially, increased to a maximum of 300 mg/day

How long should treatment last? Therapy of an initial episode should continue for at least 1 year, after which discontinuation can be tried. Withdrawal should be done slowly, reducing the

dosage by 25% every 1 to 2 months. Unfortunately, relapse is common; estimates range from 23% to as high as 90%. If relapse continues to occur after three or four attempts at withdrawal, lifelong treatment may be indicated.

36.3.2.2 Clomipramine

For patients with OCD, clomipramine [Anafranil] is as effective as SSRIs, but less well tolerated. Accordingly, clomipramine is considered a second-line drug for this disorder, and hence should be used only after treatment with one or more SSRIs has failed.

Clomipramine is the only TCA shown effective in OCD. About 70% of patients experience a significant improvement. Initial effects take 4 weeks to develop; maximal effects are seen in 12 weeks.

Clomipramine affects several neurotransmitter systems. As with the SSRIs, benefits in OCD derive from blocking uptake of serotonin. (Among the TCAs, clomipramine is the most effective inhibitor of serotonin uptake.) However, in contrast to SSRIs, which block reuptake of serotonin only, clomipramine blocks reuptake of norepinephrine as well. Like other TCAs, clomipramine also blocks *receptors* for norepinephrine, acetylcholine, and histamine.

Clomipramine can cause a variety of side effects. Sedation, dry mouth, dizziness, and tremor occur in over 50% of patients. Other common effects include weight gain, constipation, blurred vision, insomnia, headache, and nausea. Of greatest concern, clomipramine can induce *seizures*. Because of seizure risk, the drug should be avoided in patients with a history of seizures or head injury. Clomipramine greatly increases the risk of hypertensive crisis from MAOIs, and therefore is contraindicated for patients taking these drugs.

Doses should be low initially (20 to 25 mg/day) and then gradually increased. Side effects can be minimized by dividing the early doses and taking them with meals. Maintenance doses of 150 to 250 mg/day are achieved in 2 to 4 weeks.

The basic pharmacology of clomipramine and other TCAs is discussed in [Chapter 32](#).

36.4 SOCIAL ANXIETY DISORDER (SOCIAL PHOBIA)

36.4.1 Characteristics

Social anxiety disorder, formerly known as social phobia, is characterized by an intense, irrational fear of situations in which one might be scrutinized by others, or might do something that is embarrassing or humiliating. Exposure to the feared situation almost always elicits anxiety. As a result, the person avoids the situation or, if it can't be avoided, endures it with intense anxiety

(manifestations include blushing, stuttering, sweating, palpitations, dry throat, and muscle tension and twitches). Diagnostic criteria for social anxiety disorder, as defined in DSM-IV, are listed in [Table 35-5](#).

Social anxiety disorder has two forms: generalized and nongeneralized. In the generalized form, the person fears nearly all social and performance situations. In the nongeneralized form, fear is limited to a specific type of situation, such as public speaking.

Social anxiety disorder can be very debilitating. In younger people, it can retard social development, inhibit participation in social activities, impair acquisition of friends, and make dating difficult or even impossible. It can also preclude pursuit of higher education. In older people, it can severely limit social and occupational options.

TABLE 35-5 DSM-IV-TR Diagnostic Criteria for Social Anxiety Disorder (Social Phobia)

- | |
|---|
| <p>A. A marked and persistent fear of one or more social or performance situations in which the person is exposed to unfamiliar people or to possible scrutiny by others. The individual fears that he or she will act in a way that will be embarrassing or humiliating, or will show anxiety symptoms that will be embarrassing or humiliating.</p> <p>B. Exposure to the feared situation almost always provokes anxiety.</p> <p>C. The person recognizes that the fear is excessive or unreasonable (not required in children).</p> <p>D. The feared situation is avoided, or endured with intense anxiety.</p> <p>E. The avoidance or anxious anticipation causes marked distress or interferes significantly with the person's relationships, normal routine, social activities, or performance at work or at school.</p> <p>F. For persons under age 18, the fear has lasted at least 6 months.</p> <p>G. The fear or avoidance is not caused by a substance, medication, or general medical illness, and cannot be better accounted for by another psychiatric illness.</p> |
|---|

Adapted from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. Washington, DC: American Psychiatric Press, 2000, with permission. Copyright © 2000 American Psychiatric Association.

Social anxiety disorder is one of the most common psychiatric disorders, and *the* most common anxiety disorder. In the United States, 13% to 14% of the population is affected at some time in their lives. The disorder typically begins during the teenage years and, left untreated, is likely to continue lifelong.

36.4.2 Treatment

Social anxiety disorder can be treated with psychotherapy, drug therapy, or both. Studies indicate that psychotherapy—both cognitive and behavioral—can be as effective as drugs. A combination of psychotherapy and drugs may be more effective than either modality alone.

The SSRIs are considered first-line drugs for most patients. These drugs are especially well suited for patients who fear multiple situations and are obliged to face those situations on a regular basis. Currently, only three SSRIs—fluvoxamine [Luvox], paroxetine [Paxil], and sertraline [Zoloft]—are approved for social anxiety disorder. However, available data indicate that the other SSRIs are effective too. Initial effects take about 4 weeks to develop; optimal effects are seen in 8 to 12 weeks. Patients should be informed that benefits will be delayed. For paroxetine, the initial dosage is 20 mg once a day in the morning. The usual maintenance range is 20 to 40 mg/day. Treatment should continue for at least 1 year, after which gradual withdrawal can be tried. Unfortunately, withdrawal frequently results in relapse.

Benzodiazepines (eg, clonazepam [Klonopin], alprazolam [Xanax]) are an option for some patients. These drugs are well tolerated and their benefits are immediate, unlike those of the SSRIs. As a result, benzodiazepines can provide rapid relief and can be used PRN. Accordingly, these drugs are well suited for people whose fear is limited to specific situations, and who must face those situations only occasionally. The usual dosage is 1 to 3 mg/day for clonazepam, and 1 to 6 mg/day for alprazolam.

388

389

Propranolol [Inderal] and other beta blockers can benefit patients with performance anxiety, a form of nongeneralized social anxiety disorder. When taken 1 to 2 hours before a scheduled performance, these drugs can reduce symptoms caused by autonomic hyperactivity (eg, tremors, sweating, tachycardia, palpitations). Doses are relatively small—only 10 to 80 mg for propranolol.

36.5 POST-TRAUMATIC STRESS DISORDER

36.5.1 Characteristics

As described in DSM-IV (see [Table 35-6](#)), post-traumatic stress disorder (PTSD) develops following a *traumatic event* that elicited an immediate reaction of *fear, helplessness, or horror*. PTSD has three core symptoms: *re-experiencing* the event, *avoiding reminders* of the event (coupled with generalized emotional numbing), and a persistent state of *hyperarousal*. According to DSM-IV, a traumatic event is one that involves a threat of injury or death, or a threat to one's physical integrity. Many events meet this criterion. Among these are physical or sexual assault, rape, torture, combat, industrial explosions, serious accidents, natural disasters, being taken

hostage, displacement as a refugee, and terrorist attacks, such as the ones that took place against the World Trade Center and the Pentagon on September 11, 2001. It should be noted that PTSD can affect persons who were only *witnesses* to a traumatic event—not just those who were directly involved.

The epidemiology of PTSD is revealing. In the United States, more than 5 million Americans have PTSD in any given year, making PTSD the fourth most common psychiatric disorder. PTSD develops in 5% to 6% of men at some time in their lives, and in 10% to 14% of women. Traumatic events that involve interpersonal violence (eg, assault, rape, torture) are more likely to cause PTSD than are traumatic events that do not (eg, car accidents, natural disasters). For example, among rape victims, the incidence of PTSD is 45.9% for women and 65% for men. In contrast, among natural disaster survivors, the incidence is only 5.4% for women and 3.7% for men. Combat carries a high risk of PTSD: the disorder develops in 40% of soldiers who go to war.

36.5.2 Treatment

Optimal treatment for PTSD—be it psychotherapy and/or drugs—has not been established. In 2007, the Institute of Medicine (IOM) of the National Academies issued a report—*Treatment of PTSD: An Assessment of the Evidence*—that concluded that, for most PTSD treatments, evidence of efficacy is insufficient to recommend their use. This does not mean that most treatments don't work. Rather, it means we lack conclusive proof that they *do* work.

The IOM evaluated research on five kinds of psychotherapy: exposure therapy, group therapy, cognitive restructuring, coping skills training, and eye-movement desensitization and reprocessing. Of the treatments, only one—*exposure therapy*—had sufficient proof of efficacy to recommend its use. In this technique, patients repeatedly reimagine traumatic events as a way to make those events lose their power.

389

390

TABLE 35-6 DSM-IV-TR Diagnostic Criteria for Post-traumatic Stress Disorder

- A. The person participated in (or witnessed) a *traumatic event*, and reacted with a sense of intense fear, helplessness, or horror. The event could involve serious physical injury, actual or threatened death, or a threat to physical integrity.
- B. The traumatic event is *persistently re-experienced*, either through flashbacks, hallucinations, distressing dreams, or recurrent thoughts, or through intense psychologic or physiologic reactions triggered by exposure to cues associated with the event.
- C. Persistent *avoidance* of reminders of the event stimuli along with *generalized emotional numbing*, as indicated by three or more of the following:
- Efforts to avoid thoughts, feelings, or conversations associated with the trauma
 - Efforts to avoid activities, places, or people that arouse recollections of the trauma
 - Inability to recall an important aspect of the trauma
 - Markedly diminished interest or participation in significant activities
 - Feeling detached or estranged from others
 - Restricted range of affect (eg, unable to have loving feelings)
 - Sense of foreshortened future (eg, does not expect to have a career, marriage, children, or a normal life span)
- D. Persistent symptoms of increased arousal, as indicated by two or more of the following:
- Difficulty falling or staying asleep
 - Irritability or outbursts of anger
 - Difficulty concentrating
 - Hypervigilance
 - Exaggerated startle response
- E. The symptoms (B, C, and D) have lasted more than 1 month.
- F. The symptoms cause significant distress, or disrupt relationships, job performance, or some other important facet of life.

Adapted from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. Washington, DC: American Psychiatric Press, 2000, with permission. Copyright © 2000 American Psychiatric Association.

Regarding drugs used for PTSD, the IOM report found no proof that *any* of them help, including *paroxetine* [Paxil] and *sertraline* [Zoloft], the only agents approved for PTSD by the Food and Drug Administration (FDA). Other drugs lacking proof of efficacy include benzodiazepines, anticonvulsants, prazosin (an alpha-adrenergic blocker), phenelzine (an MAOI), olanzapine and risperidone (atypical antipsychotics), and all antidepressants, including all SSRIs.

36.5.2.1

KEY POINTS

- Anxiety is an uncomfortable state that has psychologic manifestations (fear, apprehension, dread, uneasiness) and physical manifestations (tachycardia, palpitations, trembling, dry mouth, sweating, weakness, fatigue, shortness of breath).
- When anxiety is persistent and disabling, intervention is indicated.
- As a rule, optimal therapy of anxiety disorders consists of psychotherapy combined with drug therapy.
- The drugs used most often for anxiety disorders are benzodiazepines and selective serotonin reuptake inhibitors (SSRIs).
- Benzodiazepines are used primarily for panic disorder and generalized anxiety disorder (GAD), whereas SSRIs are used for *all* anxiety disorders.
- GAD is a chronic condition characterized by uncontrollable worrying.
- First-line drugs for GAD are benzodiazepines, buspirone, and four antidepressants: venlafaxine, paroxetine, escitalopram, and duloxetine.
- Benzodiazepines suppress symptoms of GAD immediately. Accordingly, these drugs are preferred agents for rapid stabilization, especially when anxiety is severe.
- With buspirone, venlafaxine, paroxetine, escitalopram, and duloxetine, anxiolytic effects are delayed. Accordingly, these drugs are best suited for long-term management—not rapid relief.
- Benzodiazepines are CNS depressants and hence can cause sedation and psychomotor slowing. In addition, they can intensify CNS depression caused by other drugs.
- Benzodiazepines have some potential for abuse, and hence should be used with caution in patients known to abuse alcohol or other psychoactive drugs.

- When taken long term, benzodiazepines can cause physical dependence. To minimize withdrawal symptoms, dosage should be tapered off gradually—over a period of several months.
- Buspirone has three advantages over benzodiazepines: It does not cause CNS depression, has no abuse potential, and does not intensify the effects of CNS depressants.
- Buspirone levels can be increased by erythromycin, ketoconazole, and grapefruit juice.
- Venlafaxine, paroxetine, escitalopram, and duloxetine are especially well suited for treating patients who have depression in addition to GAD. However, they are also effective even when depression is absent.
- Patients with panic disorder experience recurrent panic attacks, characterized by palpitations, pounding heart, chest pain, derealization or depersonalization, and fear of dying or going crazy.
- Many patients with panic disorder also experience agoraphobia, a condition characterized by anxiety about being in places or situations from which escape might be difficult or embarrassing, or in which help might be unavailable if a panic attack should occur.
- SSRIs are first-line drugs for panic disorder.
- SSRIs decrease the frequency and intensity of panic attacks, anticipatory anxiety, and avoidance behavior, and they work regardless of whether the patient has depression.
- Obsessive-compulsive disorder (OCD) is characterized by persistent obsessions and compulsions that cause marked distress, consume at least 1 hour a day, and significantly interfere with daily living.
- SSRIs are first-line drugs for OCD.
- Social anxiety disorder, formerly known as social phobia, is characterized by an intense, irrational fear of being scrutinized by others, or of doing something that is embarrassing or humiliating.
- The SSRIs are first-line drugs for most patients with social anxiety disorder.

- When social anxiety disorder is limited to fear of specific situations, and when those situations arise infrequently, PRN treatment with benzodiazepines may be preferred to long-term treatment with SSRIs.
- Post-traumatic stress disorder (PTSD) develops following a traumatic event that elicited an immediate reaction of fear, helplessness, or horror.
- PTSD has three core symptoms: re-experiencing, avoidance/emotional numbing, and hyperarousal.
- Events that can precipitate PTSD include physical or sexual assault, rape, torture, combat, industrial explosions, serious accidents, natural disasters, being taken hostage, displacement as a refugee, and terrorist attacks.
- According to the IOM, exposure therapy is the only treatment for PTSD with good proof of efficacy.
- According to the IOM, there is no good proof that any drugs are effective in PTSD, even though two SSRIs—paroxetine and sertraline—are approved by the FDA for this indication.

³⁷CHAPTER 36 Central Nervous System Stimulants and Attention-Deficit/Hyperactivity Disorder

Central nervous system (CNS) stimulants increase the activity of CNS neurons. Most stimulants act by enhancing neuronal excitation. A few act by suppressing neuronal inhibition. In sufficient doses, all stimulants can cause convulsions.

Clinical applications of the CNS stimulants are limited. Currently these drugs have two principal indications: attention-deficit/hyperactivity disorder (ADHD) and narcolepsy. In the past, stimulants were used to treat obesity and counteract poisoning by CNS depressants, but these uses are no longer recommended.

Please note that CNS stimulants are not the same as antidepressants. The antidepressants act selectively to elevate mood, and hence can relieve depression without affecting other CNS functions. In contrast, CNS stimulants cannot elevate mood without producing generalized excitation. Accordingly, the role of stimulants in treating depression is minor.

Our principal focus is on *amphetamines*, *methylphenidate* [Ritalin, others], and *methylxanthines* (eg, caffeine). These agents are by far the most widely used stimulant drugs.

^{37.1} AMPHETAMINES

The amphetamine family consists of amphetamine, dextroamphetamine, methamphetamine, and lisdexamfetamine. All are powerful CNS stimulants. In addition to their CNS actions, amphetamines have significant actions in the periphery—actions that can cause cardiac stimulation and vasoconstriction. The amphetamines have a high potential for abuse.

^{37.1.1} Chemistry

^{37.1.1.1} Dextroamphetamine and Levamphetamine.

The amphetamines are molecules that contain an asymmetric carbon atom. As a result, amphetamines can exist as mirror images of each other. Such compounds are termed *optical isomers* or *enantiomers*. Dextroamphetamine and levamphetamine, whose structures are shown in [Figure 36-1](#), illustrate the mirror-image concept. As we can see, dextroamphetamine and levamphetamine both contain the same atomic components, but those components are arranged differently around the asymmetric carbon. Because of this structural difference, these compounds have somewhat different properties. For example, dextroamphetamine is more

selective than levamphetamine for causing stimulation of the CNS, and hence produces fewer peripheral side effects.

37.1.1.2 Amphetamine.

The term *amphetamine* refers not to a single compound but rather to a 50:50 mixture of dextroamphetamine and levamphetamine. (In chemistry, we refer to such equimolar mixtures of enantiomers as racemic.)

37.1.1.3 Lisdexamfetamine.

Lisdexamfetamine [Vyvanse], introduced in 2007, is a prodrug composed of dextroamphetamine covalently linked to L-lysine. Following oral dosing, the drug undergoes rapid hydrolysis by enzymes in the intestine and liver to yield lysine and dextroamphetamine, the active form of the drug. If lisdexamfetamine is inhaled or injected, hydrolysis will not take place, and hence the drug is not effective by these routes. Accordingly, it may have a lower abuse potential than other forms of amphetamine.

37.1.1.4 Methamphetamine.

Methamphetamine is simply dextroamphetamine with an extra methyl group (see [Fig. 36-1](#)).

37.1.2 Mechanism of Action

The amphetamines act primarily by promoting release of norepinephrine (NE) and dopamine (DA), and partly by inhibiting reuptake of both transmitters. These actions take place in the CNS and in peripheral nerves. Most effects result from release of NE.

391

Figure 36-1 **Structural formulas of the amphetamines.** “Amphetamine” is a 50:50 mixture of dextroamphetamine and levamphetamine. Note that dextroamphetamine and levamphetamine are simply mirror images of each other. Both compounds contain the same atomic components.

37.1.3 Pharmacologic Effects

37.1.3.1 Central Nervous System.

The amphetamines have prominent effects on mood and arousal. At usual doses, they increase wakefulness and alertness, reduce fatigue, elevate mood, and augment self-confidence and initiative. Euphoria, talkativeness, and increased motor activity are likely. Task performance that had been reduced by fatigue or boredom improves.

Amphetamines can stimulate respiration, and suppress appetite and perception of pain. Stimulation of the medullary respiratory center increases respiration. Effects on the hypothalamic feeding center depress appetite. By a mechanism that is not understood, amphetamines can enhance the analgesic effects of morphine and other opioids.

37.1.3.2 Cardiovascular System.

Cardiovascular effects occur secondary to release of NE from sympathetic neurons. Norepinephrine acts in the heart to increase heart rate, atrioventricular (AV) conduction, and force of contraction. Excessive cardiac stimulation can cause dysrhythmias. In blood vessels, NE promotes constriction. Excessive vasoconstriction can cause hypertension.

37.1.4 Tolerance

With regular amphetamine use, tolerance develops to elevation of mood, suppression of appetite, and stimulation of the heart and blood vessels. In highly tolerant users, doses up to 1000 mg (IV) every few *hours* may be required to maintain *euphoric* effects. This compares with *daily* doses of 5 to 30 mg for nontolerant individuals.

37.1.5 Physical Dependence

Chronic amphetamine use produces physical dependence. If amphetamines are abruptly withdrawn from a dependent person, an abstinence syndrome will ensue. Symptoms include exhaustion, depression, prolonged sleep, excessive eating, and a craving for more amphetamine. Sleep patterns may take months to normalize.

37.1.6 Abuse

Because amphetamines can produce euphoria (extreme mood elevation), they have a high potential for abuse. Psychologic dependence can occur. (Users familiar with CNS stimulants find the psychologic effects of amphetamines nearly identical to those of cocaine.) Because of their abuse potential, all amphetamines, including lisdexamfetamine, are classified under Schedule II of the Controlled Substances Act and must be dispensed accordingly. Whenever amphetamines are used therapeutically, their potential for abuse must be weighed against their potential benefits.

37.1.7 Adverse Effects

37.1.7.1 CNS Stimulation.

Stimulation of the CNS can cause insomnia, restlessness, and extreme loquaciousness. These effects can occur at therapeutic doses.

37.1.7.2 Weight Loss.

By suppressing appetite, amphetamines can cause weight loss. For people who are lean to start with, weight loss is considered an adverse effect. Conversely, for people who are obese, weight loss is desirable.

37.1.7.3 Cardiovascular Effects.

Stimulation of the heart and blood vessels can result in dysrhythmias, anginal pain, and hypertension. Accordingly, amphetamines must be employed with extreme caution in patients with cardiovascular disease.

Do amphetamines increase the risk of *sudden death*? Probably not. And should children *routinely* receive an electrocardiogram (ECG) before using these drugs? Probably not—despite a 2008 statement from the American Heart Association (AHA) saying it would be reasonable to consider obtaining an ECG in children being evaluated for stimulant therapy of ADHD. Why is the AHA concerned? Because 14 children, 5 with heart defects, died suddenly while using Adderall, a mixture of amphetamine and dextroamphetamine. However, given that millions of children have used the drug, the death rate is no greater than would be expected for a group this size, whether or not Adderall was being used. The bottom line? First, there are no data showing that stimulants increase the risk of sudden death, even in children with heart disease. Second, there are no data showing that limiting the use of stimulants in children with heart defects will protect them from sudden death. And third, there are no data showing that screening for heart disease with an ECG before starting stimulants will be of any benefit. Therefore, it would seem that routine ECGs are unnecessary before starting a child on stimulant therapy, especially if there is no evidence of heart disease. If there *is* evidence of heart disease, an ECG might be helpful, but certainly is not required.

392

393

37.1.7.4 Psychosis.

Excessive amphetamine use produces a state of paranoid psychosis, characterized by hallucinations and paranoid delusions (suspiciousness, feelings of being watched).

Pharmacology for Nursing Care, 7th Edition

Amphetamine-induced psychosis looks very much like schizophrenia. Symptoms are thought to result from release of DA. Consistent with this hypothesis is the observation that symptoms can be alleviated with a DA receptor blocking agent (eg, haloperidol). Following amphetamine withdrawal, psychosis usually resolves spontaneously within a week.

In some individuals, amphetamines can unmask latent schizophrenia. For these people, symptoms of psychosis do not clear spontaneously, and hence psychiatric care is needed.

37.1.8 Acute Toxicity

37.1.8.1 Symptoms.

Overdose produces dizziness, confusion, hallucinations, paranoid delusions, palpitations, dysrhythmias, and hypertension. Death is rare. Fatal overdose is associated with convulsions, coma, and cerebral hemorrhage.

37.1.8.2 Treatment.

Hallucinations can be controlled with chlorpromazine, an antipsychotic drug. An alpha-adrenergic blocker (eg, phentolamine) can reduce hypertension (by promoting vasodilation). Because of its ability to block alpha receptors, chlorpromazine helps lower blood pressure. Seizures can be managed with diazepam. Acidifying the urine can accelerate amphetamine excretion.

37.1.9 Therapeutic Uses

37.1.9.1 Attention-Deficit/Hyperactivity Disorder.

The role of amphetamines in ADHD is discussed later.

37.1.9.2 Narcolepsy.

Narcolepsy is a disorder characterized by daytime somnolence and uncontrollable attacks of sleep. By stimulating the CNS, amphetamines can promote arousal and thereby alleviate symptoms.

37.1.9.3 Obesity.

Because they suppress appetite, amphetamines have been employed in programs for weight loss. However, because of their high potential for abuse, and because they offer no advantages over less dangerous drugs, amphetamines are not recommended for weight reduction.

37.1.10 Preparations, Dosage, and Administration

Four members of the amphetamine family are used clinically: dextroamphetamine sulfate, an amphetamine/dextroamphetamine mixture, lisdexamfetamine, and methamphetamine. A fifth agent—amphetamine sulfate (racemic amphetamine)—has been discontinued. In clinical practice, amphetamines are given *orally*. (These drugs are not approved for IV administration.

Amphetamines for IV use are available only through illegal sources.) All amphetamines are regulated under Schedule II of the Controlled Substances Act and must be dispensed accordingly.

37.1.10.1 Dextroamphetamine Sulfate.

Dextroamphetamine is available in short-duration (SD) and long-duration (LD) formulations. Both are indicated for ADHD.

37.1.10.1.1 Short Duration.

SD dextroamphetamine [DextroStat] is available in 5- and 10-mg tablets. Effects begin rapidly and last 4 to 6 hours. The usual dosage for ADHD is 5 mg at 8:00 AM, noon, and 4:00 PM.

37.1.10.1.2 Long Duration.

LD dextroamphetamine [Dexedrine Spansules] is available in 5-, 10-, and 15-mg capsules. Effects begin rapidly and last 6 to 10 hours. The usual dosage for ADHD is 10 mg once daily in the morning.

37.1.10.2 Amphetamine/Dextroamphetamine Mixture.

Amphetamine mixture is available in SD and LD formulations. Both are used for ADHD.

37.1.10.2.1 Short Duration.

The SD formulation [Adderall] is available in immediate-release tablets (5, 7.5, 10, 12.5, 15, 20, and 30 mg). Effects begin rapidly and last 4 to 6 hours. The usual dosage for ADHD is 5 mg twice daily, taken 5 hours apart.

37.1.10.2.2 Long Duration.

The LD formulation [Adderall-XR] is available in 5-, 10-, 15-, 20-, 25-, and 30-mg capsules. Half the dose is released immediately, and the remainder 4 hours later. As a result, effects begin rapidly and last 10 to 12 hours. The usual dosage is 20 mg once daily in the morning. This is equivalent to taking 10 mg of SD Adderall at 8:00 AM and again around noon.

37.1.10.3 Lisdexamfetamine.

Lisdexamfetamine [Vyvanse] is available in capsules (20, 30, 40, 50, 60, and 70 mg). Effects begin rapidly and persist 10 to 12 hours. Dosing is done once daily in the morning without regard to meals. The capsules may be swallowed intact, or their contents may be dissolved in water and swallowed immediately. The usual daily dosage for ADHD is 30 mg.

37.1.10.4 Methamphetamine.

Methamphetamine [Desoxyn] is indicated for ADHD and obesity, although it is not a preferred treatment for either condition. The drug is available in 5-mg SD tablets. The usual regimen for ADHD is 20 to 25 mg/day, administered in two divided doses.

37.2 METHYLPHENIDATE AND DEXMETHYLPHENIDATE

Methylphenidate and dexmethylphenidate are nearly identical in structure and pharmacologic actions. Furthermore, the pharmacology of both drugs is nearly identical to that of the amphetamines.

37.2.1 Methylphenidate

Although methylphenidate [Ritalin, Metadate, Methylin, Concerta, Daytrana] is structurally dissimilar from the amphetamines, the pharmacologic actions of these drugs are essentially the same. Consequently, methylphenidate can be considered an amphetamine in all but structure and name. Methylphenidate and amphetamine share the same mechanism of action (promotion of NE and DA release, and inhibition of NE and DA reuptake), adverse effects (insomnia, reduced

appetite, emotional lability), and abuse liability (Schedule II). Like amphetamine, methylphenidate is not a single compound, but rather a 50:50 mixture of dextro and levo isomers. The dextro isomer is highly active; the levo isomer is not. Methylphenidate has two indications: ADHD and narcolepsy.

37.2.1.1 Preparations, Dosage, and Administration

Methylphenidate is available in three types of formulations: short duration (SD), intermediate duration (ID), and long duration (LD). All three are indicated for ADHD. As a rule, the SD and ID formulations must be taken 2 or 3 times a day, whereas the LD formulations can be taken just once a day.

37.2.1.1.1 Short Duration.

SD methylphenidate [Ritalin, Methylin] is available in standard tablets (5, 10, and 20 mg), chewable tablets (2.5, 5, and 10 mg), and an oral solution (5 and 10 mg/5 mL). Effects begin rapidly and last 3 to 5 hours. Because effects are brief, dosing must be done 2 or 3 times a day. The usual pediatric dosage for ADHD is 10 mg at 8:00 AM and noon, and 5 mg at 4:00 PM.

37.2.1.1.2 Intermediate Duration.

ID methylphenidate [Ritalin SR, Metadate ER, Methylin ER] is available in 10- and 20-mg tablets. Effects are delayed and last 6 to 8 hours. Dosing is done once or twice daily. For children with ADHD, the usual dosage is 20 to 40 mg in the morning, supplemented with 20 mg in the early afternoon if needed.

393

394

37.2.1.1.3 Long Duration.

Four LD products are available. Their trade names are Concerta, Metadate CD, Ritalin LA, and Daytrana. With all four, dosing is done once daily in the morning; no afternoon dose is needed.

37.2.1.1.3.1 Concerta.

Concerta tablets—formulated as an osmotic-release oral system (OROS)—consist of an outer coating of immediate-release methylphenidate and a special inner core that releases the remainder of each dose gradually. As a result, effects begin rapidly and last up to 14 hours. Because of their special architecture, Concerta tablets must be swallowed whole, not crushed or chewed. The tablet shell may not dissolve fully in the GI tract. Accordingly,

patients should be informed they may see tablet “ghosts” in the stool. Concerta tablets are available in four strengths: 18, 27, 36, and 54 mg.

Dosage depends on whether the patient is already taking methylphenidate (SD or ID). For children *not* already taking methylphenidate, the initial dosage is 18 mg once daily in the morning. Dosage can be increased to a maximum of 72 mg once daily. For children who *are* taking methylphenidate (SD or ID), the initial dosage of Concerta is as follows:

- For those taking 5 mg (2 or 3 times a day) of SD methylphenidate or 20 mg once daily of ID methylphenidate, start with 18 mg of Concerta.
- For those taking 10 mg (2 or 3 times a day) of SD or 40 mg once daily of ID, start with 36 mg of Concerta.
- For those taking 15 mg (2 or 3 times a day) of SD or 60 mg once daily of ID, start with 54 mg of Concerta.

37.2.1.1.3.2

Metadate CD.

Metadate CD is available in 20-mg capsules that contain immediate-release and delayed-release beads. The beads release 30% of the dose rapidly, and the remaining 70% four hours later. As a result, plasma levels peak twice—at 1.5 and 4.5 hours. This is the same pattern produced by taking SD methylphenidate twice daily. For ADHD patients *not* already taking methylphenidate, the initial dosage is 20 mg once daily in the morning. This can be gradually increased to a maximum of 60 mg once daily. For patients who *are* already taking methylphenidate, start with 20 mg of Metadate once daily (for those taking 10 mg of SD methylphenidate twice daily), or with 40 mg of Metadate once daily (for those taking 20 mg of SD methylphenidate twice daily). If needed, Metadate CD capsules can be opened and sprinkled on a small amount of soft food (eg, applesauce) just prior to ingestion.

37.2.1.1.3.3

Ritalin LA.

Ritalin LA is formulated as extended-release capsules (10, 20, 30, and 40 mg). The product is much like Metadate CD in that some of the dose is released immediately and the rest 4 hours later. Dosing is done *once daily in the morning*. As with Metadate CD and Concerta, dosage depends on whether the patient is already taking methylphenidate (SD or ID). For children *not* already taking methylphenidate, the initial dosage is 20 mg. Dosage can be gradually increased to a maximum of 60 mg. For children who *are* taking methylphenidate (SD or ID), the initial dosage is as follows:

- For those taking 10 mg twice daily of SD methylphenidate or 20 mg once daily of ID methylphenidate, start with 20 mg of Ritalin LA.
- For those taking 15 mg twice daily of SD, start with 30 mg of Ritalin LA.
- For those taking 20 mg twice daily of SD or 40 mg once daily of ID, start with 40 mg of Ritalin LA.
- For those taking 30 mg twice daily of SD or 60 mg once daily of ID, start with 60 mg of Ritalin LA.

37.2.1.1.3.4

Daytrana.

Daytrana—a *transdermal methylphenidate patch*—is the first nonoral treatment for ADHD. Following patch application, blood levels of methylphenidate rise slowly and peak in about 9 hours, after which the patch should be removed. Because of the slow rise, effects are delayed about 2 hours. Furthermore, effects will persist for about 3 hours after patch removal. Daytrana patches are available in four sizes—12.5, 18.75, 25, and 37.5 cm²—that deliver 10, 15, 20, and 30 mg/9 hours, respectively. Treatment should begin with the smallest patch, even in patients already taking methylphenidate PO. If needed, larger patches can be tried at weekly intervals. Patients should apply the patch to the hip in the morning—alternating hips each day—and remove it no more than 9 hours later. (They can remove it sooner to terminate effects early). Application to inflamed skin or applying heat will accelerate drug absorption, and hence should be avoided. Patients should be informed that bathing, showering, and swimming will not dislodge the patch.

Side effects of the patch are like those of oral methylphenidate, with two exceptions. First, users may experience erythema and pruritus at the application site. Second, exposing the skin to methylphenidate can cause a *hypersensitivity reaction*. If hypersensitivity develops, the patient may be unable to use *any* methylphenidate formulation—transdermal or oral—ever again.

37.2.2 Dexmethylphenidate

Dexmethylphenidate [Focalin, Focalin XR], a drug for ADHD, is simply the dextro isomer of methylphenidate. As noted, the dextro isomer accounts for most of the pharmacologic activity of methylphenidate, a 50:50 mixture of dextro and levo isomers. Accordingly, the pharmacology of dexmethylphenidate is nearly identical to that of methylphenidate. The only difference is that the dosage of dexmethylphenidate is one-half the dosage of methylphenidate. Dexmethylphenidate is

available in SD tablets (2.5, 5, and 10 mg) marketed as *Focalin*, and in LD capsules (5, 10, 15, and 20 mg) marketed as *Focalin XR*. Both formulations may be administered with or without food. For children currently treated with methylphenidate, the initial dosage of dexamethylphenidate is one-half the methylphenidate dosage. For children who are *not* currently being treated, the initial dosage is 2.5 mg twice daily (using Focalin), or 5 mg once daily (using Focalin XR). The maximum dosage is 10 mg twice daily (for Focalin) and 20 mg once daily (for Focalin XR). Dexamethylphenidate is a Schedule II drug and must be dispensed accordingly.

37.3 METHYLYXANTHINES

The methylxanthines are derivatives of xanthine, hence the family name. As shown in [Figure 36-2](#), these compounds consist of a xanthine nucleus to which one or more methyl groups is attached. Caffeine, the most familiar member of the family, will serve as our prototype.

37.3.1 Caffeine

Caffeine is consumed worldwide for its stimulant effects. In the United States, per capita consumption is about 200 mg/day, mostly in the form of coffee. Although clinical applications of caffeine are few, caffeine remains of interest because of its widespread ingestion for nonmedical purposes.

37.3.1.1 Dietary Sources

Caffeine can be found in chocolates, desserts, soft drinks, and beverages prepared from various natural products. Common dietary sources are coffee, tea, and cola drinks. The caffeine in cola drinks derives partly from the cola nut and partly from caffeine added by the manufacturer. Caffeine is also present in many noncola soft drinks. The caffeine content of some common foods and beverages is shown in [Table 36-1](#).

Figure 36-2 Structural formulas of the methylxanthines.

TABLE 36-1 Dietary Caffeine

Product	Amount	Caffeine (mg)
Coffee		
Brewed (typical)	8 oz	60–180
Brewed (Starbucks café latte)	16 oz	150
Instant	8 oz	30–120
Espresso (Starbucks)	1 oz	89
Decaffeinated	8 oz	1–5
Tea		
Brewed (Lipton)	8 oz	35–40
Snapple ice tea	16 oz	48
Celestial Seasonings Herbal Tea, all varieties	8 oz	0
Lipton Natural Brew Iced Tea Mix, decaffeinated	8 oz	<5
Soda		
Jolt	12 oz	71
Red Bull Cola	12 oz	45
Mountain Dew	12 oz	55
Diet Coke	12 oz	47
Coca-Cola	12 oz	45
Dr. Pepper	12 oz	41
Orange soda, Sunkist	12 oz	40
Pepsi-Cola	12 oz	37
7-UP	12 oz	0
Sprite	12 oz	0
Caffeinated Water		
Java Water	16.9 oz	125
Krank20	16.9 oz	100
Aqua Blast	16.9 oz	90
Water Joe	16.9 oz	60–70
Aqua Java	16.9 oz	50–60
Ice Cream and Yogurt		

Starbucks Coffee Ice Cream	1/2 cup	20–30
Häagen-Dazs Coffee Fudge Ice Cream	1/2 cup	15
Dannon Coffee Yogurt	4 oz	22
Miscellaneous		
Cocoa	8 oz	2–50
Chocolate milk	1.5 oz	3–11
Hershey's Bar (milk chocolate)	1.5 oz	10
Hershey's Special Dark Chocolate Bar	1.5 oz	31
Baker's chocolate	1.5 oz	38–53
Caffeinated beer	10 oz	54

37.3.1.2 Mechanism of Action

Several mechanisms of action have been proposed. These include (1) reversible blockade of adenosine receptors, (2) enhancement of calcium permeability in the sarcoplasmic reticulum, and (3) inhibition of cyclic nucleotide phosphodiesterase, resulting in accumulation of cyclic adenosine monophosphate (cyclic AMP). Blockade of adenosine receptors appears responsible for most effects.

37.3.1.3 Pharmacologic Effects

37.3.1.3.1 Central Nervous System.

In low doses, caffeine decreases drowsiness and fatigue and increases the capacity for prolonged intellectual exertion. With increasing dosage, caffeine produces nervousness, insomnia, and tremors. When administered in very large amounts, the drug can cause convulsions. Despite popular belief, there is little evidence that caffeine can restore mental function during intoxication with alcohol, although it might delay passing out.

37.3.1.3.2 Heart.

High doses of caffeine stimulate the heart. When caffeinated beverages are consumed in excessive amounts, dysrhythmias may result.

37.3.1.3.3 Blood Vessels.

Caffeine affects blood vessels in the periphery differently from those in the CNS. In the periphery, caffeine promotes *vasodilation*, whereas in the CNS, caffeine promotes

vasoconstriction. Constriction of cerebral blood vessels is thought to underlie the drug's ability to relieve headache.

37.3.1.3.4 Bronchi.

Caffeine and other methylxanthines cause relaxation of bronchial smooth muscle, and thereby promote bronchodilation. Theophylline is an especially effective bronchodilator, and hence can be used to treat asthma (see [Chapter 75](#)).

37.3.1.3.5 Kidney.

Caffeine is a diuretic. The mechanism underlying increased urine formation is not fully understood.

37.3.1.3.6 Reproduction: Birth Defects and Miscarriage.

Caffeine readily crosses the placenta and may pose a risk of birth defects. When applied to cells in culture, caffeine can cause chromosomal damage and mutations. However, the concentrations required are much greater than can be achieved by drinking caffeinated beverages. Also, although there is clear proof that caffeine can cause birth defects in animals, studies have failed to document birth defects in humans.

A study published in 2008 showed that caffeine carries a dose-dependent risk of miscarriage. Consuming less than 200 mg/day poses little risk. In contrast, consuming 200 mg/day or more appears to double the risk. Accordingly, in order to reduce the risk of miscarriage, pregnant women should consume no more than 200 mg of caffeine a day—and preferably less.

37.3.1.4 Pharmacokinetics

Caffeine is readily absorbed from the GI tract, and achieves peak plasma levels within 1 hour. Plasma half-life ranges from 3 to 7 hours. Elimination is by hepatic metabolism.

37.3.1.5 Therapeutic Uses

37.3.1.5.1 Neonatal Apnea.

Premature infants may experience prolonged apnea (lasting 15 seconds or more) along with bradycardia. Hypoxemia and neurologic damage may result. Caffeine and other methylxanthines can reduce the number and duration of apnea episodes and can promote a more regular pattern of breathing.

37.3.1.5.2 Promoting Wakefulness.

Caffeine is used commonly to aid staying awake. The drug is marketed in various over-the-counter preparations [Maximum Strength NoDoz, Vivarin, others] for this purpose. Of course, individuals desiring increased alertness needn't take a pill; they can get just as much caffeine by drinking coffee or some other caffeine-containing beverage.

37.3.1.5.3 Other Applications.

Intravenous caffeine can help relieve headache induced by spinal puncture. The drug is used orally to enhance analgesia induced by opioids and by nonopioid analgesics (eg, aspirin).

37.3.1.6 Acute Toxicity

Caffeine poisoning is characterized by intensification of the responses seen at low doses.

395

Stimulation of the CNS results in excitement, restlessness, and insomnia; if the dosage is very high, convulsions may occur. Tachycardia and respiratory stimulation are likely. Sensory phenomena (ringing in the ears, flashing lights) are common. Death from caffeine overdose is rare. When fatalities have occurred, between 5 and 10 gm have been ingested.

396

37.3.1.7 Preparations, Dosage, and Administration

37.3.1.7.1 For Promoting Wakefulness.

Caffeine is available in three formulations for promoting wakefulness: 200-mg tablets, 200-mg capsules, and 75-mg lozenges. The usual dosage for promoting alertness is 100 to 200 mg every 3 to 4 hours as needed.

37.3.1.7.2 For Neonatal Apnea.

Caffeine citrate [Cafcit] is used for neonatal apnea. The drug is available in oral and IV solutions. Both have the same concentration: 20 mg/mL. Treatment consists of an IV loading dose (20 mg/kg) followed every 24 hours by an oral or IV maintenance dose (5 mg/kg). *Note:* The amount of caffeine *base* in a 20-mg dose of caffeine citrate is only 10 mg (ie, one-half of the total dose on a milligram basis).

37.3.2 Theophylline

Theophylline has pharmacologic actions much like those of caffeine. Like caffeine, theophylline is an effective CNS stimulant. However, in contrast to caffeine, theophylline is used to treat asthma; benefits derive from causing bronchodilation. Use in asthma is discussed in [Chapter 75](#).

37.3.3 Theobromine

Theobromine is a methylxanthine that occurs naturally in the seeds of *Theobroma cacao*, from which cocoa and chocolate are made. The caffeine content of these seeds is relatively low. Although there are similarities between theobromine and caffeine, these compounds do differ. The most distinct difference is that caffeine is a more effective CNS stimulant. Accordingly, CNS excitation produced by ingestion of cocoa and chocolate derives primarily from their caffeine content and not from theobromine. Toxicity from theobromine in chocolate is discussed in [Box 36-1](#).

37.3.3.1 BOX 36-1 Special Interest Topic

37.3.3.1.1 DID KISSES KILL CALVIN?

Well...no. But they might have. Calvin, recently deceased, was a happy little Jack Russell terrier who lived with Nancy, my very significant other, on her horse farm here in central Virginia. Our country squire graciously shared his home with sundry horses and ponies, gaggles of geese, and his dearest friends: Gucci, Hannah, Sandy, and Lucy—Nancy's other four dogs. Calvin enjoyed a rich, tranquil, contented life, until being mortally wounded while defending his home and friends from a canine intruder. We loved our little man. And we miss him.

So, what's the connection between Calvin and lethal kisses? One day, when I tossed Calvin a Hershey's Chocolate Kiss, Nancy became horrified and demanded I stop. "Why?" I asked. "Because," she said, "chocolate is poisonous to dogs. Didn't you know?" Right. Death by chocolate. Needless to say, this pharmacologist was skeptical. So I did some reading. Turns out, Nancy was correct: Chocolate really can kill dogs. What follows is for readers who, like me, didn't know that chocolate could hurt those we love.

Why is chocolate toxic? Because it contains two methylxanthines: *theobromine* and *caffeine*. Both drugs are stimulants that can cause seizures and cardiac dysrhythmias. In the absence of treatment, death can result. Although both compounds are of concern, chocolate contains much more theobromine than caffeine. Accordingly, our discussion focuses on theobromine.

Why is theobromine toxic to dogs but not us? Because dogs eliminate this compound very slowly: In dogs, the half-life of theobromine is 17.5 hours, compared with only 2 hours in humans. Because of delayed elimination, theobromine climbs to higher levels in dogs, and remains at those high levels a long time. If humans took theobromine in big enough doses, it would hurt us too.

What are the symptoms of theobromine/chocolate poisoning? Initial symptoms, which typically develop in 6 to 12 hours, include vomiting, diarrhea, restlessness, and excessive fluid intake. Later symptoms involve the CNS (hyperactivity, incoordination, disturbed balance, tremors, seizures, coma), cardiovascular system (premature ventricular contractions, tachycardia or bradycardia, hypertension or hypotension), oxygenation (rapid breathing, cyanosis), and thermoregulation (hyperthermia). Symptoms may persist for 72 hours. Death, if it occurs, is usually from dysrhythmias, hyperthermia, or respiratory failure.

How is theobromine poisoning treated? There is no specific antidote to theobromine, so treatment is directed at symptom control and poison removal. Tremors and mild seizures can be controlled with diazepam. Severe seizures may require a barbiturate. Tachydysrhythmias can be controlled with a beta blocker (eg, metoprolol), bradycardias with atropine, and refractory ventricular dysrhythmias with lidocaine. Once the victim is stabilized—or if symptoms have not yet appeared—decontamination should be implemented. Theobromine can be removed from the stomach by gastric lavage, or by inducing emesis with apomorphine. Activated charcoal can prevent further absorption from the stomach and intestine. Inducing diuresis with fluids can accelerate excretion of theobromine in the urine.

How much chocolate is lethal? To answer this question, we need to know two things: (1) the average lethal dose (LD₅₀) for theobromine in dogs and (2) the theobromine content of various types of chocolate. In dogs, the LD₅₀ for theobromine is about 100 mg/kg body weight (45 mg/lb). Put another way, it takes about 450 mg of theobromine to kill a 10-pound dog. The approximate theobromine content of chocolate types is as follows:

- White chocolate—1 mg/ounce
- Milk chocolate—50 mg/ounce
- Semisweet chocolate—150 mg/ounce
- Unsweetened baker's chocolate—450 mg/ounce

396

These numbers indicate that, in order to get a lethal dose of theobromine (450 mg), a 10-pound dog would have to ingest the following:

- White chocolate—450 ounces (28 pounds), which is impossible.
- Milk chocolate—9 ounces (0.6 lb), which equals the chocolate in 3 average candy bars. Easy for a dog who likes candy.
- Semisweet chocolate—only 3 ounces.
- Unsweetened baker's chocolate—just one 1-ounce square.

397

From this information, it's clear that giving Calvin a Chocolate Kiss or two was safe, despite Nancy's alarm. However, it's also clear that it doesn't take a basket of candy to do serious harm. In fact, although the LD₅₀ for theobromine is 100 mg/kg, significant reactions can develop at much lower doses. For example, at 20 mg/kg, vomiting and diarrhea can develop; at 40 to 50 mg/kg, cardiotoxicity can develop; and at doses above 60 mg/kg, seizures may develop. Accordingly, it would seem prudent to keep your entire chocolate stash in a doggy-proof place, especially if your little friend is a chocaholic.

So, Dr. Lehne, is chocolate really going to kill my dog—or better yet, my neighbor's little yapper? Probably not. Fact is, *fatal* chocolate poisoning is rare. Nonetheless, chocolate poisoning is the most common reason for calls to the ASPCA's *Animal Poison Control Center* (APCC), which, for a small fee, can provide professional assistance 24 hours a day, 7 days a week. So, the next time your dog scarfs up an entire pan of brownies, you can call the APCC at 1-888-426-4435 for immediate help.

37.4 MISCELLANEOUS CNS STIMULANTS

37.4.1 Modafinil

37.4.1.1 Therapeutic Use.

Modafinil [Provigil], a unique nonamphetamine stimulant, is approved for promoting wakefulness in patients with excessive sleepiness associated with three disorders: narcolepsy, shift-work sleep disorder (SWSD), and obstructive sleep apnea/hypopnea syndrome (OSAHS). Investigational uses include ADHD and fatigue associated with multiple sclerosis. The military is studying the drug for use in situations that might require alertness for an extended time. And some people are using it just to stay awake so they can work or play more.

In clinical trials, modafinil has been moderately effective. In patients with narcolepsy, modafinil increased wakefulness, but only to about 50% of the level seen in normal people. In contrast, methylphenidate and dextroamphetamine increase wakefulness to about 70% of normal. In patients with SWSD and OSAHS, benefits are about the same as those seen in patients with narcolepsy.

37.4.1.2 Mechanism of Action.

How does modafinil ward off sleep? No one knows. The drug does seem to influence hypothalamic areas involved in maintaining the normal sleep-wakefulness cycle. Also, there is evidence indicating that modafinil inhibits the activity of sleep-promoting neurons (in the ventrolateral preoptic nucleus) by blocking reuptake of norepinephrine.

37.4.1.3 Pharmacokinetics.

Modafinil is rapidly absorbed from the GI tract. Plasma levels peak in 2 to 4 hours. Food decreases the rate of absorption but not the extent. Elimination is by hepatic metabolism followed by renal excretion. The half-life is about 15 hours.

37.4.1.4 Adverse Effects.

Modafinil is generally well tolerated. The most common adverse effects are headache, nausea, nervousness, diarrhea, and rhinitis. Modafinil does not disrupt nighttime sleep. In clinical trials, only 5% of patients dropped out because of undesired effects. Initially, the drug was believed devoid of cardiovascular effects. However, we now know it can increase heart rate and blood pressure, apparently by altering autonomic function. Subjective effects—euphoria; altered

perception, thinking, and feeling—are like those of other CNS stimulants. However, modafinil has less abuse potential, and hence is regulated as a Schedule IV substance. Physical dependence and withdrawal have not been reported. Modafinil is embryotoxic in laboratory animals, and hence should be avoided during pregnancy.

Postmarketing reports link modafinil to rare cases of serious skin reactions, including Stevens-Johnson syndrome, erythema multiforme, and toxic epidermal necrolysis. Patients should be informed about signs of these reactions—swelling or rash, especially in the presence of fever or changes in the oral mucosa—and instructed to discontinue the drug if they develop.

37.4.1.5 Drug Interactions.

Modafinil inhibits some forms of cytochrome P450 (CYP) and induces others. Induction of CYP3A4 may accelerate the metabolism of oral contraceptives, cyclosporine, and certain other drugs, thereby causing their levels to decline. Caution is needed.

37.4.1.6 Preparations, Dosage, and Administration.

Modafinil is available in 100- and 200-mg tablets. For patients with narcolepsy or OSAHS, the usual dosage is 200 mg/day, taken as a single dose in the morning. For patients with SWSD, the usual dosage is 200 mg/day, taken as a single dose 1 hour before the shift starts. For patients with severe hepatic impairment, doses should be decreased by 50%. Dosage reduction may also be needed in the elderly.

37.4.2 Armodafinil

Armodafinil [Nuvigil] is simply the *R*-enantiomer of modafinil, a mixture of *R*- and *S*-enantiomers. Armodafinil differs from modafinil in that the *R*-enantiomer (armodafinil) has a longer half-life than the *S*-enantiomer component of modafinil. Otherwise, the two drugs are essentially identical. Armodafinil has the same indications as modafinil—improving wakefulness in people with narcolepsy, SWSD, and OSAHS—and has similar adverse effects, including the potential for rare but severe skin reactions. Like modafinil, armodafinil is classified as a Schedule IV substance. Armodafinil is available in 50-, 150-, and 250-mg tablets. The recommended dosage for narcolepsy and OSAHS is 150 or 250 mg, taken in the morning. The recommended dosage for SWSD is 150 mg, taken 1 hour before the work shift.

37.4.3 Strychnine

Strychnine was introduced in the 16th century as a rat poison. At one time the drug was also employed therapeutically. Although strychnine is no longer used as a medicine, it remains a source of accidental poisoning.

Strychnine is a powerful convulsant that stimulates the CNS at all levels. Stimulation results from blockade of receptors for glycine, an inhibitory neurotransmitter.

37.4.3.1 Strychnine Poisoning

37.4.3.1.1 Causes.

A common cause of strychnine poisoning is accidental ingestion of strychnine-based rodenticides. Poisoning also occurs through the use of “street drugs” to which strychnine has been added. (Since strychnine does not enhance the effects of illicit drugs, the practice of mixing this agent with street drugs is not only dangerous, it also lacks any pharmacologic rationale.) The lethal dose is about 15 mg in children, and 50 to 100 mg in adults.

37.4.3.1.2 Symptoms.

The first manifestation of poisoning is stiffness in the muscles of the face and neck. This is followed by a generalized increase in reflex excitability. During the early stages of poisoning, the victim is fully conscious. As poisoning progresses, convulsions occur. Strychnine-induced convulsions are characterized by tonic contraction of all voluntary muscles; contraction of the diaphragm, abdominal muscles, and thoracic muscles stops respiration. Convulsive episodes alternate with periods of depression until the victim dies or until the poisoning is successfully treated. Few patients survive beyond the fifth convulsive episode; some are killed by the first. Death is from respiratory arrest.

397

398

37.4.3.1.3 Treatment.

Management is directed primarily at controlling convulsions and supporting respiration. Intravenous diazepam is the treatment of choice to suppress convulsions. If poisoning is severe, general anesthesia or neuromuscular blockade may be needed to eliminate convulsions. If anticonvulsant therapy fails to permit adequate breathing, mechanical support of respiration is indicated.

37.4.4 Doxapram

Doxapram [Dopram] stimulates the CNS at all levels. The drug is employed clinically to stimulate respiration. However, since the doses required are close to those that can produce generalized CNS stimulation and convulsions, doxapram must be used with great care. Furthermore, although doxapram is labeled for treatment of general CNS depressant poisoning, its use for this purpose should be discontinued: Experience has shown that respiratory depression from CNS depressant poisoning can be managed more safely and effectively with mechanical support of ventilation than with pharmacologic stimulation of respiration.

37.4.5 Cocaine

Cocaine is a powerful CNS stimulant with a high potential for abuse. The only clinical application of this drug—local anesthesia—is discussed in [Chapter 26](#). The basic pharmacology of cocaine and cocaine abuse are discussed in [Chapter 39](#).

37.5 ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

37.5.1 ADHD in Children

ADHD is the most common neuropsychiatric disorder of childhood. In the United States, over 2 million school-age children are affected—an average of one child with ADHD for every classroom. The incidence in boys is 2 to 3 times the incidence in girls. Symptoms begin between ages 3 and 7, usually persist into the teens, and often persist into adulthood. The majority (60% to 70%) of children respond well to stimulant drugs. Methylphenidate [Ritalin, Concerta, others] is the agent employed most.

37.5.1.1 Signs and Symptoms

ADHD is characterized by *inattention*, *hyperactivity*, and *impulsivity*. Affected children are fidgety, unable to concentrate on schoolwork, and unable to wait their turn; switch excessively from one activity to another; call out excessively in class; and never complete tasks. For a diagnosis to be made, symptoms must appear prior to age 7 and be present for at least 6 months. Since other disorders—especially anxiety and depression—may cause similar symptoms, diagnosis must be done carefully. Specific diagnostic criteria for ADHD, as described in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition*, are summarized in [Table 36-2](#). Depending on the symptom profile, ADHD can be subclassified as predominately inattentive type, predominately hyperactive-impulsive type, or combined type. Former names

for ADHD—*hyperkinetic syndrome* and *minimal brain dysfunction*—are misleading and have been abandoned.

37.5.1.2 Etiology

Although various theories have been proposed, the underlying pathophysiology of ADHD has not been firmly established. Neuroimaging studies indicate structural and functional abnormalities in multiple brain areas, including the frontal cortex, basal ganglia, brainstem, and cerebellum—regions involved with regulating attention, impulsive behavior, and motor activity. Several theories implicate dysregulation in neuronal pathways that employ NE and DA as transmitters. These theories would be consistent with the beneficial effects of atomoxetine (which blocks NE reuptake) and the effects of stimulant drugs (which promote release of NE and DA and, to some degree, block their reuptake). Genetic factors appear to play an important role.

TABLE 36-2 DSM-IV-TR Diagnostic Criteria for ADHD

A. Either (1) or (2)

(1) **Inattention.** Six (or more) of the following symptoms have persisted for at least 6 months:

- Often fails to give close attention to details or makes careless mistakes in schoolwork, work, or other activities
- Often has difficulty sustaining attention in tasks or play activities
- Often does not seem to listen when spoken to directly
- Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace
- Often has difficulty organizing tasks and activities
- Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (eg, schoolwork, homework)
- Often loses things necessary for tasks or activities (eg, toys, school assignments, pencils, books, tools)
- Is often easily distracted by extraneous stimuli
- Is often forgetful in daily activities

(2) **Hyperactivity-impulsivity.** Six (or more) of the following symptoms have persisted for at least 6 months:

Hyperactivity

- Often fidgets with hands or feet or squirms in seat
- Often leaves seat in classroom or in other situations in which remaining seated is expected
- Often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness)
- Often has difficulty playing or engaging in leisure activities quietly
- Is often “on the go” or often acts as if “driven by a motor”
- Often talks excessively

Impulsivity

- Often blurts out answers before questions have been completed

- Often has difficulty awaiting turn
- Often interrupts or intrudes on others (eg, butts into conversations or games)

B. Some hyperactive-impulsive or inattentive symptoms were present before age 7 years.

C. Symptoms are present in two or more settings (eg, at school [or work] and at home).

D. There must be clear evidence of clinically significant impairment in social, academic, or occupational functioning.

E. The symptoms do not occur exclusively during the course of a pervasive developmental disorder, schizophrenia, or other psychotic disorder, and are not better accounted for by another mental disorder (eg, mood disorder, anxiety disorder, dissociative disorder, or a personality disorder).

398

TABLE 36-3 Major Drugs for Attention-Deficit/Hyperactivity Disorder

Drug	Trade Name	Duration (hr)	Dosing Schedule	Usual Pediatric Dosage
STIMULANTS				
Methylphenidate				
Short Duration	Ritalin	3–5	2 or 3 times daily	10 mg at 8:00 AM and noon, and 5 mg at 4:00 PM
	Methylin			
Intermediate Duration	Ritalin SR	6–8	Once or twice daily	20 or 40 mg in AM plus 20 mg in early PM if needed
	Metadate ER			
	Methylin ER			
Long Duration	Concerta	Up to 14	Once daily	36 mg in AM
	Metadate CD	6–8	Once daily	40 mg in AM
	Ritalin LA	7–9	Once daily	60 mg in AM
	Daytrana	10–12	Once daily	One 15- or 20-mg patch, applied in AM and removed 9 hr later
Dexmethylphenidate				
Short Duration	Focalin	4–5	Twice daily	10 mg in AM plus 10 mg in early PM
	Focalin XR	Up to 12	Once daily	20 mg in AM
Dextroamphetamine				
Short Duration	DextroStat	4–6	2 or 3 times daily	5 mg at 8:00 AM, noon, and 4:00 PM
Long Duration	Dexedrine Spansules	6–10	Once or twice daily	10 mg at 8:00 AM
Amphetamine Mixture				
Short Duration	Adderall	4–6	Twice daily	5 mg in AM and 5 hr later
Long Duration	Adderall-XR	10–12	Once daily	20 mg in AM
Lisdexamfetamine				
Long Duration	Vyvanse	10–12	Once daily	30 mg in AM
NONSTIMULANT				

Atomoxetine	Strattera	24	Once or twice daily	80 mg in AM or 40 mg in AM plus 40 mg in early PM
-------------	-----------	----	---------------------	---

37.5.1.3 Management Overview

Multiple strategies may be employed to manage ADHD. In addition to drugs, the treatment program can include family therapy, parent training, and cognitive therapy for the child. In 2001, the American Academy of Pediatrics issued clinical practice guidelines emphasizing the importance of a comprehensive treatment program, involving collaboration among clinicians, families, and educators. For long-term gains, a combination of cognitive therapy and stimulant drugs appears most effective.

37.5.1.4 Drug Therapy I: CNS Stimulants

Stimulant drugs are the mainstay of therapy. Drugs with proven efficacy include *methylphenidate* [Ritalin, Concerta, others], *dexmethylphenidate* [Focalin], *dextroamphetamine* [DextroStat, others], and *amphetamine mixture* [Adderall].

The response to stimulants can be dramatic. These drugs can increase attention span and goal-oriented behavior while decreasing impulsiveness, distractibility, hyperactivity, and restlessness. Tests of cognitive function (memory, reading, arithmetic) often improve significantly. Unfortunately, although benefits can be dramatic initially, they diminish after 2 to 3 years, as reported in a 2009 paper: *MTA at 8 Years: Prospective Follow-up of Children Treated for Combined-Type ADHD in a Multisite Study*. Nonetheless, stimulant therapy can still buy time to teach youngsters behavioral strategies to help them combat inattention and hyperactivity over the long-term.

Although reduction of impulsiveness and hyperactivity with a stimulant may seem paradoxical—it isn't. Stimulants don't suppress rowdy behavior directly. Rather, they improve attention and focus. Impulsiveness and hyperactivity decline because the child is now able to concentrate on the task at hand. It should be noted that stimulants do not create *positive* behavior; they only reduce *negative* behavior. Accordingly, they cannot give a child good study skills and other appropriate behaviors. Rather, these must be learned once the disruptive behavior is no longer an impediment.

The dosing schedule employed is important, and is determined by the time course of the formulation selected. As discussed above (and shown in [Table 36-3](#)), CNS stimulants are available in short-, intermediate-, and long-duration formulations. With the SD and ID

formulations, the child usually takes two or three doses a day. In contrast, the LD formulations are taken just once a day (in the morning). Not only is once-daily dosing more convenient, it spares the child any embarrassment or stigma associated with taking medicine at school. Accordingly, LD formulations (eg, Adderall-XR, Concerta, Daytrana) are generally preferred. Dosage is determined by monitoring for improvement in symptoms and appearance of side effects.

399

Principal adverse effects of the stimulants are *insomnia* and *growth suppression*. Insomnia results from CNS stimulation, and can be minimized by reducing the size of the afternoon dose and taking it no later than 4:00 PM. Growth suppression occurs secondary to appetite suppression. Growth reduction can be minimized by administering stimulants during or after meals (which reduces the impact of appetite suppression). In addition, some clinicians recommend taking “drug holidays” on weekends and in the summer (which creates an opportunity for growth to catch up). However, other clinicians argue against this strategy. Why? Because depriving children of medication during these unstructured times can be hard on them. When stimulants are discontinued, a rebound increase in growth will take place; as a result, adult height may not be affected. Other adverse effects include *headache* and *abdominal pain*, which have an incidence of 10%, and *lethargy* and *listlessness*, which can occur when dosage is excessive.

400

37.5.1.5 Drug Therapy II: Atomoxetine

37.5.1.5.1 Description and Therapeutic Effects.

Atomoxetine [Strattera] is a unique drug approved for ADHD in children and adults. This is the first *nonstimulant* approved for ADHD, and one of only three drugs approved for ADHD in adults (the others are amphetamine mixture [Adderall XR] and lisdexamfetamine [Vyvanse]). Older nonstimulants, such as imipramine and bupropion, although *used* for ADHD, are not actually *approved* for ADHD. In contrast to the CNS stimulants, atomoxetine has no potential for abuse, and hence is not regulated as a controlled substance. As a result, prescriptions can be refilled over the phone, making atomoxetine more convenient than the stimulants. Like the long-acting stimulants, atomoxetine can be administered just once a day.

In clinical trials comparing atomoxetine with placebo in children or adults with ADHD, atomoxetine was clearly superior at reducing symptoms. Benefits were similar whether the drug was given once a day or in two divided doses. It should be noted that responses develop slowly: The initial response takes a few days to develop, and the maximal response takes 1 to

3 weeks. This contrasts with the CNS stimulants, whose effects are near-maximal with the first dose.

How does atomoxetine compare with stimulants for treating children with ADHD? In two older 3-week randomized trials, comparing atomoxetine with either methylphenidate [Concerta] or an amphetamine [Adderall XR], the stimulants were superior: More children responded to the stimulants, symptom reduction was greater, and benefits developed more quickly. In 2008, these results were reinforced in a large, 6-week, placebo-controlled trial, in which a stimulant—methylphenidate [Concerta]—was again clearly superior to atomoxetine.

37.5.1.5.2 Mechanism of Action.

Atomoxetine is a *selective inhibitor of NE reuptake*, and hence causes NE to accumulate at synapses. Although the precise relationship between this neurochemical action and symptom relief is unknown, it would appear that *adaptive changes* that occur following uptake blockade underlie benefits. Why? Because uptake blockade occurs immediately, whereas full therapeutic effects are not seen for at least a week—suggesting that, after uptake blockade occurs, additional processes must take place before benefits can be seen.

37.5.1.5.3 Pharmacokinetics.

Atomoxetine is rapidly and completely absorbed following oral administration. Plasma levels peak in 1 to 3 hours, depending on whether the drug was taken without or with food. Atomoxetine is metabolized in the liver, primarily by CYP2D6 (the 2D6 isozyme of cytochrome P450). For most patients, the half-life is 5 hours. However, for 5% to 10% of patients, the half-life is much longer: 24 hours. Why? Because they have an atypical form of CYP2D6, which metabolizes atomoxetine slowly. Dosage should be reduced in these people.

37.5.1.5.4 Adverse Effects.

Like the CNS stimulants, atomoxetine is generally well tolerated. In clinical trials, the most common effects were GI reactions (dyspepsia, nausea, and vomiting), reduced appetite, dizziness, somnolence, mood swings, and trouble sleeping. Sexual dysfunction and urinary retention were seen in adults. Severe allergic reactions, including angioneurotic edema, occurred rarely. If allergy develops, patients should discontinue the drug and contact the prescriber immediately. Atomoxetine may cause a small increase in blood pressure and heart rate, and hence should be used with caution by patients with hypertension, tachycardia, and other cardiovascular disorders.

Atomoxetine may cause *suicidal thinking* in children and adolescents, but not in adults. Fortunately, the incidence is relatively low: about 4 cases per 1000 patients. Risk is greatest during the first few months of treatment. Young patients should be monitored closely for suicidal thinking and behavior, and for signs of clinical worsening (eg, agitation, irritability).

Appetite suppression may result in *weight loss and growth retardation*. Among children who took atomoxetine for 18 months or longer, mean height and weight percentiles declined. Because experience with the drug is limited, we don't know if expected adult height will be affected. Nor do we know if “drug holidays” would have an impact on growth.

Atomoxetine poses a small risk of *severe liver injury* that may progress to outright liver failure, resulting in death or the need for a liver transplant. Patients should be informed about signs of liver injury—jaundice, dark urine, abdominal tenderness, unexplained flu-like symptoms—and instructed to report these immediately. In the event of jaundice or laboratory evidence of liver injury, atomoxetine should be discontinued.

37.5.1.5.5 Drug Interactions.

Combining atomoxetine with a *monoamine oxidase inhibitor* (eg, isocarboxazid [Marplan], phenelzine [Nardil]) can cause hypertensive crisis, owing to accumulation of NE at synapses in the periphery. Accordingly, these drugs must not be used together or within 3 weeks of each other.

Inhibitors of CYP2D6 can increase levels of atomoxetine, and hence must be used with caution. Common examples include paroxetine [Paxil], fluoxetine [Prozac], and quinidine.

37.5.1.5.6 Role in ADHD Therapy.

Because atomoxetine is a relatively new drug, its role in ADHD has not been firmly established. Yes, atomoxetine appears both safe and effective, and it lacks the potential for abuse. However, we have little information on its long-term dangers, including detrimental effects on growth. Furthermore, current evidence indicates that stimulants work better. Accordingly, because CNS stimulants are more effective and have a long record of safety and efficacy, it would seem prudent to reserve atomoxetine for patients who are unresponsive to or intolerant of the stimulants. In the absence of a compelling reason, patients doing well on the stimulants shouldn't switch.

400

401

37.5.1.5.7 Preparations, Dosage, and Administration.

Atomoxetine [Strattera] is available in capsules (10, 18, 25, 40, 60, 80, and 100 mg) that should be swallowed whole, with or without food. Dosage is based on body weight as follows:

- Children who weigh *less than 70 kg*—Start with 0.5 mg/kg/day and then, after at least 3 days, increase to the recommended target of 1.2 mg/kg/day. The maximum dosage is 1.4 mg/kg/day or 100 mg, whichever is smaller.
- Children who weigh *more than 70 kg* and *all adults*—Start with 40 mg/day and then, after at least 3 days, increase to the recommended target of 80 mg/day. Do not exceed 100 mg/day.

Two dosing schedules may be used: patients may either (1) take the total daily dose all at once in the morning or (2) divide the dosage up, taking half in the morning and half in the late afternoon or early evening. Note that, with either schedule, dosing during school hours is unnecessary.

Dosage should be reduced in patients who are slow metabolizers, either because of hepatic insufficiency or atypical CYP2D6.

37.5.1.6 Drug Therapy III: Antidepressants

Three antidepressants—desipramine, imipramine, and bupropion—can reduce behavioral symptoms in children with ADHD. However, these antidepressants are less effective than CNS stimulants and are not approved for ADHD. Accordingly, they are generally reserved for children who have not responded to trials with at least two different stimulants.

37.5.1.6.1 Tricyclic Antidepressants.

Desipramine [Norpramin] and imipramine [Tofranil] can reduce symptoms in children with ADHD. These drugs decrease hyperactivity but have little effect on impulsivity and inattention. Responses develop slowly. Beneficial effects begin in 2 to 3 weeks and reach a maximum at around 6 weeks. Tolerance frequently develops within a few months. In contrast to the stimulants, which can be discontinued on weekends, antidepressants must be taken continuously. Adverse effects include sedation and anticholinergic effects (eg, dry mouth, blurred vision, urinary retention, constipation). More importantly, sudden death (from cardiotoxicity) has occurred in at least three children. Compared with stimulants,

antidepressants have their benefits (no insomnia, abuse potential, or suppression of appetite and growth) as well as their drawbacks (anticholinergic effects, delayed onset, tolerance, less efficacy, risk of sudden death). Because these antidepressants are less effective and more dangerous than the stimulants, they are considered second-line drugs. Dosages for ADHD range from 2 to 5 mg/kg/day, administered in two or three divided doses. The basic pharmacology of the antidepressants is presented in [Chapter 32](#).

37.5.1.6.2 Bupropion.

Bupropion [Wellbutrin] can reduce behavioral symptoms of ADHD, but is less effective than stimulants. The drug lacks the adverse effects associated with tricyclic antidepressants (eg, cardiotoxicity, anticholinergic effects), but does pose a risk of seizures. Like the tricyclic antidepressants, bupropion is considered a second-line drug for ADHD. Dosage is 100 to 150 mg twice a day. The basic pharmacology of bupropion is presented in [Chapter 32](#).

37.5.2 ADHD in Adults

Contrary to traditional assumptions, we now know that, in about 60% of cases, ADHD persists into adulthood. In the United States, about 10 million adults are afflicted. Symptoms include poor concentration, stress intolerance, antisocial behavior, outbursts of anger, and inability to maintain a routine. Also, adults with ADHD experience more job loss, divorce, and driving accidents. As in childhood ADHD, stimulants are the preferred drugs for treatment. Methylphenidate is prescribed most often. About 33% of adults fail to respond to stimulants or cannot tolerate their side effects. For these patients, a trial with atomoxetine, desipramine, or bupropion may help.

37.5.2.1 KEY POINTS

- The amphetamine family consists of dextroamphetamine, amphetamine (a racemic mixture of dextroamphetamine and levamphetamine), methamphetamine, and lisdexamfetamine.
- The amphetamines work primarily by promoting neuronal release of NE and DA, and partly by blocking NE and DA reuptake.
- Through actions in the CNS, the amphetamines can increase wakefulness and alertness, reduce fatigue, elevate mood, stimulate respiration, and suppress appetite.

- By promoting release of norepinephrine from peripheral neurons, amphetamines can cause vasoconstriction and cardiac effects (increased heart rate, increased AV conduction, and increased force of contraction).
- The most common adverse effects of amphetamines are insomnia and weight loss. Amphetamines may also cause psychosis and cardiovascular effects (dysrhythmias, angina, hypertension).
- The principal indication for amphetamines is ADHD.
- The pharmacology of methylphenidate is nearly identical to that of the amphetamines.
- Methylphenidate is the drug most frequently prescribed for ADHD.
- Methylphenidate and other CNS stimulants reduce symptoms of ADHD by enhancing the patient's ability to focus.
- Atomoxetine is the only nonstimulant approved for ADHD.
- Caffeine and other methylxanthines act primarily by blocking adenosine receptors.
- Responses to caffeine are dose dependent: low doses decrease drowsiness and fatigue; higher doses cause nervousness, insomnia, and tremors; and huge doses cause convulsions.
- Caffeine has two principal uses: treatment of apnea in premature infants and reversal of drowsiness.

401
402

37.5.2.2

Summary of Major Nursing Implications*

37.5.2.2.1

AMPHETAMINES, METHYLPHENIDATE, AND DEXMETHYLPHENIDATE

37.5.2.2...

Preadministration Assessment

37.5.2.2...

Therapeutic Goal

Reduction of symptoms in children and adults with ADHD. Reduction of sleep attacks in patients with narcolepsy.

Baseline Data

Children with ADHD.

Document the degree of inattention, impulsivity, hyperactivity, and other symptoms of ADHD. Symptoms must be present for at least 6 months to allow a diagnosis of ADHD. Obtain baseline values of height and weight.

Narcolepsy.

Document the degree of daytime sleepiness and the frequency and circumstances of sleep attacks.

Identifying High-Risk Patients

All amphetamines are *contraindicated* for patients with symptomatic cardiovascular disease, advanced atherosclerosis, hypertension, hyperthyroidism, agitated states, and a history of drug abuse, and in those who have taken monoamine oxidase inhibitors within the previous 2 weeks. *Amphetamine mixture* [Adderall XR] is *generally contraindicated* for patients with structural cardiac defects.

Implementation: Administration

Routes

Oral.

Amphetamines, methylphenidate, and dexamethylphenidate.

Transdermal.

Methylphenidate only.

Administration

Oral.

Instruct patients to swallow long-acting formulations intact, without crushing or chewing.

Children with ADHD should take the morning dose after breakfast and the last daily dose by 4:00 PM.

37.5.2.2...

Transdermal.

Instruct patients using transdermal methylphenidate [Daytrana] to apply one patch to alternating hips each morning, and to remove each patch not more than 9 hours after applying it. Instruct patients to avoid application to skin that is inflamed.

37.5.2.2...

Ongoing Evaluation and Interventions

37.5.2.2...

Evaluating Therapeutic Effects

37.5.2.2...

Children with ADHD.

Monitor for reductions in symptoms (impulsiveness, hyperactivity, inattention) and for improvement in cognitive function.

37.5.2.2...

Minimizing Adverse Effects

37.5.2.2...

Excessive CNS Stimulation.

These drugs can cause restlessness and insomnia. **Advise patients to use the smallest dose required and to avoid dosing late in the day. Advise patients to minimize or eliminate dietary caffeine (eg, coffee, tea, caffeinated soft drinks).**

37.5.2.2...

Weight Loss.

Appetite suppression can cause weight loss. **Advise patients to take the morning dose after breakfast and the last daily dose early in the afternoon to minimize interference with eating.**

37.5.2.2...

Cardiovascular Effects.

Warn patients about cardiovascular responses (palpitations, hypertension, angina, dysrhythmias) and instruct them to notify the prescriber if these develop.

Very rarely, children using stimulants for ADHD have experienced sudden cardiac death. In response, the AHA says it is reasonable to consider giving a child an ECG before starting stimulant therapy. However, there is no proof that stimulants actually cause sudden death, or that withholding stimulants will protect from sudden death, or that screening for cardiac defects with an ECG will be of any benefit. Therefore, it would seem that routine ECG screening is unnecessary, especially in children with no signs or symptoms of heart defects.

37.5.2.2...

Psychosis.

If amphetamine-induced psychosis develops, therapy should be discontinued. For most individuals, symptoms resolve within a week. For some patients, drug-induced psychosis may represent unmasking of latent schizophrenia, indicating a need for psychiatric care.

37.5.2.2...

Withdrawal Reactions.

Abrupt discontinuation can produce extreme fatigue and depression. Minimize by withdrawing amphetamines and methylphenidate gradually.

37.5.2.2...

Hypersensitivity Reactions.

Transdermal methylphenidate [Daytrana] can cause hypersensitivity reactions, which may necessitate discontinuing *all* methylphenidate products, oral as well as transdermal. **Inform patients about signs of hypersensitivity—erythema, edema, papules, vesicles—and instruct them to inform the prescriber if these develop.**

37.5.2.2...

Minimizing Abuse

If the medical history reveals the patient is prone to drug abuse, monitor use of these drugs closely.

Avoid routine use of amphetamines for weight loss.

CAFFEINE

General Considerations

Caffeine is usually administered to promote wakefulness. **Warn patients against habitual caffeine use to compensate for chronic lack of sleep. Advise patients to consult the prescriber if fatigue is persistent or recurrent.**

Minimizing Adverse Effects

Cardiovascular Effects.

Inform patients about cardiovascular responses to caffeine (palpitations, rapid pulse, dizziness) and instruct them to discontinue caffeine if these occur.

Excessive CNS Stimulation.

Warn patients that overdose can cause convulsions. Advise them to ingest no more caffeine than needed.

Miscarriage.

Caffeine increases the risk of miscarriage, especially at doses above 200 mg/day. **Advise pregnant women to consume no more than 200 mg/day—and preferably less.**

* Patient education information is highlighted as **blue text**.

³⁸CHAPTER 37 Drug Abuse I: Basic Considerations

Mind-altering drugs have intrigued human beings since the dawn of civilization. Throughout history, people have taken drugs to elevate mood, release inhibitions, distort perceptions, induce hallucinations, and modify thinking. Many of those who take mind-altering drugs restrict usage to socially approved patterns. However, many others self-administer drugs to excess. Excessive drug use is our focus in this chapter and the two that follow.

Drug abuse confronts clinicians in a variety of ways, making knowledge of abuse a necessity. Important areas in which expertise on drug abuse may be applied include (1) diagnosis and treatment of acute toxicity, (2) diagnosis and treatment of secondary medical complications of drug abuse, (3) facilitating drug withdrawal, and (4) providing education and counseling to maintain long-term abstinence.

Our discussion of drug abuse occurs in two stages. In this chapter we discuss basic concepts in drug abuse. In [Chapters 38](#) and [39](#), we focus on the pharmacology of specific abused agents and methods of treatment.

^{38.1} DEFINITIONS

^{38.1.1} Drug Abuse

Drug abuse can be defined as *using a drug in a fashion inconsistent with medical or social norms*. Traditionally, the term also implies drug usage that is harmful to the individual or society. As we shall see, although we can give abuse a general definition, deciding whether a particular instance of drug use constitutes “abuse” is often difficult.

Whether or not drug use is considered abuse depends, in part, on the purpose for which a drug is taken. Not everyone who takes large doses of psychoactive agents is an abuser. For example, we do not consider it abuse to take opioids in large doses long term to relieve pain caused by cancer. However, we do consider it abusive for an otherwise healthy individual to take those same opioids in the same doses to produce euphoria.

Abuse can have different degrees of severity. Some people, for example, use heroin only occasionally, whereas others use it habitually and compulsively. Although both patterns of drug use are socially condemned, and therefore constitute abuse, there is an obvious quantitative difference between taking heroin once or twice and taking it routinely and compulsively.

Note that, by the definition above, *drug abuse is culturally defined*. Because abuse is culturally defined, and because societies differ from one another and are changeable, there can be wide

variations in what is labeled abuse. *What is defined as abuse can vary from one culture to another.* For example, in the United States, moderate consumption of alcohol is not usually considered abuse. In contrast, *any ingestion of alcohol would be considered abuse in some Muslim societies.* Furthermore, *what is defined as abuse can vary from one time to another within the same culture.* For example, when a few Americans first experimented with lysergic acid diethylamide (LSD) and other psychedelic drugs, these agents were legal and their use was not generally disapproved. However, when use of psychedelics became widespread, our societal posture changed and legislation was passed to make the manufacture, sale, and use of these drugs illegal.

Within the United States, there is divergence of opinion about what constitutes drug abuse. For example, some people would consider any use of marijuana to be abuse, whereas others would call smoking marijuana abusive only if it were done *habitually*. Similarly, although many Americans do not consider cigarette smoking abuse (even though the practice is compulsive and clearly harmful to the individual and society), others believe very firmly that cigarette smoking is a blatant form of abuse.

As we can see, distinguishing between culturally acceptable drug use and drug use that is to be called abuse is more in the realm of social science than pharmacology. Accordingly, since this is a pharmacology text and not a sociology text, we will not attempt to define just what patterns of drug use do or do not constitute abuse. Instead, we will focus on the pharmacologic properties of abused drugs—leaving distinctions about what is and is not abuse to sociologists and legislators. Fortunately, we can identify the drugs that tend to be abused and discuss their pharmacology without having to resolve all arguments about what patterns of use should or should not be considered abusive.

As discussed later, the American Psychiatric Association has established diagnostic criteria for *substance abuse*, a specific substance use disorder. These objective criteria are largely independent of cultural bias, and should not be confused with the concept of drug abuse as just presented.

38.1.2 Addiction

The American Society of Addiction Medicine defines addiction as *a disease process characterized by the continued use of a specific psychoactive substance despite physical, psychological, or social harm.* Please note that nowhere in this definition is addiction equated with physical dependence. As discussed below, although physical dependence can contribute to addictive behavior, it is neither necessary nor sufficient for addiction to occur. Addiction can be considered essentially equivalent to substance dependence as defined in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)* (see below).

403

404

38.1.3 Other Definitions

Tolerance results from regular drug use and can be defined as a state in which a particular dose elicits a smaller response than it did with initial use. As tolerance increases, higher and higher doses are needed to elicit desired effects.

Cross-tolerance is a state in which tolerance to one drug confers tolerance to another. Cross-tolerance generally develops among drugs within a particular class, and not between drugs in different classes. For example, tolerance to one opioid (eg, heroin) confers cross-tolerance to other opioids (eg, morphine), but not to central nervous system (CNS) depressants, psychostimulants, psychedelics, or nicotine.

Psychologic dependence can be defined as an intense subjective need for a particular psychoactive drug.

Physical dependence can be defined as a state in which an abstinence syndrome will occur if drug use is discontinued. Physical dependence is the result of neuroadaptive processes that take place in response to prolonged drug exposure.

Cross-dependence refers to the ability of one drug to support physical dependence on another drug. When cross-dependence exists between drug A and drug B, drug A will be able to prevent withdrawal in a patient physically dependent on drug B, and vice versa. As with cross-tolerance, cross-dependence generally exists among drugs in the same pharmacologic family, but not between drugs in different families.

A **withdrawal syndrome** is a constellation of signs and symptoms that occurs in physically dependent individuals when they discontinue drug use. Quite often, the symptoms seen during withdrawal are opposite to effects the drug produced before it was withdrawn. For example, discontinuation of a CNS depressant can cause CNS excitation.

38.2 DIAGNOSTIC CRITERIA FOR SUBSTANCE ABUSE AND SUBSTANCE DEPENDENCE

Diagnostic criteria for substance abuse and substance dependence are set forth in DSM-IV, published by the American Psychiatric Association. A summary appears in [Table 37-1](#). As defined in DSM-IV, substance dependence, which can be equated with addiction, is a more severe disorder than substance abuse. Accordingly, individuals whose drug problem is not bad enough to meet the criteria for substance dependence might nonetheless meet the criteria for substance abuse.

As indicated in [Table 37-1](#), tolerance and withdrawal are among the criteria for substance dependence. Please note, however, that tolerance and withdrawal, by themselves, are neither necessary nor sufficient for substance dependence (addiction) to exist. Put another way, the pattern of drug use that constitutes substance dependence can exist in persons who are not physically dependent on drugs and who have not developed tolerance. Because this distinction is extremely important, I will express it another way: *Being physically dependent on a drug is not the same as being addicted!* Many people are physically dependent but do not meet the criteria for substance dependence. These people are not considered addicts because they do not demonstrate the behavior pattern that constitutes substance dependence. Patients with terminal cancer, for example, are often physically dependent on opioids. However, since their lives are not disrupted by their medication (quite the contrary), their drug use does not meet the criteria for substance dependence (or substance abuse, for that matter). Similarly, some degree of physical dependence occurs in all patients who take phenobarbital to control epilepsy; despite their physical dependence, epileptics do not carry out stereotypic addictive behavior, and therefore are not substance dependent as defined in DSM-IV.

404

405

TABLE 37-1 DSM-IV-TR Diagnostic Criteria for Substance Abuse and Substance Dependence

Substance Abuse

Substance abuse is a maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one (or more) of the following within a 12-month period:

- Recurrent substance use that results in a failure to fulfill major role obligations at work, school, or home
- Recurrent substance use in situations in which it is physically hazardous
- Recurrent substance-related legal problems
- Continued substance use despite persistent or recurrent social or interpersonal problems caused or exacerbated by the substance

Individuals who display tolerance, withdrawal, and other symptoms of substance dependence would be diagnosed under substance dependence, a more severe disorder, rather than under substance abuse.

Substance Dependence

Substance dependence is a maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

- Tolerance to the substance
- Withdrawal, as manifested by either:
 - the characteristic withdrawal syndrome for the substance, *or*
 - the same (or closely related) substance is taken to relieve or avoid withdrawal symptoms
- The substance is often taken in larger amounts or over a longer time than intended
- Substance use continues despite a persistent desire or repeated efforts to cut down or control consumption
- A great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects
- Important social, occupational, or recreational activities are given up or reduced because of substance use
- Substance use continues despite knowledge of a persistent or recurrent physical or psychologic problem that substance use probably caused or exacerbated (eg, drinking despite knowing that alcohol made an ulcer worse)

Modified from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. Washington, DC: American Psychiatric Association, 2000, with permission. Copyright © 2000 American Psychiatric Association.

Having stressed that physical dependence and substance dependence (addiction) are different from each other, we must note that the two states are not entirely unrelated. As discussed below, although physical dependence is not the same as addiction, physical dependence often contributes to addictive behavior.

38.3 FACTORS THAT CONTRIBUTE TO DRUG ABUSE

Drug abuse is the end result of a progressive involvement with drugs. Taking psychoactive drugs is usually initiated out of curiosity. From this initial involvement, the user can progress to occasional use. Occasional use can then evolve into compulsive use. Factors that play a role in the progression from experimental use to compulsive use are discussed below.

38.3.1 Reinforcing Properties of Drugs

Although there are several reasons for initiating drug use (eg, curiosity, peer pressure), individuals would not continue drug use unless drugs produced desirable feelings or experiences. By making people feel “good,” drugs reinforce the reasons for their use. Conversely, if drugs did not give people experiences that they found desirable, the reasons for initiating drug use would not be reinforced, and drug use would stop.

Reinforcement by drugs can occur in two ways. First, drugs can give the individual an experience that is pleasurable. Cocaine, for example, produces a state of euphoria. Second, drugs can reduce the intensity of unpleasant experience. For example, drugs can reduce anxiety and stress.

The reinforcing properties of drugs can be clearly demonstrated in experiments with animals. In the laboratory, animals will self-administer most of the drugs that are abused by humans (eg, opioids, barbiturates, alcohol, cocaine, amphetamines, phencyclidine, nicotine, caffeine). When these drugs are made freely available, animals develop patterns of drug use that are similar to those of humans. Animals will selfadminister these drugs (except for nicotine and caffeine) in preference to eating, drinking, and sex. When permitted, they often die from lack of food and fluid. These observations strongly suggest that pre-existing psychopathology is not necessary for drug abuse to develop. Rather, these studies suggest that drug abuse results, in large part, from the reinforcing properties of drugs themselves.

38.3.2 Physical Dependence

As defined, physical dependence is a state in which an abstinence syndrome will occur if drug use is discontinued. The degree of physical dependence is determined largely by dosage and duration of drug use. Physical dependence is greatest in people who take large doses for a long time. The more physically dependent a person is, the more intense the withdrawal syndrome. Substantial physical dependence develops to the opioids (eg, morphine, heroin) and CNS depressants (eg, barbiturates, alcohol). Physical dependence tends to be less prominent with other abused drugs (eg, psychostimulants, psychedelics, marijuana).

Physical dependence can contribute to compulsive drug use. Once dependence has developed, the desire to avoid withdrawal becomes a motivator for continued dosing. Furthermore, if the drug is administered after the onset of withdrawal, its ability to alleviate the discomfort of withdrawal can reinforce its desirability. Please note, however, that although physical dependence plays a role in the abuse of drugs, physical dependence should not be viewed as the primary cause of addictive behavior. Rather, physical dependence is just one of several factors that can contribute to the development and continuation of compulsive use.

38.3.3 Psychologic Dependence

Psychologic dependence is defined as *an intense subjective need for a drug*. Individuals who are psychologically dependent feel very strongly that their sense of well-being is dependent upon continued drug use; a sense of “craving” is felt when the drug is unavailable. There is no question that psychologic dependence can be a major factor in addictive behavior. For example, it is psychologic dependence—and not physical dependence—that plays the principal role in causing renewed use of opioids by addicts who had previously gone through withdrawal.

38.3.4 Social Factors

Social factors can play an important role in the development of abuse. The desire for social status and approval is a common reason for initiating drug use. Also, since initial drug experiences are frequently unpleasant, the desire for social approval can be one of the most compelling reasons for repeating drug use after the initial exposure. For example, most people do not especially enjoy their first cigarette; were it not for peer pressure, many would quit before they smoked enough for it to be pleasurable. Similarly, initial use of heroin, with its associated nausea and vomiting, is often deemed unpleasant; peer pressure is a common reason for continuing heroin use long enough to develop tolerance to these undesirable effects.

38.3.5 Drug Availability

Drug availability is clearly a factor in the development and maintenance of abuse. Abuse can flourish only in environments where drugs can be readily obtained. In contrast, where procurement of drugs is difficult, abuse is minimal. The ready availability of drugs in hospitals and clinics is a major reason for the unusually high rate of addiction among pharmacists, nurses, and physicians.

38.3.6 Vulnerability of the Individual

Some individuals are more prone to becoming drug abusers than others. By way of illustration, let's consider three individuals from the same social setting who have equal access to the same psychoactive drug. The first person experiments with the drug briefly and never uses it again. The second person progresses from experimentation to occasional use. The third goes on to take the drug compulsively. Since social factors, drug availability, and the properties of the drug itself are the same for all three people, these factors cannot explain the three different patterns of drug use. We must conclude, therefore, that the differences must lie in the people: one individual was not prone to drug abuse, one had only moderate tendencies toward abuse, and the third was highly vulnerable to becoming an abuser.

405

406

Several psychologic factors have been associated with tendencies toward drug abuse. Drug abusers are frequently individuals who are impulsive, have a low tolerance for frustration, and are rebellious against social norms. Other psychologic factors that seem to predispose individuals to abusing drugs include depressive disorders, anxiety disorders, and antisocial personality. It is also clear that individuals who abuse one type of drug are likely to abuse other drugs.

There is speculation that some instances of drug abuse may actually represent self-medication to relieve emotional discomfort. For example, some people may use alcohol and other depressants to control severe anxiety. Although their drug use may appear excessive, it may be no more than they need to neutralize intolerable feelings.

Genetics also contribute to drug abuse. Vulnerability to alcoholism, for example, may result from an inherited predisposition.

38.4 NEUROBIOLOGY OF ADDICTION

How does repeated use of an addictive drug contribute to the transition from voluntary drug use to compulsive use? By causing molecular changes in the brain. Each time the drug is taken, it causes changes that promote further drug use. With repeated drug exposure, these changes are reinforced, making drug use more and more difficult to control.

Where do these molecular changes occur? The most important site is the so-called *reward circuit*—a system that normally serves to reinforce behaviors essential for survival, such as eating and reproductive activities. Neurons of the reward circuit originate in the ventral tegmental area of the midbrain, and project to the nucleus accumbens. Their major transmitter is *dopamine*. Under normal circumstances, biologically critical behavior, such as sexual intercourse, activates the circuit. The resultant release of dopamine rewards and reinforces the behavior. Like natural positive stimuli, addictive drugs can also activate the system, causing synaptic levels of dopamine to rise. Whether the system is activated by use of drugs or by behavior essential for survival, the outcome is the same: a tendency to repeat the behavior that turned the system on. With repeated activation over time, the system eventually undergoes synaptic remodeling, thereby consolidating changes in brain function, and hence in addiction-related behavior. Remodeling persists after drug use has ceased.

38.5 PRINCIPLES OF ADDICTION TREATMENT

Drug addiction is a treatable disease. With therapy, between 40% and 60% of addicts can reduce drug use. In 1999, treatment underwent a significant advance when the National Institute on Drug Abuse published *Principles of Drug Addiction Treatment*, the first science-based guide on addiction therapy. The guide centers on 13 principles of effective treatment, summarized in [Table 37-2](#).

Ideally, the goal of treatment is *complete cessation* of drug use. However, total abstinence is not the only outcome that can be considered successful. Treatment that changes drug use from compulsive to moderate will permit increased productivity, better health, and a decrease in socially unacceptable behavior. Clearly, this outcome is beneficial both to the individual and to society—even though some degree of drug use continues. It must be noted, however, that in the treatment of some forms of abuse, nothing short of total abstinence can be considered a true success. Experience has shown that abusers of *cigarettes*, *alcohol*, and *opioids* are rarely capable of sustained moderation. Hence, for many of these individuals, abstinence must be complete if there is to be any hope of avoiding a return to compulsive use.

Recovery from addiction is a prolonged process that typically requires multiple treatment episodes. Why? Because addiction is a *chronic, relapsing* illness. As such, periods of treatment-induced abstinence will very likely be followed by relapse. This does not mean that treatment has failed. Rather, it simply means that at least one more treatment episode is needed. Eventually, many patients achieve stable, long-term abstinence, along with a more productive and rewarding life.

Because addiction is a complex illness that affects all aspects of life, the treatment program must be comprehensive and multifaceted. In addition to addressing drug use itself, the program should address any related medical, psychologic, social, vocational, and legal problems. Obviously, treatment must be tailored to the individual; no single approach works for all people. Multiple

techniques are employed. Techniques with proven success include (1) therapy directed at resolving emotional problems that underlie drug use, (2) substitution of alternative rewards for the rewards of drug use, (3) threats and external pressure to discourage drug use, and (4) use of pharmacologic agents to modify the effects of abused drugs. The most effective treatment programs incorporate two or more of these methods.

38.6 THE CONTROLLED SUBSTANCES ACT

The *Comprehensive Drug Abuse Prevention and Control Act* of 1970, known informally as the *Controlled Substances Act* (CSA), is the principal federal legislation addressing drug abuse. One objective of the CSA is to reduce the chances that drugs originating from legitimate sources will be diverted to abusers. To accomplish this goal, the CSA sets forth regulations for the handling of controlled substances by manufacturers, distributors, pharmacists, nurses, and physicians. Enforcement of the CSA is the responsibility of the *Drug Enforcement Agency* (DEA), an arm of the U.S. Department of Justice.

38.6.1 Record Keeping

In order to keep track of controlled substances that originate from legitimate sources, a written record must be made of all transactions involving these agents. Every time a controlled substance is purchased or dispensed, the transfer must be recorded. Physicians, pharmacists, and hospitals must keep an inventory of all controlled substances in stock. This inventory must be reported to the DEA every 2 years. Although not specifically obliged to do so by the CSA, many hospitals require that floor stocks of controlled substances be counted at the beginning and end of each nursing shift.

406

TABLE 37-2 Principles of Drug-Addiction Treatment

- 1. No single treatment is appropriate for all individuals.** Matching treatment settings, interventions, and services to each patient's problems and needs is critical.
- 2. Treatment needs to be readily available.** Treatment applicants can be lost if treatment is not immediately available or readily accessible.
- 3. Effective treatment must attend to multiple needs of the individual, not just his or her drug use.** In addition to addressing drug use, treatment must address the individual's medical, psychologic, social, vocational, and legal problems.
- 4. Because needs of the individual can change, the treatment plan must be reassessed continually and modified as indicated.** At different times during treatment, a patient may develop a need for medical services, family therapy, vocational rehabilitation, and social and legal services.
- 5. Remaining in treatment for an adequate time is critical for effectiveness.** The time depends on the individual's needs. For most patients, the threshold for significant improvement is reached at about 3 months. Additional treatment can produce further progress. Programs should include strategies to prevent patients from leaving prematurely.
- 6. Individual and/or group counseling and other behavioral therapies are critical components of treatment.** In therapy, patients address motivation, build skills to resist drug use, replace drug-using activities with constructive and rewarding non-drug-related activities, and improve problem-solving abilities. Behavioral therapy also facilitates interpersonal relationships.
- 7. Medication can be an important element of treatment, especially when combined with counseling and other behavioral therapies.** Methadone, buprenorphine, and naltrexone can help persons addicted to opiates. Nicotine replacement therapy (eg, patches, gum), bupropion, and/or varenicline can help patients addicted to nicotine.
- 8. Addicted individuals who also have mental disorders should have both conditions treated in an integrated way.**
- 9. Medical detoxification is only the first stage of addiction treatment and, by itself, does little to change long-term drug use.** Medical detoxification manages the acute physical symptoms of withdrawal—and can serve as a precursor to effective drug addiction treatment.
- 10. Treatment needn't be voluntary to be effective.** Sanctions or enticements coming from the family, employer, or criminal justice system can significantly increase treatment entry, retention, and success.
- 11. Individuals in treatment must undergo continuous monitoring for possible drug use.** Monitoring drug use (eg, through urinalysis) can help the patient withstand urges to use drugs. Monitoring also can provide early evidence of drug use, thereby allowing appropriate adjustment of the treatment program.
- 12. Treatment programs should provide assessment for HIV/AIDS, hepatitis B and C, tuberculosis, and other infectious diseases, along with counseling to help patients modify behaviors that place them or others at risk.**

13. Recovery from drug addiction is typically a long-term process, and often requires multiple treatment episodes. As with other chronic illnesses, relapses can occur during or after successful treatment episodes. Participation in self-help support programs during and following treatment can help maintain abstinence.

HIV/AIDS = human immunodeficiency virus/acquired immunodeficiency syndrome.

38.6.2 DEA Schedules

Each drug preparation regulated under the Controlled Substances Act has been assigned to one of five categories: Schedule I, II, III, IV, or V. Drugs in Schedule I have a high potential for abuse and no approved medical use in the United States. In contrast, drugs in Schedules II through V all have approved applications. Assignment to Schedules II through V is based on abuse potential and potential for causing physical or psychologic dependence. Of the drugs that have medical applications, those in Schedule II have the highest potential for abuse and dependence. Drugs in the remaining schedules have decreasing abuse and dependence liabilities. [Table 37-3](#) lists the primary drugs that come under the five DEA Schedules.

Scheduling of drugs under the Controlled Substances Act undergoes periodic re-evaluation. With increased understanding of the abuse and dependence liabilities of a drug, the DEA may choose to reassign it to a different Schedule. For example, glutethimide (a general CNS depressant) was recently switched from Schedule III to Schedule II.

38.6.3 Prescriptions

The Controlled Substances Act places restrictions on prescribing drugs in Schedules II through V. (Drugs in Schedule I have no approved uses, and hence are not prescribed.) Only prescribers registered with the DEA are authorized to prescribe controlled drugs. Regulations on prescribing controlled substances are summarized below.

407

408

TABLE 37-3 Classification of Controlled Substances by the Drug Enforcement Agency

Schedule I Drugs	Schedule II Drugs	Schedule III Drugs	Schedule IV Drugs	Schedule V Drugs
------------------	-------------------	--------------------	-------------------	------------------

Pharmacology for Nursing Care, 7th Edition

Opioids	Opioids	Opioids	Opioids	Opioids
Acetylmethadol	Alfentanil	Buprenorphine	Butorphanol	Diphenoxylate plus atropine
Heroin	Codeine	Hydrocodone	Pentazocine	
Normethadone	Fentanyl	Paregoric	Propoxyphene	
Many others	Hydromorphone	Cannabinoids	Stimulants	
Psychedelics	Levorphanol	Dronabinol (THC)	Diethylpropion	
Bufotenin	Meperidine	Stimulants	Fenfluramine	
Diethyltryptamine	Methadone	Benzphetamine	Mazindol	
Dimethyltryptamine	Morphine	Phendimetrazine	Pemoline	
Ibogaine	Opium tincture	Barbiturates	Phentermine	
<i>d</i> -Lysergic acid diethylamide (LSD)	Oxycodone	Aprobarbital	Barbiturates	
Mescaline	Oxymorphone	Butabarbital	Mephobarbital	
3,4-Methylenedioxy-methamphetamine (MDMA)	Remifentanil	Metharbital	Methohexital	
Psilocin	Sufentanil	Talbutal	Phenobarbital	
Psilocybin	Psychostimulants	Thiamylal	Benzodiazepines	
Cannabis Derivatives	Amphetamine	Thiopental	Alprazolam	
Hashish	Cocaine	Miscellaneous Depressants	Chlordiazepoxide	
Marijuana	Dextroamphetamine		Clonazepam	
Others	Methamphetamine	Anabolic Steroids	Clorazepate	
Flunitrazepam	Methylphenidate	Fluoxymesterone	Diazepam	
Gamma-hydroxybutyrate	Phenmetrazine	Methyltestosterone	Estazolam	
Methaqualone	Barbiturates	Nandrolone	Flurazepam	
Phencyclidine	Amobarbital	Oxandrolone	Halazepam	
	Pentobarbital	Stanozolol	Lorazepam	
	Secobarbital	Testosterone	Midazolam	
	Miscellaneous Depressants	Many others	Oxazepam	
	Glutethimide	Others	Prazepam	
		Ketamine	Quazepam	
			Temazepam	
			Triazolam	
			Benzodiazepine-like	
			Drugs	

	Eszopiclone
	Zaleplon
	Zolpidem
	Miscellaneous Depressants
	Chloral hydrate
	Dichloralphenazone
	Ethchlorvynol
	Ethinamate
	Meprobamate
	Paraldehyde

38.6.3.1 Schedule II.

All prescriptions for Schedule II drugs must be typed or filled out in ink or indelible pencil and signed by the prescriber. Oral prescriptions may be made, but only in emergencies, and a written prescription must follow within 72 hours. Prescriptions for Schedule II drugs cannot be refilled. However, a DEA rule issued in 2007 now allows a prescriber to write multiple prescriptions on the same day—for the same patient and same drug—to be filled sequentially for up to a 90-day supply.

38.6.3.2 Schedules III and IV.

Prescriptions for drugs in Schedules III and IV may be oral or written. If authorized by the prescriber, these prescriptions may be refilled up to 5 times. Refills must be made within 6 months of the original order. If additional medication is needed beyond the amount provided for in the original prescription, a new prescription must be written.

38.6.3.3 Schedule V.

The same regulations for prescribing drugs in Schedules III and IV apply to drugs in Schedule V. In addition, Schedule V drugs may be dispensed without a prescription provided the following conditions are met: (1) the drug is dispensed by a pharmacist; (2) the amount dispensed is very limited; (3) the recipient is at least 18 years old and can prove it; (4) the pharmacist writes and initials a record indicating the date, the name and amount of the drug, and the name and address of the recipient; and (5) state and local laws do not prohibit dispensing Schedule V drugs without a prescription.

408

38.6.4 Labeling

When drugs in Schedules II, III, and IV are dispensed, their containers must bear this label:

Caution—Federal law prohibits the transfer of this drug to any person other than the patient for whom it was prescribed. The label must also indicate whether the drug belongs to Schedule II, III, or IV. The symbols C-II, C-III, and C-IV are used to indicate the Schedule.

38.6.5 State Laws

All states have their own laws regulating drugs of abuse. In many cases, state laws are more stringent than federal laws. As a rule, whenever there is a difference between state and federal laws, the more restrictive of the two takes precedence.

38.6.5.1

KEY POINTS

- Drug abuse can be defined as drug use that is inconsistent with medical or social norms.
- Drug abuse is a culturally defined term. Hence, what is considered abuse can vary from one culture to another and from one time to another within the same culture.
- Addiction can be defined as a disease process characterized by the continued use of a specific psychoactive substance despite physical, psychologic, or social harm.
- Addiction is largely equivalent to substance dependence as defined in DSM-IV.
- Tolerance is a state in which a particular drug dose elicits a smaller response than it formerly did.
- Cross-tolerance is a state in which tolerance to one drug confers tolerance to another drug.
- Psychologic dependence is defined as an intense subjective need for a particular psychoactive drug.
- Physical dependence is a state in which an abstinence syndrome will occur if drug use is discontinued. Physical dependence is *not* the same as addiction.
- Cross-dependence refers to the ability of one drug to support physical dependence on another drug.
- A withdrawal syndrome is a group of signs and symptoms that occur in physically dependent individuals when they discontinue drug use.

- As defined in DSM-IV, substance dependence is a more severe substance use disorder than substance abuse.
- Although tolerance and withdrawal are among the diagnostic criteria for substance dependence, they are neither necessary nor sufficient for a diagnosis.
- Although physical dependence is not the same as addiction (substance dependence), physical dependence can certainly contribute to addictive behavior.
- Drugs can reinforce their own use by providing pleasurable experiences, reducing the intensity of unpleasant experiences, and warding off a withdrawal syndrome.
- All addictive drugs activate the brain's dopamine reward circuit. Over time, they cause adaptive changes in the circuit that make it more and more difficult to control use.
- Some individuals, because of psychologic or genetic factors, are more prone to drug abuse than others.
- Because addiction is a chronic, relapsing illness, recovery is a prolonged process that typically requires multiple episodes of treatment.
- The ideal goal of treatment is complete abstinence. However, treatment that substantially reduces drug use can still be considered a success.
- Under the Controlled Substances Act, drugs in Schedule I have a high potential for abuse and no medically approved use in the United States. Drugs in Schedules II through V have progressively less abuse potential and are all medically approved.

³⁹CHAPTER 38 Drug Abuse II: Alcohol

Alcohol (ethyl alcohol, ethanol) is the most commonly used and abused psychoactive agent in the United States. Although alcohol does have some therapeutic applications, the drug is of interest primarily for its nonmedical use. When consumed in moderation, alcohol prolongs life; reduces the risk of dementia and cardiovascular disorders; and, many would argue, contributes to the joy of living. Conversely, when consumed in excess, alcohol does nothing but diminish life both in quality and quantity. These dose-related contrasts between the detrimental and beneficial effects of alcohol were aptly summed up by our 16th president, Abraham Lincoln, when he noted:

“None seemed to think the injury arose from use of a bad thing, but from the abuse of a very good thing.”

In approaching our study of alcohol, we begin by discussing the basic pharmacology of alcohol, and then we discuss alcohol use disorders and the drugs employed for their treatment.

^{39.1}BASIC PHARMACOLOGY OF ALCOHOL

^{39.1.1} Central Nervous System Effects

^{39.1.1.1} Acute Effects.

Alcohol has two acute effects on the brain: (1) general depression of central nervous system (CNS) function (like that seen with barbiturates) and (2) activation of the reward circuit.

How does alcohol affect neuronal activity? For many years, we believed that alcohol simply dissolved into the neuronal membrane, thereby disrupting the ordered arrangement of membrane phospholipids. However, we now know that alcohol interacts with specific proteins—certain receptors, ion channels, and enzymes—that regulate neuronal excitability. Two target proteins are of particular importance, namely (1) receptors for gamma-aminobutyric acid (GABA) and (2) the 5-HT₃ subset of receptors for serotonin (5-hydroxytryptamine, 5-HT). The *depressant* effects of alcohol result from binding with receptors for GABA, the principal inhibitory transmitter in the CNS. When alcohol binds with GABA receptors, it enhances GABA-mediated inhibition, thereby causing widespread depression of CNS function. The *rewarding* effects of alcohol result from binding with 5-HT₃ receptors in the brain's reward circuit. When these receptors are activated (by serotonin), they promote release of dopamine, the major transmitter of the reward system. When alcohol binds with these receptors, it enhances serotonin-mediated release of dopamine, and thereby intensifies the reward process.

TABLE 38-1 Central Nervous System Responses at Various Blood Alcohol Levels

The depressant effects of alcohol are dose dependent. When dosage is low, higher brain centers (cortical areas) are primarily affected. As dosage increases, more primitive brain areas (eg, medulla) become depressed. With depression of cortical function, thought processes and learned behaviors are altered, inhibitions are released, and self-restraint is replaced by increased sociability and expansiveness. Cortical depression also impairs motor function. As CNS depression deepens, reflexes diminish greatly and consciousness becomes impaired. At very high doses, alcohol produces a state of general anesthesia. (Alcohol can't be used for anesthesia because the doses required are close to lethal.) [Table 38-1](#) summarizes the effects of alcohol as a function of blood alcohol level and indicates the brain areas involved.

39.1.1.2 Chronic Effects.

When consumed chronically and in excess, alcohol can produce severe neurologic and psychiatric disorders. Injury to the CNS is caused by the direct actions of alcohol and by the nutritional deficiencies often seen in chronic heavy drinkers.

410

411

Two neuropsychiatric syndromes are common in alcoholics: *Wernicke's encephalopathy* and *Korsakoff's psychosis*. Both disorders are caused by thiamin deficiency, which results from poor diet and alcohol-induced suppression of thiamin absorption. Wernicke's encephalopathy is characterized by confusion, nystagmus, and abnormal ocular movements. This syndrome is readily reversible with thiamin. Korsakoff's psychosis is characterized by polyneuropathy, inability to convert short-term memory into long-term memory, and confabulation (unconscious filling of gaps in memory with fabricated facts and experiences). Korsakoff's psychosis is not reversible.

Perhaps the most dramatic effect of long-term excessive alcohol consumption is enlargement of the cerebral ventricles, presumably in response to atrophy of the cerebrum itself. These gross

anatomic changes are associated with impairment of memory and intellectual function. With cessation of drinking, ventricular enlargement and cognitive deficits partially reverse, but only in some individuals.

39.1.1.3 Impact on Cognitive Function.

Low to moderate drinking helps preserve cognitive function in older people and may protect against development of dementia.

39.1.1.4 Effect on Sleep.

Although alcohol is commonly used as a sleep aid, it actually disrupts sleep. Drinking can alter sleep cycles, decrease total sleeping time, and reduce the quality of sleep. In addition, alcohol can intensify snoring and exacerbate obstructive sleep apnea. Having a drink with dinner won't affect sleep—but drinking late in the evening will.

39.1.2 Other Pharmacologic Effects

39.1.2.1 Cardiovascular System.

When alcohol is consumed acutely and in moderate doses, cardiovascular effects are minor. The most prominent effect is *dilation of cutaneous blood vessels*, which increases blood flow to the skin. By doing so, alcohol imparts a sensation of warmth—but at the same time promotes loss of heat. Hence, despite images of Saint Bernards with little barrels of whiskey about their necks, alcohol may do more harm than good for the individual stranded in the snow with hypothermia.

Although the cardiovascular effects of moderate alcohol consumption are unremarkable, chronic and excessive consumption is clearly harmful. Abuse of alcohol results in *direct damage to the myocardium*, thereby increasing the risk of heart failure. Some investigators believe that alcohol may be the major cause of cardiomyopathy in the Western world.

In addition to damaging the heart, alcohol produces a dose-dependent *elevation of blood pressure*. The cause is vasoconstriction in vascular beds of skeletal muscle brought on by increased activity of the sympathetic nervous system. Estimates suggest that heavy drinking may be responsible for 10% of all cases of hypertension.

Not all of the cardiovascular effects of alcohol are deleterious: There is clear evidence that people who drink *moderately* (2 drinks a day or less for men, 1 drink a day or less for women) experience less ischemic stroke, coronary artery disease (CAD), myocardial infarction (MI), and heart failure than do abstainers. It is important to note, however, that with heavy drinking (5 or more drinks/day) the risk of heart disease and stroke is increased. Available data suggest that

alcohol protects against heart disease largely by raising levels of high-density lipoprotein (HDL) cholesterol. As discussed in [Chapter 49](#), HDL cholesterol protects against CAD, whereas low-density lipoprotein (LDL) cholesterol promotes CAD. In addition to raising HDL cholesterol, alcohol may confer protection through three other mechanisms: decreasing platelet aggregation, increasing levels of tissue plasminogen activator (a clot-dissolving enzyme), and suppressing the inflammatory component of atherosclerosis. The degree of cardiovascular protection is nearly equal for beer, wine, and distilled spirits. That is, protection is determined primarily by the *amount* of alcohol consumed—not by the particular beverage the alcohol is in. Red wine may confer additional protection because it contains flavonoids and polyphenols—compounds that can (1) induce endothelium-dependent vasodilation, (2) suppress synthesis of endothelin-1 (a potent vasoconstrictor), and (3) protect LDL from oxidation (LDL must first be oxidized before it can promote atherosclerosis).

39.1.2.2 Respiration.

Like all other CNS depressants, alcohol depresses respiration. Respiratory depression from moderate drinking is negligible. However, when consumed in excess, alcohol can cause death by respiratory arrest. The respiratory depressant effects of alcohol are potentiated by other CNS depressants (eg, benzodiazepines, opioids, barbiturates).

39.1.2.3 Liver.

Alcohol-induced liver damage can progress from fatty liver to hepatitis to cirrhosis, depending on the amount consumed. Acute drinking causes reversible accumulation of fat and protein in the liver. With more chronic drinking, *hepatitis* develops in about 90% of heavy users. In 8% to 20% of chronic alcoholics, hepatitis evolves into cirrhosis—a condition characterized by proliferation of fibrous tissue and destruction of liver parenchymal cells. Although various factors other than alcohol can cause cirrhosis, alcohol abuse is unquestionably the major cause of *fatal* cirrhosis.

39.1.2.4 Stomach.

Immoderate use of alcohol can cause *erosive gastritis*. About one-third of alcoholics have this disorder. Two mechanisms are involved. First, alcohol stimulates secretion of gastric acid. Second, when present in high concentrations, alcohol can injure the gastric mucosa directly.

39.1.2.5 Kidney.

Alcohol is a diuretic. It promotes urine formation by inhibiting the release of antidiuretic hormone (ADH) from the pituitary. Since ADH acts on the kidney to promote water

reabsorption, thereby decreasing urine formation, a reduction in circulating ADH will increase urine production.

39.1.2.6 Pancreas.

Approximately 35% of cases of acute pancreatitis can be attributed to alcohol, making alcohol the second most common cause of the disorder. Flare-ups typically occur after a bout of heavy drinking. Only 5% of alcoholics develop pancreatitis, and then only after years of overindulgence.

39.1.2.7 Sexual Function.

Alcohol has both psychologic and physiologic effects related to human sexual behavior. Although alcohol is not exactly an aphrodisiac, its ability to release inhibitions has been known to motivate sexual activity. Ironically, the physiologic effects of alcohol may frustrate attempts at consummating the activity that alcohol inspired: Objective measurements in males and females show that alcohol significantly decreases our physiologic capacity for sexual responsiveness. The opposing psychologic and physiologic effects of alcohol on sexual function were aptly described long ago by no less an authority than William Shakespeare. In *Macbeth* (Act II, Scene 1), Macduff inquires of a porter “What ... does drink especially provoke?” To which the porter replies,

411

412

“Lechery, sir, it provokes, and unprovokes; it provokes the desire, but it takes away the performance.”

In males, long-term use of alcohol may induce *feminization*. Symptoms include testicular atrophy, impotence, sterility, and breast enlargement.

39.1.2.8 Cancer.

Alcohol—even in moderate amounts—is associated with an increased risk of several common cancers, including cancer of the breast, rectum, liver, esophagus, and oropharynx. Regarding cancer risk, no dose can be considered safe.

39.1.2.9 Pregnancy.

Fetal alcohol exposure can cause structural and functional abnormalities, ranging from mild neurobehavioral deficits to facial malformation and mental retardation. The term *fetal alcohol spectrum disorder* (FASD) is used in reference to the *full range* of outcomes—from mild to severe—that drinking during pregnancy can cause. In contrast, the term *fetal alcohol syndrome*

(FAS) is reserved for the most severe cases of FASD, characterized by craniofacial malformations, growth restriction (including microcephaly), and neurodevelopmental abnormalities, manifesting during childhood as cognitive and social dysfunction. In addition to causing FASD and FAS, drinking during pregnancy can result in stillbirth, spontaneous abortion, and giving birth to an alcohol-dependent infant.

How much alcohol can be consumed safely during pregnancy? No one knows. What we do know is that fetal exposure from even moderate drinking can result in mood disorders, distractibility, learning problems, and memory deficits. In fact, drinking at social levels is considered the most common cause of mental retardation in the United States, and the leading cause of preventable birth defects. These observations suggest that, if there is some amount of alcohol that is safe during pregnancy, that amount must be very low. Accordingly, in the interests of fetal health, pregnant women should be advised to avoid alcohol entirely. Having said that, it is important to appreciate that a few drinks early in pregnancy are not likely to harm the fetus. Consequently, if a woman consumed a little alcohol before realizing she was pregnant, she should be reassured that the risk to her baby—if any—is extremely low.

39.1.2.10 Lactation.

The concentration of alcohol in breast milk parallels the concentration in blood. Recent data indicate that drinking while breast-feeding can adversely affect the infant's feeding and behavior.

39.1.3 Impact on Longevity

The effects of alcohol on life span depend on the amount consumed. *Heavy* drinkers have a higher mortality rate than the population at large. Causes of death include cirrhosis, respiratory disease, cancer, and fatal accidents. The risk of mortality associated with alcohol abuse increases markedly in individuals who consume 6 or more drinks a day.

Interestingly, people who consume *moderate* amounts of alcohol live *longer* than those who abstain—and combining regular exercise with moderate drinking prolongs life even more. Compared with nondrinkers, moderate drinkers have a 30% lower mortality rate, a 50% lower incidence of MI, and a 59% lower incidence of heart failure. According to a study by the American Medical Association, if all Americans were to give up drinking, deaths from heart disease would *increase* by 81,000 a year. Hence, for people who already *are* moderate drinkers, continued moderate drinking would seem beneficial. Conversely, despite the apparent benefits of drinking—and the apparent health disadvantage of abstinence—no one is recommending that abstainers take up drinking. Furthermore, when the risks of alcohol outweigh any possible benefits—as in the examples listed in [Table 38-2](#)—then alcohol consumption should be avoided entirely.

TABLE 38-2 People Who Should Avoid Alcohol^{*}

- Women who are pregnant or trying to conceive.
- People who plan to drive or perform other activities that require unimpaired attention or muscular coordination.
- People taking antihistamines, sedatives, or other drugs that can intensify alcohol's effects.
- Recovering alcoholics.
- People under age 21.

Caution is indicated for people with a strong family history of alcoholism and for those with diabetes, peptic ulcer disease, and other medical conditions that can be exacerbated by alcohol.

^{*} According to the National Institute on Alcohol Abuse and Alcoholism.

How does alcohol prolong life? In large part by reducing cardiovascular disease. For people who drink red wine, a small benefit may come from *resveratrol*, although the amount present appears too small to have a significant effect.

39.1.4 Pharmacokinetics

39.1.4.1 Absorption.

Alcohol is absorbed from the stomach and small intestine. About 20% of ingested alcohol is absorbed from the stomach. Gastric absorption is relatively slow and is delayed even further by the presence of food. Milk is especially effective at retarding absorption. Absorption from the small intestine is rapid and largely independent of food; about 80% of ingested alcohol is absorbed from this site. Because most alcohol is absorbed from the small intestine, gastric emptying time is a major determinant of individual variation in alcohol absorption.

39.1.4.2 Distribution.

Alcohol is distributed to all tissues and body fluids. The drug crosses the blood-brain barrier with ease, allowing alcohol in the brain to equilibrate rapidly with alcohol in the blood. Alcohol also crosses the placenta and hence can affect the developing fetus.

39.1.4.3 Metabolism.

Alcohol is metabolized in both the liver and stomach. The liver is the primary site. The pathway for alcohol metabolism is shown in [Figure 38-1](#). As depicted, the process begins with conversion of alcohol to acetaldehyde, a reaction catalyzed by *alcohol dehydrogenase*. This

reaction is slow and puts a limit on the rate at which alcohol can be inactivated. Once formed, acetaldehyde undergoes *rapid* conversion to acetic acid. Through a series of reactions, acetic acid is then used to synthesize cholesterol, fatty acids, and other compounds.

The kinetics of alcohol metabolism differ from those of most other drugs. With most drugs, as plasma drug levels rise, the amount of drug metabolized per unit time increases too. This is not true for alcohol: As the alcohol content of blood increases, there is almost no change in the speed of alcohol breakdown. That is, alcohol is metabolized at a relatively *constant rate*—regardless of how much alcohol is present.

412
413

Figure 38-1 **Ethanol metabolism and the effect of disulfiram.**

Conversion of ethanol into acetaldehyde takes place slowly (about 15 mL/hr). Consumption of more than 15 mL/hr will cause ethanol to accumulate. Effects of disulfiram result from accumulation of acetaldehyde secondary to inhibition of aldehyde dehydrogenase.

Blood Alcohol Level (%)	Pharmacologic Response	Brain Area Affected
0.50	Peripheral collapse	} Medulla
0.45	Respiratory depression	
0.40	Stupor, coma	} Diencephalon
0.35	Apathy, inertia	
0.30	Altered equilibrium	} Cerebellum
0.25	Double vision	
0.20	Altered perception	} Occipital lobe
0.15	↓ Motor skills	
0.10	Slurred speech	} Parietal lobe
0.05	Tremors	
0.05	Ataxia	} Frontal lobe
0.05	↓ Attention	
0.05	Loquaciousness	} Frontal lobe
0.05	Altered judgment	
0.05	Increased confidence	} Frontal lobe
0.05	Euphoria, ↓ inhibitions	

The average rate at which individuals can metabolize alcohol is about *15 mL (0.5 oz) per hour*.

Because alcohol is metabolized at a slow and constant rate, there is a limit to how much alcohol one can consume without having the drug accumulate. For practical purposes, that limit is about *1 drink per hour*. Consumption of more than 1 drink per hour—be that drink beer, wine, straight whiskey, or a cocktail—will result in alcohol buildup.

The information in [Table 38-3](#) helps explain why we can't metabolize more than 1 drink's worth of alcohol per hour. As the table indicates, beer, wine, and whiskey differ from one another with respect to alcohol concentration and usual serving size. However, despite these differences, it turns out that *the average can of beer, the average glass of wine, and the average shot of whiskey all contain the same amount of alcohol—namely, 18 mL (0.6 oz)*. Since the liver can metabolize about 15 mL of alcohol per hour, and since the average alcoholic drink contains 18 mL of alcohol, 1 drink contains just about the amount of alcohol that the liver can comfortably process each hour. Consumption of more than 1 drink per hour will overwhelm the capacity of the liver for alcohol metabolism, and therefore alcohol will accumulate.

TABLE 38-3 Alcohol Content of Beer, Wine, and Whiskey

	Wine	Beer	Whiskey
Usual serving	1 glass	1 can or bottle	1 shot
Serving size	150 mL (5 oz)	360 mL (12 oz)	45 mL (1.5 oz)
Alcohol concentration	12% ^a	5% ^b	40% ^c
Alcohol per serving	18 mL ^d (0.6 oz)	18 mL ^e (0.6 oz)	18 mL ^f (0.6 oz)

- a The alcohol content of wine varies from 8% to 20%; typical table wines contain 12%.
- b The alcohol content of beer varies: 5% alcohol is typical of American premium beers; cheaper American beers and light beers have less alcohol (2.4% to 5%); and imported beers may have more alcohol (6%). Beer sold in Europe may have 7% to 8% alcohol.
- c Whiskeys and other distilled spirits (eg, rum, vodka, gin) are usually 80 proof (40% alcohol) but may also be 100 proof (50% alcohol).
- d The alcohol in a 5-ounce glass of wine varies from 12 to 30 mL, depending on the alcohol concentration in the wine. Wine with 12% alcohol has 18 mL of alcohol per 5-ounce glass.
- e The alcohol in a 12-ounce can of beer varies from 9 to 29 mL, depending on the alcohol concentration in the beer. Beer with 5% alcohol has 18 mL per 12-ounce can.

f The alcohol in a 1.5-ounce shot of whiskey can be either 18 or 22.5 mL, depending on the proof of the whiskey. Eighty-proof whiskey has 18 mL alcohol per 1.5-ounce serving.

When used on a regular basis, alcohol induces hepatic drug-metabolizing enzymes, thereby increasing the rate of its own metabolism and that of other drugs. As a result, individuals who consume alcohol routinely in high amounts can metabolize the drug faster than people who drink occasionally and moderately.

Males and females differ with respect to activity of alcohol dehydrogenase in the stomach. Specifically, women have much lower activity than men. As a result, gastric metabolism of alcohol is significantly less in women. This difference partly explains why women achieve higher blood alcohol levels than men after consuming the same number of drinks.

39.1.4.4 Blood Levels of Alcohol.

Since alcohol in the brain rapidly equilibrates with alcohol in the blood, blood levels of alcohol are predictive of CNS effects. The behavioral effects associated with specific blood levels are summarized in [Table 38-1](#). The earliest effects (euphoria, reduced inhibitions, increased confidence) are seen when blood alcohol content is about 0.05%. As blood alcohol rises, intoxication becomes more intense. When blood alcohol exceeds 0.4%, there is a substantial risk of respiratory depression, peripheral collapse, and death. In all states of the Union, a level of 0.08% defines intoxication.

39.1.5 Tolerance

Chronic consumption of alcohol produces tolerance. As a result, in order to alter consciousness, people who drink on a regular basis require larger amounts of alcohol than people who drink occasionally. Tolerance to alcohol confers cross-tolerance to general anesthetics, barbiturates, and other general CNS depressants. However, no cross-tolerance develops to opioids. Tolerance subsides within a few weeks following drinking cessation.

Although tolerance develops to many of the effects of alcohol, *very little tolerance develops to respiratory depression*. Consequently, the lethal dose of alcohol for chronic, heavy drinkers is not much bigger than the lethal dose for nondrinkers. Alcoholics may tolerate blood alcohol levels as high as 0.4% (5 times the amount defined by law as intoxicating) with no marked reduction in consciousness. However, if blood levels rise only slightly above this level, death may ensue.

413

39.1.6 Physical Dependence

Chronic use of alcohol produces physical dependence. If alcohol is withdrawn abruptly, an abstinence syndrome will result. The intensity of the abstinence syndrome is proportional to the degree of physical dependence. Individuals who are physically dependent on alcohol show cross-dependence with other general CNS depressants (eg, barbiturates, chloral hydrate, benzodiazepines) but not with opioids. The alcohol withdrawal syndrome and its management are discussed in detail below.

39.1.7 Drug Interactions

39.1.7.1 CNS Depressants.

The CNS effects of alcohol are additive with those of other CNS depressants (eg, barbiturates, benzodiazepines, opioids). Consumption of alcohol with other CNS depressants intensifies the psychologic and physiologic manifestations of CNS depression, and greatly increases the risk of death from respiratory depression.

39.1.7.2 Nonsteroidal Anti-inflammatory Drugs.

Like alcohol, aspirin, ibuprofen, and other nonsteroidal anti-inflammatory drugs (NSAIDs) can injure the GI mucosa. The combined effects of alcohol and NSAIDs can result in significant gastric bleeding.

39.1.7.3 Acetaminophen.

The combination of acetaminophen [Tylenol, others] with alcohol poses a risk of potentially fatal liver injury. There is evidence that relatively modest alcohol consumption (2 to 4 drinks a day) can cause fatal liver damage when combined with acetaminophen taken in normal therapeutic doses. Accordingly, some authorities recommend that people who drink take no more than 2 gm of acetaminophen a day (ie, half the normal dosage). The interaction between alcohol and acetaminophen is discussed further in [Chapter 70](#).

39.1.7.4 Disulfiram.

The combination of alcohol with disulfiram [Antabuse] can cause a variety of adverse effects, some of which are dangerous. These effects, and the use of disulfiram to maintain abstinence, are discussed later.

39.1.7.5 Antihypertensive Drugs.

Since alcohol raises blood pressure, it tends to counteract the effects of antihypertensive medications. However, elevation of blood pressure is significant only when alcohol dosage is high. Conversely, when the dosage is low, alcohol may actually help: Among hypertensive men, light to moderate alcohol consumption is associated with reduced risk for both cardiovascular mortality and all-cause mortality.

39.1.8 Acute Overdose

Acute overdose produces vomiting, coma, pronounced hypotension, and respiratory depression. The combination of vomiting and unconsciousness can result in aspiration, which in turn can result in pulmonary obstruction and pneumonia. Alcohol-induced hypotension results from a direct effect on peripheral blood vessels, and cannot be corrected with vasoconstrictors (eg, epinephrine). Hypotension can lead to renal failure (secondary to compromised renal blood flow) and cardiovascular shock, a common cause of alcohol-related death. Although death can also result from respiratory depression, this is not the usual cause.

Because symptoms of acute alcohol poisoning can mimic symptoms of other pathologies (eg, diabetic coma, skull fracture), a definitive diagnosis may not be possible without measuring alcohol in the blood, urine, or expired air. The smell of “alcohol” on the breath is not a reliable means of diagnosis, since the breath odors we associate with alcohol are due to impurities in alcoholic beverages—and not to alcohol itself. Hence, these odors may or may not be present.

Alcohol poisoning is treated like poisoning with all other general CNS depressants. Details of management are discussed in [Chapter 34](#). Alcohol can be removed from the body by gastric lavage and dialysis. Stimulants (eg, caffeine, pentylentetrazol) should not be given.

39.1.9 Summary of Precautions and Contraindications

Alcohol can injure the GI mucosa and should not be consumed by persons with *peptic ulcer disease*. Alcohol is harmful to the liver and should not be used by individuals with *liver disease*. Alcohol should be avoided during *pregnancy* because of the risk of FASD (including FAS), stillbirth, and spontaneous abortion.

Alcohol must be used with caution by patients with *epilepsy*. During alcohol use, the CNS is depressed. When alcohol consumption ceases, the CNS undergoes rebound excitation; seizures can result.

Alcohol increases the risk of *breast cancer*. All women—and especially those at high risk—should minimize alcohol consumption.

Consuming more than 2 drinks a day appears to increase the risk of *colorectal cancer*.

Alcohol can cause serious adverse effects if combined with *CNS depressants*, *NSAIDs*, *acetaminophen*, *vasodilators*, and *disulfiram*. These combinations should be avoided.

39.1.10 Therapeutic Uses

Although our emphasis has been on the nonmedical use of alcohol, it should be remembered that alcohol does have therapeutic applications.

39.1.10.1 Topical.

Alcohol applied to the skin can promote cooling in febrile patients. Topical alcohol is also an effective skin disinfectant. In addition, alcohol application can help prevent decubitus ulcers.

39.1.10.2 Oral.

Because of its ability to promote gastric secretion, alcohol can serve as an aid to digestion in bedridden patients. Oral alcohol is frequently used as self-medication for insomnia—although it can actually disrupt sleep.

39.1.10.3 Intravenous.

Solutions of alcohol (5% or 10%) in 5% dextrose are administered by slow IV infusion to provide calories and fluid replacement. Intravenous alcohol is also used to treat poisoning by methanol and ethylene glycol. Intravenous alcohol should not be used to manage alcohol withdrawal symptoms.

39.1.10.4 Local Injection.

Injection of alcohol in the vicinity of nerves produces nerve block. This technique can relieve pain of trigeminal neuralgia, inoperable carcinoma, and other causes.

39.2 ALCOHOL USE DISORDERS

Alcoholism is a chronic, relapsing disorder characterized by impaired control over drinking, preoccupation with alcohol consumption, use of alcohol despite awareness of adverse consequences, and distortions in thinking, especially as evidenced by denial of a drinking problem. The development and manifestations of alcoholism are influenced by genetic, psychosocial, and

environmental factors. The disease is progressive and often fatal. In the United States, about 8 million adults are alcoholics.

In the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV), the pattern of alcohol use that constitutes alcoholism is termed *alcohol dependence* (if tolerance and withdrawal are present) or *alcohol abuse* (if tolerance and withdrawal are absent). Complete diagnostic criteria from DSM-IV for alcohol dependence and alcohol abuse are presented in [Table 38-4](#).

414

TABLE 38-4 DSM-IV Diagnostic Criteria for Alcohol Dependence and Alcohol Abuse

Alcohol Dependence

Alcohol dependence is a maladaptive pattern of alcohol use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

- Tolerance to alcohol
- Withdrawal from alcohol
- Consumption of alcohol in larger amounts or over longer periods than intended
- Continued alcohol use despite a persistent desire or repeated efforts to cut down or control consumption
- A great deal of time is spent drinking alcohol or recovering from its effects.
- Important social, occupational, or recreational activities are given up or reduced because of alcohol.
- Alcohol use continues despite knowledge of a persistent or recurrent physical or psychologic problem that alcohol probably caused or exacerbated (eg, drinking despite knowing that alcohol made an ulcer worse).

Alcohol Abuse

Alcohol abuse is a maladaptive pattern of alcohol use leading to clinically significant impairment or distress, as manifested by one (or more) of the following within a 12-month period:

- Recurrent alcohol use that results in a failure to fulfill major role obligations at work, school, or home
- Recurrent alcohol use in situations in which it is physically hazardous
- Recurrent alcohol-related legal problems
- Continued alcohol use despite persistent or recurrent social or interpersonal problems caused or exacerbated by alcohol

Individuals who display tolerance, withdrawal, and other symptoms of alcohol dependence would be diagnosed under alcohol dependence rather than alcohol abuse.

Adapted from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. Washington, DC: American Psychiatric Association, 2000, with permission. Copyright © 2000 American Psychiatric Association.

Misuse of alcohol is responsible for 6 million nonfatal injuries each year, and 85,000 deaths. Causes of death range from liver disease to automobile wrecks. Fully 45% of all fatal highway crashes are

alcohol related. Among teens, alcohol-related crashes are the leading cause of death. Alcohol also causes industrial accidents, and is responsible for 40% of industrial fatalities.

Alcohol abuse is a major public health problem, and its consequences are numerous. Alcoholism produces psychologic derangements, including anxiety, depression, and suicidal ideation. Malnutrition, secondary to inadequate diet and malabsorption, is common. Poor work performance and disruption of family life reflect the social deterioration suffered by alcoholics. Alcohol abuse during pregnancy can result in FASD (including FAS), stillbirth, and spontaneous abortion. Lastly, chronic alcohol abuse is harmful to the body; consequences include liver disease, cardiomyopathy, and brain damage—not to mention injury and death from accidents.

Chronic alcohol consumption produces substantial tolerance. Tolerance is both pharmacokinetic (accelerated alcohol metabolism) and pharmacodynamic. Pharmacodynamic tolerance is evidenced by an increase in the blood alcohol level required to produce intoxication. Alcoholics may tolerate blood alcohol levels of 200 to 400 mg/dL—2.5 to 5 times the level that defines legal intoxication—with no marked reduction in consciousness. It should be noted, however, that very little tolerance develops to respiratory depression. Hence, as the alcoholic consumes increasing amounts in an effort to produce desired psychologic effects, the risk of death from respiratory arrest gets increasingly high. Cross-tolerance exists with general anesthetics and other CNS depressants, but not with opioids.

Chronic use of alcohol produces physical dependence, and abrupt withdrawal produces an abstinence syndrome. When the degree of physical dependence is low, withdrawal symptoms are mild (disturbed sleep, weakness, nausea, anxiety, mild tremors) and last less than a day. In contrast, when the degree of dependence is high, withdrawal symptoms can be severe. Initial symptoms appear 12 to 72 hours after the last drink and continue 5 to 7 days. Early manifestations include cramps, vomiting, hallucinations, and intense tremors; heart rate, blood pressure, and temperature may rise, and tonic-clonic seizures may develop. As the syndrome progresses, disorientation and loss of insight occur. A few alcoholics (less than 1%) experience *delirium tremens* (severe persecutory hallucinations). Hallucinations can be so vivid and lifelike that alcoholics often can't distinguish them from reality. In extreme cases, alcohol withdrawal can result in cardiovascular collapse and death. Drugs used to ease withdrawal are discussed below.

In 2005, the National Institute on Alcohol Abuse and Alcoholism issued a document—*Helping Patients Who Drink Too Much: A Clinician's Guide*—that contains clear and concise information on screening, counseling, and treatment of alcohol use disorders. By following this guide, clinicians can help reduce morbidity and mortality among people who drink more than is safe, defined as more than 4 drinks in a day (or 14/week) for men, or more than 3 drinks in a day (or 7/week) for women. Helping patients involves four simple steps:

- Ask about alcohol use.
- Assess for alcohol use disorders, using the Alcohol Use Disorders Identification Test (AUDIT).
- Advise and assist (brief intervention).
- At follow-up: continue support.

This process is founded in part on two lines of evidence. First, we can identify people who misuse alcohol with an easily administered questionnaire, such as AUDIT ([Table 38-5](#)). Second, for many people, alcohol consumption can be reduced through brief interventions, such as offering feedback and advice about drinking and about setting goals. Long-term follow-up studies have shown that these simple interventions can decrease hospitalization and lower mortality rates. The guide is available online at www.niaaa.nih.gov/guide.

39.3 DRUGS FOR ALCOHOL USE DISORDERS

In the United States, about 1 million alcoholics seek treatment every year. Although the success rate is discouraging—nearly 50% relapse during the first few months—treatment should nonetheless be tried. The objective is to modify drinking patterns (ie, to reduce or completely eliminate alcohol consumption). Drugs can help in two ways. First, they can facilitate withdrawal. Second, they can help maintain abstinence after withdrawal has been accomplished.

415

416

TABLE 38-5 Screening Instrument: The Alcohol Use Disorders Identification Test (AUDIT)

	0	1	2	3	4	Score
1. How often do you have a drink containing alcohol?	Never	Monthly or less	2 to 4 times a month	2 to 3 times a week	4 or more times a week	
2. How many drinks containing alcohol do you have on a typical day when you are drinking?	1 or 2	3 or 4	5 or 6	7 to 9	10 or more	
3. How often do you have 5 or more drinks on one occasion?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
4. How often during the last year have you found that you were not able to stop drinking once you had started?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
5. How often during the last year have you failed to do what was normally expected of you because of drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
7. How often during the last year have you had a feeling of guilt or remorse after drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
8. How often during the last year have you been unable to remember what happened the night before because of your drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
9. Have you or someone else been injured because of your drinking?	No		Yes, but not in the last year		Yes, during the last year	
10. Has a relative, friend, doctor, or other healthcare worker been concerned about your drinking or suggested you cut down?	No		Yes, but not in the last year		Yes, during the last year	

Total Score
Reprinted with permission from the World Health Organization. To reflect standard drink sizes in the United States, the number of drinks in question 3 was changed from 6 to 5.
Instructions to patient: Place an X in the box that best describes your answer to each question.
Scoring: Record the score (0, 1, 2, 3, or 4) for each response in the blank box at the end of each line, and then add up the total score. The maximum possible is 40. A total score of 8 or more (for men up to age 60), or 4 or more (for women, adolescents, and men over 60) is considered a positive screen. For patients with totals near the cut-points, clinicians may wish to examine individual responses to questions and clarify them during the clinical examination.

39.3.1 Drugs Used to Facilitate Withdrawal

Management of withdrawal depends on the degree of dependence. When dependence is mild, withdrawal can be accomplished on an outpatient basis without drugs. However, when dependence is great, withdrawal carries a risk of death. Accordingly, hospitalization and drug therapy are indicated. The goals of management are to minimize symptoms of withdrawal, prevent seizures and delirium tremens, and facilitate transition to a program for maintaining abstinence. In theory, any drug that has cross-dependence with alcohol (ie, any of the general CNS depressants) should be effective. However, in actual practice, benzodiazepines are the drugs of choice. The benefits of benzodiazepines and other drugs used during withdrawal are summarized in [Table 38-6](#).

416
417

TABLE 38-6 Drugs Used to Facilitate Alcohol Withdrawal

Drug	Benefit During Withdrawal
Benzodiazepines	
Chlordiazepoxide	Decrease withdrawal symptoms; stabilize vital signs; prevent seizures and delirium tremens
Diazepam	
Oxazepam	
Lorazepam	
Beta-Adrenergic Blockers	
Atenolol	Improve vital signs; decrease craving; decrease autonomic component of withdrawal symptoms
Propranolol	
Central Alpha-Adrenergic Agonist	
Clonidine	Decreases autonomic component of withdrawal symptoms
Antiepileptic Drug	
Carbamazepine	Decreases withdrawal symptoms; prevents seizures

39.3.1.1 Benzodiazepines

Of the drugs used to facilitate alcohol withdrawal, benzodiazepines are the most effective. Furthermore, they are safe. In patients with severe alcohol dependence, benzodiazepines can stabilize vital signs, reduce symptom intensity, and decrease the risk of seizures and delirium tremens. Although all benzodiazepines are effective, agents with longer half-lives are generally preferred. Why? Because they provide the greatest protection against seizures and breakthrough symptoms. The benzodiazepines employed most often are chlordiazepoxide [Librium, others], diazepam [Valium], oxazepam [Serax], and lorazepam [Ativan]. Traditionally, benzodiazepines have been administered around-the-clock on a fixed schedule. However, PRN administration (in response to symptoms) is just as effective and permits speedier withdrawal.

39.3.1.2 Adjuncts to Benzodiazepines

Combining a benzodiazepine with another drug may improve withdrawal outcome. Agents that have been tried include carbamazepine (an antiepileptic drug), clonidine (an alphaadrenergic blocker), and atenolol and propranolol (betaadrenergic blockers). Carbamazepine may reduce withdrawal symptoms and the risk of seizures. Clonidine and the beta blockers reduce the autonomic component of withdrawal symptoms. In addition, the beta blockers may improve vital signs and decrease craving. It should be stressed, however, that these drugs are not very effective as monotherapy. Hence, they should be viewed only as adjuncts to benzodiazepines—not as substitutes.

39.3.2 Drugs Used to Maintain Abstinence

Once detoxification has been accomplished, the goal is to prevent—or at least minimize—future drinking. The ideal goal is complete abstinence. However, if drinking must resume, keeping it to a minimum is still beneficial, since doing so will reduce alcohol-related morbidity.

In trials of drugs used to maintain abstinence, several parameters are used to measure efficacy. These include

- Proportion of patients who maintain complete abstinence
- Days to relapse
- Number of drinking days
- Number of drinks per drinking day

In the United States, only three drugs—disulfiram, naltrexone, and acamprosate—are approved for maintaining abstinence. Disulfiram works by causing an unpleasant reaction if alcohol is consumed. Naltrexone blocks the pleasurable effects of alcohol and decreases craving. Acamprosate reduces some of the unpleasant feelings (eg, tension, dysphoria, anxiety) brought on by alcohol abstinence. Of the three drugs, naltrexone appears most effective. However, even with this agent, benefits are modest.

Because of the risk of relapse, prolonged treatment is needed. The minimum duration is 3 months. However, continuing for a year or more is not unreasonable. If the first drug fails, clinicians often try another one.

39.3.2.1 Disulfiram Aversion Therapy

39.3.2.1.1 Therapeutic Effects.

Disulfiram [Antabuse] helps alcoholics avoid drinking. How? By causing unpleasant effects if alcohol is ingested. Disulfiram has no applications outside the treatment of alcoholism.

Although disulfiram has been employed for over 50 years, its efficacy is only moderate. In clinical trials, the drug is no better than placebo at maintaining abstinence: The proportion of patients who relapse and the time to relapse are the same as with placebo. However, although disulfiram doesn't prevent drinking, it does decrease the frequency of drinking after relapse has occurred—presumably because of the unpleasant reaction that the patient is now familiar with. There is some indication that supervised administration of disulfiram may be more effective than when patients self-administer the drug.

39.3.2.1.2 Mechanism of Action.

As indicated in [Figure 38-1](#), disulfiram disrupts alcohol metabolism. Specifically, the drug causes *irreversible inhibition of aldehyde dehydrogenase*, the enzyme that converts acetaldehyde to acetic acid. As a result, if alcohol is ingested, *acetaldehyde* will accumulate to toxic levels, producing unpleasant and potentially harmful effects.

39.3.2.1.3 Pharmacologic Effects.

The constellation of effects caused by alcohol plus disulfiram is referred to as the *acetaldehyde syndrome*, a potentially dangerous event. In its “mild” form, the syndrome manifests as nausea, copious vomiting, flushing, palpitations, headache, sweating, thirst, chest pain, weakness, blurred vision, and hypotension; blood pressure may ultimately decline to

shock levels. This reaction, which may last from 30 minutes to several hours, can be brought on by consuming as little as 7 mL of alcohol.

In its most severe manifestation, the acetaldehyde syndrome is life threatening. Possible reactions include marked respiratory depression, cardiovascular collapse, cardiac dysrhythmias, myocardial infarction, acute congestive heart failure, convulsions, and death. Clearly, the acetaldehyde syndrome is not simply unpleasant; this syndrome can be extremely hazardous and must be avoided.

In the absence of alcohol, disulfiram rarely causes significant effects. Drowsiness and skin eruptions may occur during initial use, but they diminish with time.

417

39.3.2.1.4

Patient Selection.

418

Because of the severity of the acetaldehyde syndrome, candidates must be carefully chosen. Alcoholics who lack the determination to stop drinking should not receive disulfiram. In other words, disulfiram must not be administered to alcoholics who are likely to attempt drinking while undergoing treatment.

39.3.2.1.5

Patient Education.

Patient education is an extremely important component of therapy. Patients must be thoroughly informed about the potential hazards of treatment. That is, they must be made aware that consuming any alcohol while taking disulfiram may produce a severe, potentially fatal, reaction. Patients must be warned to avoid all forms of alcohol, including alcohol found in sauces and cough syrups, and alcohol applied to the skin in aftershave lotions, colognes, and liniments. Patients should be made aware that the effects of disulfiram will persist about 2 weeks after the last dose, and hence continued abstinence is necessary. Individuals using disulfiram should be encouraged to carry identification indicating their status.

39.3.2.1.6

Preparations, Dosage, and Administration.

Disulfiram [Antabuse] is supplied in 250- and 500-mg tablets. At least 12 hours must elapse between the patient's last drink and starting treatment. The initial dosage is 500 mg once daily for 1 to 2 weeks. Maintenance dosages range from 125 to 500 mg/day, usually taken as a single dose in the morning. Therapy may last months or even years.

39.3.2.2

Naltrexone

Naltrexone [ReVia, Vivitrol] is a pure opioid antagonist that decreases craving for alcohol and blocks alcohol's reinforcing (pleasurable) effects. Alcoholics report that naltrexone decreases

their “high.” Although the mechanism underlying these effects is uncertain, one possibility is blockade of dopamine release secondary to blockade of opioid receptors. Naltrexone is generally well tolerated. Nausea is the most common adverse effect (10%), followed by headache (7%), anxiety (2%), and sedation (2%). Since naltrexone is an opioid antagonist, the drug will precipitate withdrawal if given to individuals who are opioid dependent. Conversely, if a patient taking naltrexone needs emergency treatment with an opioid analgesic, high doses of the opioid will be required.

Naltrexone was approved for alcoholism on the basis of randomized clinical trials that combined extensive counseling along with the drug. In these trials, naltrexone cut the relapse rate by 50%. Compared with patients taking placebo, those taking naltrexone reported less craving for alcohol, fewer days drinking, fewer drinks per occasion, and reduced severity of alcohol-related problems. In contrast to the original trials, a more recent trial, conducted by the U.S. Department of Veterans Affairs, failed to show any benefit of naltrexone in maintaining abstinence. Why did naltrexone work in the original trials but not in the more recent one? The most likely reason is that the subjects in the two trials were very different: The alcoholic veterans suffered from long-term alcoholism, had little or no social support, and received minimal counseling during the trial, whereas subjects in the earlier studies were younger, had good support systems, and received extensive counseling along with naltrexone. Hence, the new study does not prove that naltrexone doesn't work. Rather, it only proves that naltrexone doesn't work for all drinkers, and doesn't work in the absence of adequate counseling.

Naltrexone is available in two formulations: 50-mg tablets [ReVia] for oral use, and a 380-mg depot formulation [Vivitrol] for IM injection. The oral dosage is 50 mg once a day. The IM dosage is 380 mg once a month. Depot naltrexone is especially good when patient adherence is a concern. As with disulfiram, patients must stop drinking before starting naltrexone.

The basic pharmacology of naltrexone is discussed in [Chapter 28](#).

39.3.2.3 Acamprosate

39.3.2.3.1 Therapeutic Use.

Acamprosate [Campral] is approved for maintaining abstinence in patients with alcohol dependence following detoxification. Benefits derive from reducing unpleasant feelings (eg, tension, dysphoria, anxiety) brought on by abstinence. This effect contrasts with the effects of disulfiram (which makes drinking unpleasant) and naltrexone (which blocks the pleasant feelings that alcohol can cause). Acamprosate should be used only as part of a comprehensive management program that includes psychosocial support.

In clinical trials, acamprosate was moderately effective. Compared with patients taking placebo, those taking acamprosate abstained from their first drink longer, had greater rates of complete abstinence, and were abstinent for more total days. However, in patients who lacked psychosocial support, little or no benefit was seen. Acamprosate is somewhat less effective than naltrexone: Patients taking naltrexone abstain from their first drink longer and accumulate more days of abstinence. Combining acamprosate with naltrexone is more effective than acamprosate alone, but no better than naltrexone alone.

39.3.2.3.2 Mechanism of Action.

Just how acamprosate works is unknown. One theory suggests that acamprosate enhances inhibitory neurotransmission (mediated by GABA) and suppresses excitatory neurotransmission (mediated by glutamate), and thereby restores a balance between these transmitter systems. When given to alcohol-dependent animals, the drug reduces voluntary alcohol intake. Acamprosate is devoid of direct anxiolytic, anticonvulsant, and antidepressant activity, and does not cause alcohol aversion.

39.3.2.3.3 Pharmacokinetics.

Acamprosate is administered orally, and bioavailability is low (11%). Food reduces absorption even further. The drug has a long half-life (20 to 33 hours), and hence about 5 days are required for plasma levels to reach a plateau. Acamprosate does not undergo metabolism, and is excreted unchanged in the urine.

39.3.2.3.4 Adverse Effects and Drug Interactions.

Acamprosate is generally well tolerated. With most adverse effects, the incidence is no greater than with placebo. The principal exception is diarrhea, which occurs in 17% of acamprosate users compared with 10% of those taking placebo. Reports of suicide-related events (suicidal ideation, suicide attempts, completed suicide) are rare, but more common than with placebo. Acamprosate can cause fetal malformations in animals (at doses close to those used by humans). Accordingly, it would seem prudent to avoid this drug during pregnancy, especially since alternatives are available. Acamprosate has no potential for dependence or abuse, and appears devoid of significant drug interactions.

39.3.2.3.5 Preparations, Dosage, and Administration.

Acamprosate [Campral] is available in 333-mg delayed-release tablets. The recommended dosage is 2 tablets (666 mg) 3 times a day, taken with meals. (The reason for administration with meals is to promote compliance—not to influence absorption or GI effects.) Dosing

should start immediately after detoxification is over, and should continue even if relapse occurs. For patients with *mild* renal impairment, the recommended initial dosage is 333 mg 3 times a day. If the patient has *severe* renal impairment, acamprosate should not be used.

418

39.3.2.4 Topiramate

419

Preliminary evidence suggests that topiramate [Topamax], a drug currently approved for epilepsy and migraine, can reduce craving for alcohol, and hence may reduce alcohol consumption in problem drinkers. In a double-blind, placebo-controlled study, subjects taking topiramate had fewer drinks per day (compared with subjects taking placebo), a lower percentage of drinking days, and a higher percentage of days with no drinking. Benefits took about 6 weeks to develop. As with acamprosate, benefits are believed to result from reducing neuronal excitation by glutamate and boosting neuronal inhibition by GABA. In addition, topiramate may normalize the activity of calcium channels, which can be disrupted by chronic alcohol exposure. To minimize adverse effects (tingling or numbness, altered taste, anorexia, difficulty concentrating, memory problems), dosages should be low initially (25 mg daily at bedtime) and then gradually increased (by 25 to 50 mg daily each week) to a target dose of 200 mg/day. Compared with other drugs for maintaining abstinence, topiramate has one distinct advantage: Patients can start topiramate without first giving up drinking for several days. Despite its use in epilepsy, topiramate should not be given to manage convulsions triggered by alcohol withdrawal. The basic pharmacology of topiramate is discussed in [Chapter 24](#).

39.3.2.5 Ondansetron

Ondansetron [Zofran], a selective 5-HT₃ receptor antagonist, is under investigation as an aid for maintaining sobriety. The drug was originally developed to suppress nausea and vomiting caused by anticancer drugs (see [Chapter 79](#)). Why give ondansetron to alcoholics? Because, by blocking 5-HT₃ receptors, the drug could, in theory, prevent alcohol from activating the brain's reward system, and hence could decrease motivation for drinking. In a preliminary trial, ondansetron did help suppress alcohol ingestion—but only among certain alcoholics: The drug reduced drinking by people with *early-onset* alcoholism (alcoholism that began before age 25) but had no effect on people with *late-onset* alcoholism (alcoholism that began after age 25). Among those with early-onset alcoholism, ondansetron increased the proportion of days spent without drinking (by 40% compared with placebo) and decreased the number of drinks consumed on drinking days (by 39% compared with placebo). The most effective dosage was 4 mg/kg twice a day. These results are important in that they suggest that dysfunction of serotonergic transmission is different in early-onset alcoholism compared with late-onset alcoholism. This implies that, for treatment to be most effective, it should be tailored to the patient's clinical subtype: early-onset alcoholism or late-onset alcoholism.

39.3.3 Nutritional Support, Fluid Replacement, and Antibiotics

Malnutrition is a common problem in the chronic alcoholic. The underlying causes are poor diet and malabsorption of nutrients and vitamins. Malabsorption results from alcohol-induced damage to the GI mucosa. Poor diet occurs in part because alcoholics meet up to 50% of their caloric needs with alcohol, and therefore consume subnormal amounts of foods with high nutritional value. Because of their poor nutritional state, alcoholics are in need of fat, protein, and vitamins. The B vitamins (thiamin, folic acid, cyanocobalamin) are especially needed. To correct nutritional deficiencies, a program of dietary modification and vitamin supplements should be implemented.

Alcoholics frequently require fluid replacement therapy and antibiotics. Fluids are needed to replace fluids lost because of gastritis, or because of vomiting associated with withdrawal. Antibiotics may be needed to manage pneumonitis, a common complication of alcoholism.

39.3.3.1

KEY POINTS

- Alcohol is generally beneficial when consumed in moderation and always detrimental when consumed in excess.
- As blood levels of alcohol rise, CNS depression progresses from cortical areas to more primitive brain areas (eg, medulla).
- Long-term, excessive drinking reduces the size of the cerebrum.
- Alcohol produces a dose-dependent increase in blood pressure.
- Moderate drinking is defined as 2 drinks per day or less for men, and 1 drink per day or less for women.
- Moderate drinking significantly reduces the risk of CAD, MI, ischemic stroke, and heart failure—primarily by raising HDL cholesterol, and partly by suppressing platelet aggregation, enhancing fibrinolysis, and suppressing the inflammatory component of atherosclerosis.
- Excessive drinking causes direct damage to the myocardium.
- Like all other CNS depressants, alcohol depresses respiration.
- Chronic, heavy drinking can cause hepatitis and cirrhosis. People with liver disease should avoid alcohol.
- Heavy drinking can cause erosive gastritis.

- Alcohol is a diuretic.
- Alcohol increases the risk of breast cancer and colorectal cancer.
- Excessive drinkers die younger than the population at large.
- Because of the cardioprotective effects of alcohol, moderate drinkers live longer than those who abstain.
- Alcohol dehydrogenase is the rate-limiting enzyme in alcohol metabolism.
- Alcohol is metabolized at a constant rate, regardless of how high blood levels rise. In contrast, the rate of metabolism of most drugs increases as their blood levels rise.
- Most people can metabolize about 1 drink per hour—be it beer, wine, straight whiskey, or a cocktail. Consuming more than 1 drink per hour causes alcohol to accumulate.
- Chronic drinking produces tolerance to many of alcohol's effects—but not to respiratory depression.
- Tolerance to alcohol confers cross-tolerance to general anesthetics, barbiturates, and other general CNS depressants—but not to opioids.
- The CNS-depressant effects of alcohol are additive with those of other CNS depressants.
- The combined effects of alcohol and NSAIDs can cause significant gastric bleeding. People with peptic ulcer disease should avoid alcohol.
- The combination of alcohol and acetaminophen can cause fatal hepatic failure.
- Alcohol use during pregnancy can result in FASD (including FAS), stillbirth, and spontaneous abortion. Women who are pregnant or trying to conceive should not drink.
- Benzodiazepines (eg, chlordiazepoxide, diazepam, lorazepam) are drugs of choice for facilitating withdrawal in alcohol-dependent individuals. Benzodiazepines suppress symptoms because of cross-dependence with alcohol.
- Three drugs are approved for maintaining alcohol abstinence: disulfiram, naltrexone, and acamprosate.

- Disulfiram blocks aldehyde dehydrogenase. As a result, if alcohol is consumed, acetaldehyde will accumulate, thereby causing a host of unpleasant and potentially dangerous symptoms.
- Naltrexone blocks opioid receptors, and thereby decreases craving for alcohol and blocks alcohol's reinforcing effects.
- Acamprosate decreases tension, anxiety, and other unpleasant feelings caused by the absence of alcohol. The underlying mechanism is unclear.

419

39.3.3.2

Summary of Major Nursing Implications*

420

39.3.3.2.1

DISULFIRAM

39.3.3.2...

Preadministration Assessment

39.3.3.2...

Therapeutic Goal

Maintaining alcohol abstinence.

39.3.3.2...

Patient Selection

Candidates for therapy must be chosen carefully. Disulfiram must not be given to alcoholics who are likely to attempt drinking while taking this drug.

39.3.3.2...

Identifying High-Risk Patients

Disulfiram is *contraindicated* for patients suspected of being incapable of abstinence from alcohol; for patients with myocardial disease, coronary occlusion, or psychosis; and for patients who have recently received alcohol, metronidazole, or alcohol-containing medications (eg, cough syrups, tonics).

39.3.3.2...

Implementation: Administration

39.3.3.2...

Route

Oral.

39.3.3.2...

Administration

Instruct the patient not to administer the first dose until at least 12 hours after his or her last drink.

Dosing is done once daily and may continue for months or even years.

Inform patients that tablets may be crushed or mixed with liquid.

39.3.3.2...

Implementation: Measures to Enhance Therapeutic Effects

Patient education is essential for safety. **Inform patients about the potential hazards of treatment, and warn them to avoid all forms of alcohol, including alcohol in vinegar, sauces, and cough syrups, and alcohol applied to the skin in aftershave lotions, colognes, and liniments. Inform patients that the effects of disulfiram will persist about 2 weeks after the last dose and that alcohol must not be consumed during this time. Encourage patients to carry identification to alert emergency healthcare personnel to their condition.**

* Patient education information is highlighted as **blue text**.

⁴⁰CHAPTER 39 Drug Abuse III: Major Drugs of Abuse (Other Than Alcohol)

In this chapter, we discuss all of the major drugs of abuse except alcohol, which is discussed in [Chapter 38](#). As indicated in [Table 39-1](#), abused drugs fall into seven major categories: (1) opioids, (2) psychostimulants, (3) depressants, (4) psychedelics, (5) dissociative drugs, (6) anabolic steroids, and (7) miscellaneous drugs of abuse. The basic pharmacology of many of these drugs is presented in previous chapters, and hence their discussion here is brief. Agents that have not been addressed previously (eg, marijuana, *d*-lysergic acid diethylamide [LSD], nicotine) are discussed in depth. Structural formulas of representative controlled substances are shown in [Figure 39-1](#). Street names for abused drugs are given in [Table 39-2](#).

^{40.1} HEROIN AND OTHER OPIOIDS

The opioids (eg, heroin, oxycodone, morphine) are major drugs of abuse. As a result, most opioids are classified as Schedule II substances. The basic pharmacology of the opioids is discussed in [Chapter 28](#).

TABLE 39-1 Pharmacologic Categorization of Abused Drugs

Category	Examples
Opioids	Heroin
	Morphine
	Meperidine
	Hydromorphone
Psychostimulants	Cocaine
	Dextroamphetamine
	Methamphetamine
	Methylphenidate
Depressants	
Barbiturates	Amobarbital
	Secobarbital
	Pentobarbital
	Phenobarbital
Benzodiazepines	Diazepam
	Flunitrazepam
	Lorazepam
Miscellaneous	Alcohol
	Methaqualone
	Gamma-hydroxybutyrate
	Meprobamate
Psychedelics	LSD
	Mescaline
	Psilocybin
	Dimethyltryptamine
Dissociative Drugs	Phencyclidine
	Ketamine
Anabolic Steroids	Nandrolone
	Oxandrolone
	Testosterone

Miscellaneous	Dextromethorphan
	Marijuana
	Nicotine
	Nitrous oxide
	Amyl nitrite

40.1.1 Patterns of Use

In the United States, an estimated 3.7 million people have used heroin at some time in their lives. Of these, between 750,000 and 1 million are considered hard-core users. Use is greatest among persons 18 to 25 years old. In addition to people who abuse heroin, millions more abuse prescription opioids.

Opioid abuse is encountered in all segments of American society. Formerly, opioid use was limited almost exclusively to lower socioeconomic groups residing in cities. However, opioids are now used by people outside cities and by people of means.

421

422

Figure 39-1 Structural formulas of representative drugs of abuse.
(LSD = *d*-lysergic acid diethylamide; THC = tetrahydrocannabinol.)

For most abusers, initial exposure to opioids occurs either socially (ie, illicitly) or in the context of pain management in a medical setting. The overwhelming majority of individuals who go on to abuse opioids begin their drug use illicitly. Only an exceedingly small percentage of those exposed to opioids therapeutically develop a pattern of compulsive drug use.

Opioid abuse by healthcare providers deserves special consideration. It is well established that physicians, nurses, and pharmacists, as a group, abuse opioids to a greater extent than all other groups with similar educational backgrounds. The vulnerability of healthcare professionals to opioid abuse is due primarily to drug access.

40.1.2 Subjective and Behavioral Effects

Moments after IV injection, heroin produces a sensation in the lower abdomen similar to sexual orgasm. This initial reaction, known as a “rush” or “kick,” persists for about 45 seconds. After this, the user experiences a prolonged sense of euphoria (well-being); there is a feeling that “all is well with the world.” These extended effects, rather than the initial rush, are the primary reason for opioid abuse.

Interestingly, when individuals first use opioids, nausea and vomiting are prominent, and an overall sense of *dysphoria* may be felt. In many cases, were it not for peer pressure, individuals would not continue opioid use long enough to allow these unpleasant reactions to be replaced by a more agreeable experience.

40.1.3 Preferred Drugs and Routes of Administration

40.1.3.1 Heroin.

Among street users, heroin is the opioid of choice. This agent is easy to procure and is taken by about 90% of opioid abusers. The popularity of heroin is related to its high lipid solubility, which allows the drug to cross the blood-brain barrier with ease, thereby producing effects that are both immediate and intense. This combination of speed and intensity sets heroin apart from other opioids, and makes it such a desirable drug of abuse.

Heroin can be administered in several ways. The order of preference is IV injection, smoking, and nasal inhalation (known as sniffing or snorting). Intravenous injection produces effects with the greatest intensity and most rapid onset (7 to 8 seconds). When heroin is smoked or snorted, effects develop more slowly, reaching a peak in 10 to 15 minutes. Among users who seek addiction treatment, injection is the predominant method of administration. However, because

422

423

sniffing and smoking are safer and easier than injection, these routes are becoming increasingly popular.

TABLE 39-2 Street Names for Abused Drugs

Drug	Street Names
Opioids	
Heroin	H, Harry, horse, junk, smack, skag
Hydromorphone	Juice
Methadone	Dolly
Psychedelics	
<i>d</i> -Lysergic acid diethylamide	LSD, LSD-25, acid, blotter, microdot
Dimethyltryptamine	DMT, businessman's trip
Mescaline	Peyote, cactus buttons
2,5-Dimethoxy-4-methylamphetamine	DOM, STP
Psilocybin	Magic mushrooms
Psilocin	Magic mushrooms
Psychostimulants	
Amphetamine	Bennies, hearts, whites, cartwheels
Dextroamphetamine	Dexies, oranges, footballs
Methamphetamine	Speed, bombita, crank, crystal meth, ice, glass
Methylphenidate	Kiddie dope, R-ball, vitamin R
Biphetamine	Black beauties
Cocaine	Coke, crack, snow, blow, flake, nose candy, toot
General CNS Depressants	
Amobarbital	Blue devils
Flunitrazepam [Rohypnol] ⁺	Forget-me pill, Roche, R2, roofies, rope, rophies
Gamma-hydroxybutyrate (GHB) ⁺	Grievous bodily harm, Georgia homeboy, liquid ecstasy
Pentobarbital	Yellow jackets
Secobarbital	Red devils
Methaqualone	Ludes, sopors
Dissociative Drugs	
Phencyclidine	PCP, angel dust, dummy dust, hog, ozone, peace pill, rocket fuel, sheets, wack
Ketamine	Special K, vitamin K, cat Valium

Miscellaneous Agents

3,4-Methylenedioxymethamphetamine	MDMA, ecstasy, hug, XTC, the love drug
Marijuana	Pot, grass, reefer, weed, Panama red, Acapulco gold, Mary Jane, many others

Combinations

Heroin + cocaine	Speedball
Heroin + crack cocaine	Moon rock
Heroin + marijuana	Atom bomb
Marijuana + phencyclidine	Killer joints, crystal supergrass

* Associated with sexual assault.

It should be noted that, when heroin is administered orally or subcutaneously, as opposed to intravenously, its effects cannot be distinguished from those of morphine and other opioids. This observation is not surprising given that, once in the brain, heroin is rapidly converted into morphine, its active form.

40.1.3.2 Meperidine.

Nurses and physicians who abuse opioids often select meperidine [Demerol], a drug with distinct advantages for these users. First, unlike heroin, meperidine is highly effective when administered orally, and hence abuse need not be associated with telltale signs of repeated injections. Second, meperidine produces less pupillary constriction than other opioids, thereby minimizing awkward questions about miosis. Lastly, meperidine has minimal effects on smooth muscle function; hence, constipation and urinary retention are less problematic than with other opioids.

40.1.3.3 Oxycodone.

In some parts of the United States, people are abusing the *controlled-release* formulation of oxycodone [OxyContin], an opioid similar to morphine. The controlled-release tablets were designed to provide steady levels of oxycodone over an extended time, and are safe and effective when swallowed intact. However, abusers do not ingest the tablets whole. Rather, they crush the tablets, and then either snort the powder, or dissolve it in water and then inject it IV. As a result, the entire dose is absorbed *immediately*, producing blood levels that are dangerously high. Hundreds of deaths have been reported. The risk of respiratory depression and death is greatest in people who have not developed tolerance to opioids.

423

40.1.4 Tolerance and Physical Dependence

40.1.4.1 Tolerance.

With prolonged opioid use, tolerance develops to some pharmacologic effects, but not others. Effects to which tolerance does develop include euphoria, respiratory depression, and nausea. In contrast, little or no tolerance develops to constipation and miosis. Because tolerance to respiratory depression develops in parallel with tolerance to euphoria, respiratory depression does not increase as higher doses are taken to produce desired subjective effects. Persons tolerant to one opioid are cross-tolerant to other opioids. However, there is no cross-tolerance between opioids and general central nervous system (CNS) depressants (eg, barbiturates, benzodiazepines, alcohol).

40.1.4.2 Physical Dependence.

Long-term use produces substantial physical dependence. The abstinence syndrome resulting from opioid withdrawal is described in [Chapter 28](#). It is important to note that, although the opioid withdrawal syndrome can be extremely unpleasant, it is rarely dangerous.

Following the acute abstinence syndrome, which fades in 10 days, opioid addicts may experience a milder but protracted phase of withdrawal. This second phase, which may persist for months, is characterized by insomnia, irritability, and fatigue. Gastrointestinal hyperactivity and premature ejaculation may also occur.

40.1.5 Treatment of Acute Toxicity

Treatment of acute opioid toxicity is discussed at length in [Chapter 28](#) and summarized here. Overdose produces a classic triad of symptoms: *respiratory depression*, *coma*, and *pinpoint pupils*. *Naloxone* [Narcan], an opioid antagonist, is the treatment of choice. This agent rapidly reverses all signs of opioid poisoning. However, dosage must be titrated carefully. Why? Because if too much is given, the addict will swing from a state of intoxication to one of withdrawal. Owing to its short half-life, naloxone must be re-administered every few hours until opioid concentrations have dropped to nontoxic levels, which may take days. Failure to repeat naloxone dosing may result in the death of patients who had earlier been rendered symptom free.

Nalmefene [Revex], a long-acting opioid antagonist, is an alternative to naloxone. Because of its long half-life, nalmefene does not require repeated dosing—an obvious advantage. However, if

the dose is excessive, nalmefene will put opioid-dependent patients into prolonged withdrawal—an obvious disadvantage.

40.1.6 Detoxification

Persons who are physically dependent on opioids experience unpleasant symptoms if drug use is abruptly discontinued. Techniques for minimizing discomfort are presented below.

40.1.6.1 Methadone Substitution.

Methadone, a long-acting oral opioid, is the agent most commonly employed for easing withdrawal. The first step in methadone-aided withdrawal is to substitute methadone for the opioid upon which the addict is dependent. Because opioids display cross-dependence with one another, methadone will prevent an abstinence syndrome. Once the subject has been stabilized on methadone, withdrawal is accomplished by administering methadone in gradually smaller doses. The resultant abstinence syndrome is mild, with symptoms resembling those of moderate influenza. The entire process of methadone substitution and withdrawal takes about 10 days.

When substituting methadone for another opioid, suppression of the abstinence syndrome requires that methadone dosage be closely matched to the existing degree of physical dependence. Hence, to ensure that methadone dosing is adequate, the extent of physical dependence must be assessed. This can be accomplished by taking a history on the extent of drug use and by observing the patient for symptoms of withdrawal. Of the two approaches, observation is the more reliable. Estimates of drug use based on patient histories may be unreliable because (1) street users don't know the purity of the drugs they have taken, (2) claims of drug use may be inflated in hopes of receiving larger doses of methadone, and (3) addicts from the ranks of the healthcare professions may report minimal consumption to downplay the extent of abuse. Because information from addicts is not likely to permit accurate assessment of dependence, it is essential to observe the patient to make certain methadone dosage is sufficient to suppress withdrawal.

Use of methadone for *maintenance therapy* and *suppressive therapy* is discussed separately below.

40.1.6.2 Clonidine-Assisted Withdrawal.

Clonidine is a centrally acting α_2 -adrenergic agonist. When administered to an individual physically dependent on opioids, clonidine can suppress some symptoms of abstinence.

Clonidine is most effective against symptoms related to autonomic hyperactivity (nausea,

vomiting, diarrhea). Modest relief is provided from muscle aches, restlessness, anxiety, and insomnia. Opioid craving is not diminished. The basic pharmacology of clonidine is discussed in [Chapter 19](#).

40.1.6.3 Rapid and Ultrarapid Withdrawal.

In both procedures, the addict is given an opioid *antagonist* (naloxone or naltrexone) to precipitate immediate withdrawal, and thereby accelerate the withdrawal process. The ultrarapid procedure is carried out under general anesthesia or heavy sedation with IV midazolam [Versed]. In both procedures, clonidine may be added to ease symptoms. These procedures permit a rapid switch to maintenance therapy with an opioid antagonist. However, they are no more effective than standard withdrawal techniques, and they are considerably more expensive.

40.1.7 Drugs for Long-Term Management of Opioid Addiction

Three kinds of drugs are employed for long-term management: *opioid agonists*, *opioid agonist-antagonists*, and *opioid antagonists*. Opioid agonists (eg, methadone) substitute for the abused opioid and are given to patients who are not yet ready for detoxification. In contrast, opioid antagonists (eg, naltrexone) are used to discourage renewed opioid use after detoxification has been accomplished. An opioid agonist-antagonist (eg, buprenorphine) can be used both for maintenance therapy and to facilitate detoxification.

40.1.7.1 Methadone.

In addition to its role in facilitating opioid withdrawal, methadone can be used for *maintenance therapy* and *suppressive therapy*. These strategies are employed to modify drug-using behavior in addicts who are not ready to try withdrawal.

Methadone maintenance consists of transferring the addict from the abused opioid to oral methadone. By taking methadone, the addict avoids both withdrawal and the need to procure illegal drugs. Maintenance dosing is done once a day. Maintenance is most effective when done in conjunction with nondrug measures directed at altering patterns of drug use.

Suppressive therapy is done to prevent the reinforcing effects of opioid-induced euphoria. Suppression is achieved by giving the addict progressively larger doses of methadone until a very high dose (120 mg/day) is reached. Building up to this dose creates a high degree of tolerance, and hence no subjective effects are experienced from the methadone itself. Because cross-tolerance exists among opioids, once the patient is tolerant to methadone, taking street

424

425

drugs, even in high doses, cannot produce significant desirable effects. As a result, individuals made tolerant with methadone will be less likely to seek out illicit opioids.

Use of methadone to treat opioid addicts is restricted to agencies approved by the Food and Drug Administration (FDA) and state authorities. These restrictions on the nonanalgesic use of methadone are needed to control methadone abuse, since the drug has about the same abuse liability as morphine and other strong opioids. Since the number of approved clinics is limited, gaining access to one is hard in many parts of the country.

40.1.7.2 Buprenorphine.

Buprenorphine [Subutex, Suboxone], an agonist-antagonist opioid, was approved in 2002 for treating addiction. As discussed in [Chapter 28](#), the drug is a partial agonist at mu receptors and a full antagonist at kappa receptors. Buprenorphine can be used for maintenance therapy and to facilitate detoxification. When used for maintenance, buprenorphine alleviates craving, reduces use of illicit opioids, and increases retention in therapeutic programs. When used for detoxification, it reduces symptoms of withdrawal.

Unlike methadone, which is available only through approved treatment centers, buprenorphine can be prescribed by any physician or nurse practitioner who has (1) received at least 8 hours of authorized training and (2) registered with the Substance Abuse and Mental Health Services Administration. By 2005 more than 4500 prescribers had qualified.

Buprenorphine has several properties that make it attractive for treating addiction. Because it is a partial agonist at mu receptors, it has a low potential for abuse—but can still suppress craving for heroin. If the dosage is sufficiently high, the drug can completely block access of heroin to mu receptors, and can thereby prevent heroin-induced euphoria. With buprenorphine, there is a ceiling to respiratory depression, which makes it safer than methadone. Development of physical dependence is low, and hence withdrawal is relatively mild.

Buprenorphine is available in two *sublingual* formulations, marketed as *Subutex* (buprenorphine alone) and *Suboxone* (buprenorphine combined with naloxone). Subutex is used for the first few days of treatment, and then Suboxone is used for long-term maintenance. What's the purpose of the naloxone in Suboxone? It's there to discourage IV abuse. If taken IV, the naloxone in Suboxone will precipitate withdrawal. However, with sublingual administration, very little naloxone is absorbed, and hence, when the drug is administered as intended, the risk of withdrawal is low. Nonetheless, because there is a small risk with sublingual Suboxone, treatment is initiated with Subutex, thereby allowing substitution of buprenorphine for the abused opioid. Thereafter, Suboxone is taken for maintenance.

40.1.7.3 Naltrexone.

Once a patient has undergone opioid detoxification, an opioid antagonist can be used to discourage renewed opioid abuse. Benefits derive from blocking euphoria and all other opioid-induced effects. By preventing pleasurable effects, opioid antagonists eliminate the reinforcing properties of drug use. When the former addict learns that taking an opioid cannot produce the desired response, drug-using behavior will cease. Of the opioid antagonists available, *naltrexone* is best suited for this application. Why? Because naltrexone can be taken orally and because its long half-life permits alternate-day dosing. Furthermore, an IM depot preparation, currently approved only for alcoholism, would permit dosing just once a month. In contrast, naloxone has low oral efficacy and, because its half-life is very short, would require multiple daily doses. These properties make naloxone impractical.

40.1.8 Sequelae of Compulsive Opioid Use

Surprisingly, chronic opioid use has very few *direct* detrimental effects. Addicts in treatment programs have been maintained on high doses of methadone for a decade with no significant impairment of health. Furthermore, individuals on methadone maintenance can be successful socially and at work. It appears, then, that opioid use is not necessarily associated with poor health, lack of productivity, or inadequate social interaction.

Although opioids have few direct ill effects, there are many *indirect* hazards. These risks stem largely from the lifestyle of the opioid user and from impurities common to street drugs.

Infections secondary to sharing nonsterile needles occur frequently. The infections that opioid abusers acquire include septicemia, subcutaneous ulcers, tuberculosis, hepatitis C, and HIV.

Foreign-body emboli have resulted from impurities in opioid preparations. Opioid users suffer an unusually high death rate. Some deaths reflect the violent nature of the subculture in which opioid use often takes place. Many others result from accidental overdose.

40.2 GENERAL CNS DEPRESSANTS

The family of CNS depressants consists of barbiturates, benzodiazepines, alcohol, and other agents. With the exception of the benzodiazepines, all of these drugs are more alike than different. The benzodiazepines have properties that set them apart. The basic pharmacology of the benzodiazepines, barbiturates, and most other CNS depressants is presented in [Chapter 34](#); the pharmacology of alcohol is presented in [Chapter 38](#). Discussion here is limited to abuse of these drugs. Two CNS depressants notorious for their roles in date rape are discussed in [Box 39-1](#).

40.2.1 Barbiturates

The barbiturates embody all of the properties that typify general CNS depressants, and hence can be considered prototypes of the group. Depressant effects are dose dependent and range from mild sedation to sleep to coma to death. With prolonged use, barbiturates produce tolerance and physical dependence.

The abuse liability of the barbiturates stems from their ability to produce subjective effects similar to those of alcohol. The barbiturates with the highest potential for abuse have a short-to-intermediate duration of action. These agents—amobarbital, pentobarbital, and secobarbital—are classified under Schedule II of the Controlled Substances Act. Other barbiturates appear under Schedules III and IV (see [Table 37-3](#)). Despite legal restrictions, barbiturates are available cheaply and in abundance.

40.2.1.1 Tolerance.

Regular use of barbiturates produces tolerance to some effects, but not to others. Tolerance to subjective effects is significant. As a result, progressively larger doses are needed to produce desired psychologic responses. Unfortunately, very little tolerance develops to respiratory depression. Consequently, as barbiturate use continues, the dose needed to produce subjective effects moves closer and closer to the dose that can cause respiratory arrest. (Note that this differs from the pattern seen with opioids, in which tolerance to subjective effects and to respiratory depression develop in parallel.) Individuals tolerant to barbiturates show cross-tolerance with other CNS depressants (eg, alcohol, benzodiazepines, general anesthetics). However, little or no cross-tolerance develops to opioids.

425

427

40.2.1.1.1 BOX 39-1 Special Interest Topic

40.2.1.1.1.1 DATE-RAPE DRUGS: ROHYPNOL AND GHB

Over the past decade, two drugs—Rohypnol and gammahydroxybutyrate (GHB)—have gained notoriety over their use to facilitate rape. Both agents are powerful sedative-hypnotics. Use of either drug to commit sexual assault is a federal crime, punishable under the *Drug-Induced Rape Prevention and Punishment Act*. Street names for Rohypnol include roofies, Roche, rope, rophies, R2, forget-me pill, and Mexican Valium. Street names for GHB include Georgia homeboy, grievous bodily harm, and liquid ecstasy.

40.2.1.1.1....

Rohypnol

Rohypnol is the trade name for flunitrazepam, a potent benzodiazepine. Like diazepam [Valium] and other benzodiazepines, Rohypnol causes sedation, psychomotor slowing, muscle relaxation, and retrograde amnesia. When used to facilitate sexual assault, the drug is slipped into the victim's drink. The combination of alcohol and flunitrazepam produces a vulnerable state characterized by suggestibility, impaired judgment, loss of inhibition, extreme sleepiness, weakness, and inability to remember what happened after the drugs took effect; most victims eventually lose consciousness. Because an intoxicated person is considered legally incapable of consent, performing sex with such a person is considered an aggressive criminal act, and can be prosecuted as felony sexual assault. Unfortunately, because of Rohypnol-induced amnesia, the victim is often unsure that rape actually took place, and certainly can't attest to details. As a result, prosecution is difficult. Two precautions can reduce the risk of being secretly drugged: In public settings (parties, night-clubs, etc.), never leave a drink unattended and never accept a drink from a person you don't know and trust.

Facilitation of rape is neither the only nor the principal reason for Rohypnol abuse. Most people take it just to get high. As a rule, the drug is combined with another abused substance, typically alcohol or heroin. Because Rohypnol is relatively cheap (about \$5 a dose), it is especially popular among high school and college students. In the United States, abuse of Rohypnol is most common in the East and Southwest.

Rohypnol, manufactured by Hoffmann LaRoche, is available for medical use in several countries, but not the United States. In Europe, Rohypnol is widely prescribed for relieving insomnia. Effects begin within 30 minutes, peak in 2 hours, and persist for 8 hours. The principal difference between Rohypnol and other benzodiazepines is that Rohypnol is very potent—about 10 times more potent than diazepam. Hence, a small dose has a big effect. One source claims that taking 2 mg of Rohypnol is like drinking an entire six-pack of beer.

To make secretive use of Rohypnol more difficult, Hoffmann LaRoche has reformulated the pill. The new formulation dissolves more slowly than the old one and contains a dye that turns pale drinks bright blue and makes dark drinks murky. In addition, the pill contains insoluble particles that will float on top of all drinks. However, since flunitrazepam is also made in clandestine laboratories, not all formulations will produce these conspicuous effects.

Because of its abuse potential, the legal status of flunitrazepam has changed. Initially, this drug, like all other benzodiazepines, was classified under Schedule IV. In 1995, the World Health Organization reclassified it under Schedule III. In the United States, importation of flunitrazepam has been banned, and the Drug Enforcement Agency is considering placing it in Schedule I.

In 1996, Congress passed the *Drug-Induced Rape Prevention and Punishment Act*. The law imposes a maximum prison term of 20 years for importing and distributing 1 gm or more of flunitrazepam. The act also stiffens the penalty for administering a controlled substance without consent and with the intent of committing rape or any other violent crime.

40.2.1.1.1....

GHB

Gamma-hydroxybutyrate, or GHB, has two notable actions: it depresses CNS function and, by causing release of growth hormone, it promotes muscle growth. During the 1990s, GHB gained popularity as a drug of abuse, primarily among adolescents and young adults. The drug is taken in social settings (parties, raves, clubs, etc.) to produce relaxation, euphoria, and disinhibition. It is taken by athletes to increase strength. And it is administered clandestinely to facilitate sexual assault. When used for assault, GHB is much like Rohypnol. The perpetrator simply slips a few drops of the colorless, odorless, tasteless liquid into the intended victim's drink; within 20 minutes, the GHB produces incoordination, confusion, and deep sedation, along with amnesia about what has taken place.

The pharmacology of GHB is similar to that of other CNS depressants. This is no surprise given that GHB is a metabolite of gamma-aminobutyric acid, the major inhibitory transmitter in the brain. When taken in moderate doses, GHB produces sedation, relaxation, and mild euphoria. Overdose produces significant respiratory depression, which is made worse by concurrent use of alcohol. Seizures may occur, especially with combined use of methamphetamine. Overdose can also cause nausea, vomiting, bradycardia, hypothermia, agitation, delirium, unconsciousness, and coma. GHB has been linked to more than 60 deaths and thousands of emergency department admissions.

Repeated use of GHB appears to cause tolerance and physical dependence. Tolerance is indicated by the need for bigger and bigger doses to produce relaxation and euphoria.

Physical dependence is indicated by signs of withdrawal—agitation, delirium, tachycardia, insomnia, anxiety, tremors, sweating—when regular use stops.

GHB has only one approved use: reduction of cataplexy in patients with narcolepsy (see [Chapter 106](#)). The drug is regulated as a Schedule III substance.

A precursor of GHB, known as *1,4-butanediol*, undergoes conversion to GHB in the body, and hence has effects identical to those of GHB itself. Butanediol is used as an industrial solvent, and is also available as a “dietary supplement.” The supplements are claimed to enhance muscle growth, fight aging, increase sexual desire, promote relaxation, and elevate mood. Trade names for the supplements include Thunder Nectar, Inner G, and Zen.

40.2.1.2 Physical Dependence and Withdrawal Techniques.

Chronic barbiturate use can produce substantial physical dependence. Cross-dependence exists between barbiturates and other CNS depressants but not with opioids. When physical dependence is great, the associated abstinence syndrome can be severe—sometimes fatal (see [Chapter 34](#)). In contrast, the opioid abstinence syndrome, although unpleasant, is rarely life threatening.

One technique for easing barbiturate withdrawal employs phenobarbital, a barbiturate with a long half-life. Because of cross-dependence, substitution of phenobarbital for the abused barbiturate suppresses symptoms of abstinence. Once the patient has been stabilized, the dosage of phenobarbital is gradually tapered off, thereby minimizing symptoms of abstinence.

40.2.1.3 Acute Toxicity.

Overdose with barbiturates produces a triad of symptoms: *respiratory depression*, *coma*, and *pinpoint pupils*—the same symptoms that accompany opioid poisoning. Treatment is directed at maintaining respiration and removing the drug; endotracheal intubation and ventilatory assistance may be required. Details of management are presented in [Chapter 34](#). Barbiturate overdose has no specific antidote; naloxone, which reverses poisoning by opioids, is not effective against poisoning by barbiturates.

40.2.2 Benzodiazepines

Benzodiazepines differ significantly from barbiturates. Benzodiazepines are much safer than the barbiturates, and overdose with *oral* benzodiazepines *alone* is rarely lethal. However, the risk of

death is greatly increased when oral benzodiazepines are combined with other CNS depressants (eg, alcohol, barbiturates) or when benzodiazepines are administered IV. If severe overdose occurs, signs and symptoms can be reversed with *flumazenil*, a benzodiazepine antagonist. As a rule, tolerance and physical dependence are only moderate when benzodiazepines are taken for legitimate indications, but can be substantial when these drugs are abused. In patients who develop physical dependence, the abstinence syndrome can be minimized by withdrawing benzodiazepines very slowly—over a period of months. The abuse liability of the benzodiazepines is much lower than that of the barbiturates. As a result, all benzodiazepines are classified under Drug Enforcement Agency (DEA) Schedule IV. Benzodiazepines are discussed at length in [Chapter 34](#).

40.2.3 Alcohol and Miscellaneous CNS Depressants

Alcohol, alcohol abuse, and alcoholism treatment are discussed in [Chapter 38](#).

In addition to barbiturates, benzodiazepines, and alcohol, other CNS depressants (eg, paraldehyde, meprobamate, chloral hydrate) are subject to abuse. The pharmacology of these drugs is similar to that of the barbiturates.

Methaqualone is unique among the CNS depressants and requires comment. At one time, methaqualone [Quaalude] was available legally for sedation. However, because of its high abuse potential and the availability of superior alternatives (ie, benzodiazepines), methaqualone was withdrawn from the market. The drug differs from other depressants in that overdose is not characterized by obvious signs of CNS depression. Rather, poisoning can produce restlessness, hypertonia, and convulsions.

40.3 PSYCHOSTIMULANTS

Discussion here focuses on CNS stimulants that have a high potential for abuse: amphetamines, cocaine, and related substances. Because of their considerable abuse liability, these drugs are classified as Schedule II agents. (If they lacked approved medical uses, they would be classified in Schedule I.) In addition to stimulating the CNS, the amphetamines and cocaine can stimulate the heart, blood vessels, and other structures under sympathetic control. Because of these peripheral actions, these agents are also referred to as *sympathomimetics*.

Stimulants with little or no abuse potential are not addressed in this chapter. Included in this group are Schedule III stimulants (eg, benzphetamine), Schedule IV stimulants (eg, diethylpropion), and stimulants that are not regulated at all (eg, caffeine, ephedrine).

40.3.1 Cocaine

Cocaine is a stimulant extracted from the leaves of the coca plant. The drug has CNS effects similar to those of the amphetamines. In addition, cocaine can produce local anesthesia (see [Chapter 26](#)) as well as vasoconstriction and cardiac stimulation. Among abusers, a form of cocaine known as “crack” is used widely. Crack is extremely addictive, and the risk of lethal overdose is high.

According to the National Survey on Drug Use and Health (NSDUH), 5.5 million Americans reported using cocaine in 2005, and 1.4 million reported using crack. The number of new users in 2005 was 872,000, most of them over the age of 18.

40.3.1.1 Forms.

Cocaine is available in two forms: *cocaine hydrochloride* and *cocaine base* (alkaloidal cocaine, freebase cocaine, “crack”). Cocaine base is heat stable, whereas cocaine hydrochloride is not. Cocaine hydrochloride is available as a white powder that is frequently diluted (“cut”) before sale. Cocaine base is sold in the form of crystals (“rocks”) that consist of nearly pure cocaine. Cocaine base is widely known by the street name “crack,” a term inspired by the sound the crystals make when heated.

40.3.1.2 Routes of Administration.

Cocaine hydrochloride is usually administered *intranasally*. The drug is “snorted” and absorbed across the nasal mucosa into the bloodstream. A few users (about 5%) administer cocaine hydrochloride IV. Cocaine hydrochloride cannot be smoked because it is unstable at high temperature.

Cocaine base is administered by *smoking*, a process referred to as “freebasing.” Smoking delivers large amounts of cocaine to the lungs, where absorption is very rapid. Subjective and physiologic effects are equivalent to those elicited by IV injection.

427

40.3.1.3 Subjective Effects and Addiction.

428

At usual doses, cocaine produces euphoria similar to that produced by amphetamines. In a laboratory setting, individuals familiar with the effects of cocaine are unable to distinguish between cocaine and amphetamine. How does cocaine cause euphoria? The drug inhibits neuronal reuptake of dopamine, and thereby increases activation of dopamine receptors in the brain's reward circuit.

As with many other psychoactive drugs, the intensity of subjective responses depends on the rate at which plasma drug levels rise. Since cocaine levels rise relatively slowly with intranasal administration, and almost instantaneously with IV injection or smoking, responses produced by intranasal cocaine are much less intense than those produced by the other two routes.

When crack cocaine is smoked, desirable subjective effects begin to fade within minutes and are often replaced by dysphoria. In an attempt to avoid dysphoria and regain euphoria, the user may administer repeated doses at short intervals. This usage pattern—termed *binging*—can rapidly lead to addiction.

40.3.1.4 Acute Toxicity: Symptoms and Treatment.

Overdose is frequent, and deaths have occurred. Mild overdose produces agitation, dizziness, tremor, and blurred vision. Severe overdose can produce hyperpyrexia, convulsions, ventricular dysrhythmias, and hemorrhagic stroke. Angina pectoris and myocardial infarction may develop secondary to coronary artery spasm. Psychologic manifestations of overdose include severe anxiety, paranoid ideation, and hallucinations (visual, auditory, or tactile). Because cocaine has a short half-life, symptoms subside in 1 to 2 hours.

Although there is no specific antidote to cocaine toxicity, most symptoms can be controlled with drugs. Intravenous *diazepam* or *lorazepam* can reduce anxiety and suppress seizures. *Diazepam* may also alleviate hypertension and dysrhythmias, since these result from increased central sympathetic activity. If hypertension is severe, it can be corrected with intravenous *nitroprusside* or *phentolamine*. Dysrhythmias associated with prolonging the QT interval may respond to *hypertonic sodium bicarbonate*. Although beta blockers can suppress dysrhythmias, they can further compromise coronary perfusion (by preventing beta₂-mediated coronary vasodilation). Reduction of thrombus formation with aspirin can lower the risk of myocardial ischemia. Hyperthermia should be reduced with external cooling.

40.3.1.5 Chronic Toxicity.

When administered intranasally on a long-term basis, cocaine can cause atrophy of the nasal mucosa and loss of sense of smell. In extreme cases, necrosis and perforation of the nasal septum have occurred. Nasal pathology results from local ischemia secondary to chronic vasoconstriction. Injury to the lungs can occur from smoking cocaine base.

40.3.1.6 Use During Pregnancy.

Cocaine is highly lipid soluble and readily crosses the placenta, allowing it to accumulate in the fetal circulation. However, according to a report in *JAMA* (March 28, 2001, pages 1613–1625), fetal injury from cocaine is minimal—and, in all likelihood, considerably less than injury caused by tobacco or alcohol. Specifically, the *JAMA* report noted that there is no solid proof that *in utero* exposure to cocaine diminishes growth, affects developmental scores during the first 6 years, produces any lasting effect on motor development, or causes significant alterations in responses to behavioral stimuli. In short, available data fail to show that prenatal cocaine exposure has *major* adverse developmental effects.

40.3.1.7 Tolerance, Dependence, and Withdrawal.

In animal models, regular administration of cocaine results in *increased* sensitivity to the drug, not tolerance. Whether this holds true for humans is not clear.

The degree of physical dependence produced by cocaine is in dispute. Some observers report little or no evidence of withdrawal following cocaine discontinuation. In contrast, others report symptoms similar to those associated with amphetamines: dysphoria, craving, fatigue, depression, and prolonged sleep.

40.3.1.8 Treatment of Cocaine Addiction.

Although achieving complete abstinence from cocaine is extremely difficult, treatment *can* greatly reduce cocaine use. For the cocaine addict, psychosocial therapy is the cornerstone of treatment. This therapy is directed at motivating users to commit to a drug-free life, and then helping them work toward that goal. A combination of individual therapy and group drug counseling is most effective, producing a 70% reduction in cocaine use at 12-month follow-up.

Can medication help with cocaine addiction? To date, no drug has been proved broadly effective in treating cocaine abuse. However, ongoing work with two agents—a *cocaine vaccine* and *disulfiram* [Antabuse]—is encouraging. Subjects receiving the vaccine develop antibodies that bind cocaine, and thereby render it inactive. The higher the antibody titer, the greater the reduction in cocaine use. In one study with disulfiram, subjects receiving a combination of disulfiram plus cognitive behavioral therapy reduced their cocaine use from 2 or 3 times daily to 0.5 times daily. Disulfiram is the same drug we discussed in [Chapter 38](#) for treating alcohol abuse.

40.3.2 Amphetamines

The basic pharmacology of the amphetamines is discussed in [Chapter 36](#). Discussion here is limited to amphetamine abuse.

40.3.2.1 Forms and Routes.

The amphetamine family includes dextroamphetamine, methamphetamine, lisdexamfetamine, and amphetamine (a racemic mixture of dextroamphetamine and levamphetamine). When taken for purposes of abuse, amphetamines are usually administered orally or IV. In addition, a form of dextroamphetamine known as “ice” or “crystal meth” can be smoked, snorted, or inserted in the rectum. Abuse of methamphetamine is a growing problem in the United States.

40.3.2.2 Subjective and Behavioral Effects.

Amphetamines produce arousal and elevation of mood. Euphoria is likely and talkativeness is prominent. A sense of increased physical strength and mental capacity occurs. Self-confidence rises. The amphetamine user feels little or no need for food and sleep. Orgasm is delayed, intensified, and more pleasurable.

40.3.2.3 Adverse CNS Effects.

Amphetamines can produce a psychotic state characterized by hallucinations and paranoid ideation, and hence presents much like schizophrenia. Although psychosis can be triggered by a single dose, it occurs more commonly in the context of long-term abuse. Amphetamine-induced psychosis usually resolves spontaneously following drug withdrawal. If needed, an antipsychotic agent (eg, haloperidol) can be given to suppress symptoms.

40.3.2.4 Adverse Cardiovascular Effects.

Because of their sympathomimetic actions, amphetamines can cause vasoconstriction and excessive stimulation of the heart. These actions can lead to hypertension, angina pectoris, and dysrhythmias. Overdose may also cause cerebral and systemic vasculitis and renal failure.

428

429

Changes in cerebral blood vessels can lead to stroke. Vasoconstriction can be relieved with an alpha-adrenergic blocker (eg, phentolamine). Cardiac stimulation can be reduced with a beta blocker (eg, labetalol). Drug elimination can be accelerated by giving ammonium chloride to acidify the urine.

40.3.2.5 Tolerance, Dependence, and Withdrawal.

Prolonged amphetamine use results in tolerance to mood elevation, appetite suppression, and cardiovascular effects. Although physical dependence is only moderate, psychologic dependence can be intense. Amphetamine withdrawal can produce dysphoria and a strong sense of craving. Other symptoms include fatigue, prolonged sleep, excessive eating, and depression. Depression can persist for months and is a common reason for resuming amphetamine use.

40.4 MARIJUANA AND RELATED PREPARATIONS

Marijuana is the most commonly used illicit drug in the United States. Over 95 million Americans have tried it at least once. In 2006, 14.8 million Americans age 12 and older used marijuana at least once in the month prior to being surveyed. Among young adults 18 to 25 years old, 54% used marijuana at least once in 2002, compared with only 5.1% in 1965.

40.4.1 ***Cannabis sativa***, the Source of Marijuana

Marijuana is prepared from *Cannabis sativa*, the Indian hemp plant—an unusual plant in that it has separate male and female forms. Psychoactive compounds are present in all parts of the male and female plants. However, the greatest concentration of psychoactive substances is found in the flowering tops of the females.

The two most common *Cannabis* derivatives are *marijuana* and *hashish*. Marijuana is a preparation consisting of leaves and flowers of male and female plants. Alternative names for marijuana include *grass*, *weed*, *pot*, and *dope*. The terms *joint* and *reefer* refer to marijuana cigarettes. Hashish is a dried preparation of the resinous exudate from female flowers. Hashish is considerably more potent than marijuana.

40.4.2 Psychoactive Component

The major psychoactive substance in *Cannabis sativa* is *delta-9-tetrahydrocannabinol* (THC), an oily chemical with high lipid solubility. The structure of THC appears in [Figure 39-1](#).

The THC content of *Cannabis* preparations is variable. The highest concentrations are found in the flowers of the female plant. The lowest concentrations are in the seeds. Depending on growing conditions and the strain of the plant, THC in marijuana preparations may range from 1% to 11%.

40.4.3 Mechanism of Action

THC has several possible mechanisms. Perhaps the most important is activation of specific cannabinoid receptors found in various parts of the brain. The endogenous ligand for these receptors appears to be *anandamid*, a derivative of arachidonic acid unique to the brain. Other proposed mechanisms are (1) activation of phospholipase A₂ in the brain, resulting in increased production of prostaglandin E₂, and (2) augmentation of neuronal membrane fluidity through interaction with membrane lipids.

There is evidence that marijuana may act in part through the same reward system as opioids and cocaine. Both heroin and cocaine produce pleasurable sensations by promoting release of dopamine in the brain's reward circuit. In rats, intravenous THC also causes dopamine release. Interestingly, release of dopamine by THC is blocked by naloxone, a drug that blocks the effects of opioids. This suggests that THC causes release of dopamine by first causing release of endogenous opioids.

40.4.4 Pharmacokinetics

40.4.4.1 Administration by Smoking.

When marijuana or hashish is smoked, about 60% of the THC content is absorbed. Absorption from the lungs is rapid. Subjective effects begin in minutes and peak 10 to 20 minutes later. Effects from a single marijuana cigarette may persist 2 to 3 hours. Termination results from metabolism of THC to inactive products.

40.4.4.2 Oral Administration.

When marijuana or hashish is ingested, practically all of the THC undergoes absorption. However, the majority is inactivated on its first pass through the liver. Hence only 6% to 20% of absorbed drug actually reaches the systemic circulation. Because of this extensive first-pass metabolism, oral doses must be 3 to 10 times greater than smoked doses to produce equivalent effects. With oral administration, effects are delayed and prolonged; responses begin 30 to 50 minutes after administration and persist up to 12 hours.

40.4.5 Behavioral and Subjective Effects

Marijuana produces three principal subjective effects: *euphoria*, *sedation*, and *hallucinations*. This set of responses is unique to marijuana; no other psychoactive drug causes all three. Because of this singular pattern of effects, marijuana is in a class by itself.

40.4.5.1 Effects of Low to Moderate Doses.

Responses to low doses of THC are variable and depend on several factors, including dosage size, route of administration, setting of drug use, and expectations and previous experience of the user. The following effects are common: euphoria and relaxation; gaiety and a heightened sense of the humorous; increased sensitivity to visual and auditory stimuli; enhanced sense of touch, taste, and smell; increased appetite and ability to appreciate the flavor of food; and distortion of time perception such that short spans seem much longer than they really are. In addition to these effects, which might be considered pleasurable (or at least innocuous), moderate doses can produce undesirable responses. Among these are impairment of short-term memory; decreased capacity to perform multistep tasks; impairment of driving skills (which can be substantially worsened by concurrent use of alcohol); temporal disintegration (inability to distinguish between past, present, and future); depersonalization (a sense of strangeness about the self); decreased ability to perceive the emotions of others; and reduced interpersonal interaction.

40.4.5.2 High-Dose Effects.

In high doses, marijuana can have serious adverse psychologic effects. The user may experience hallucinations, delusions, and paranoia. Euphoria may be displaced by intense anxiety, and a dissociative state may occur in which the user feels “outside of himself or herself.” In extremely high doses, marijuana can produce a state resembling toxic psychosis, which may persist for weeks. Because of the widespread use of marijuana, psychiatric emergencies caused by the drug are relatively common.

Not all users are equally vulnerable to the adverse psychologic effects of marijuana. Some individuals experience ill effects only at extremely high doses. In contrast, others routinely experience adverse effects at moderate doses. Schizophrenics are at unusually high risk for adverse reactions. In the stabilized schizophrenic, marijuana can precipitate an acute psychotic episode.

429

430

40.4.5.3 Effects of Chronic Use.

Chronic, excessive use of marijuana is associated with a behavioral phenomenon known as an *amotivational syndrome*, characterized by apathy, dullness, poor grooming, reduced interest in achievement, and disinterest in the pursuit of conventional goals. The precise relationship between marijuana and development of the syndrome is not known, nor is it certain what other factors may contribute. Available data do not suggest that the amotivational syndrome is due to organic brain damage.

40.4.6 Physiologic Effects

40.4.6.1 Cardiovascular Effects.

Marijuana produces a dose-related increase in heart rate. Increases of 20 to 50 beats/min are typical. However, rates up to 140 beats/min are not uncommon. Pretreatment with propranolol prevents marijuana-induced tachycardia but does not block the drug's subjective effects. Marijuana causes orthostatic hypotension and pronounced reddening of the conjunctivae. These responses apparently result from vasodilation.

40.4.6.2 Respiratory Effects.

When used *acutely*, marijuana produces *bronchodilation*. However, when smoked chronically, the drug causes airway constriction. In addition, chronic use is closely associated with development of bronchitis, sinusitis, and asthma. Lung cancer is another possible outcome. Animal studies have shown that tar from marijuana smoke is a more potent carcinogen than tar from cigarettes.

40.4.6.3 Effects on Reproduction.

Research in animals has shown multiple effects on reproduction. In males, marijuana decreases spermatogenesis and testosterone levels. In females, the drug reduces levels of follicle-stimulating hormone, luteinizing hormone, and prolactin.

Multiple effects may be seen in babies and children who were exposed to marijuana *in utero*. Some babies present with trembling, altered responses to visual stimuli, and a high-pitched cry. Preschoolers may have a decreased ability to perform tasks that involve memory and sustained attention. Schoolchildren may exhibit deficits in memory, attentiveness, and problem solving.

40.4.6.4 Altered Brain Structure.

Long-term marijuana use is associated with structural changes in the brain. Specifically, the volume of the hippocampus and amygdala is reduced, by an average of 12% and 7.1%, respectively. We don't know if volume reduction is due to reduced cell size, reduced synaptic density, or loss of glial cells and/or neurons. Interestingly, hippocampal volume loss occurred primarily in the left hemisphere.

40.4.7 Tolerance and Dependence

When taken in extremely high doses, marijuana can produce tolerance and physical dependence. Neither effect, however, is remarkable. Some tolerance develops to the cardiovascular, perceptual, and motor effects of marijuana. Little or no tolerance develops to subjective effects.

To demonstrate physical dependence on marijuana, the drug must be given in very high doses—and even then the degree of dependence is only moderate. Symptoms brought on by abrupt discontinuation of high-dose marijuana include irritability, restlessness, nervousness, insomnia, reduced appetite, and weight loss. Tremor, hyperthermia, and chills may occur too. Symptoms subside in 3 to 5 days. With moderate marijuana use, no withdrawal symptoms occur.

40.4.8 Therapeutic Uses

At this time, there are no approved medical uses for marijuana itself. However, there *are* approved uses for purified THC, the major active component of marijuana.

40.4.8.1 Therapeutic Uses for THC.

40.4.8.1.1 Suppression of Emesis.

Intense nausea and vomiting are common side effects of cancer chemotherapy. In certain patients, these responses can be suppressed more effectively with cannabinoids than with traditional antiemetics (eg, prochlorperazine, metoclopramide). At this time, only one cannabinoid—dronabinol (THC)—is available for antiemetic use. Dosage forms and dosages are presented in [Chapter 79](#). Another cannabinoid—nabilone—has been withdrawn from the market.

40.4.8.1.2 Appetite Stimulation.

Dronabinol is approved for stimulating appetite in patients with AIDS. By relieving anorexia, treatment may prevent or reverse loss of weight.

40.4.8.1.3 Neuropathic Pain.

In 2005, Canadian regulators approved *Sativex*—a mouth-spray formulation of THC—for relieving neuropathic pain caused by multiple sclerosis (MS). Because the THC in *Sativex* is absorbed through the oral mucosa, the product has a rapid onset (like smoked marijuana), while being devoid of dangerous tars present in marijuana smoke. *Sativex* is not available in the United States, and cannot be legally imported, owing to classification in DEA Schedule I.

40.4.8.2 Medical Research on Marijuana.

Proponents of making marijuana available by prescription argue that smoked marijuana can reduce chronic pain, suppress nausea caused by chemotherapy, improve appetite in patients with AIDS, lower intraocular pressure in patients with glaucoma, and suppress spasticity associated with MS and spinal cord injury. However, the evidence supporting most of these claims is weak—largely because federal regulations effectively barred marijuana research.

In 1999, two developments opened the doors to marijuana research. First, an expert panel, convened by the National Academy of Sciences' Institute of Medicine, recommended that clinical trials on marijuana proceed. Because smoking marijuana poses a risk of lung cancer and other respiratory disorders, the panel also recommended development of a rapid-onset nonsmoked delivery system. In response to this report and to pressure from scientists and voters, the government created new guidelines that loosened restraints on marijuana research. Under the guidelines, researchers will be allowed to purchase marijuana directly from the federal government. (On behalf of the government, the University of Mississippi maintains a plot of marijuana on 1.8 closely guarded acres.) The only catch is that all proposed research must be approved by the FDA, the National Institute on Drug Abuse, and the DEA. Despite these formidable obstacles, at least one institute—the Center for Medicinal Cannabis Research (CMCR) at the University of California—has begun coordinating and supporting research on medical marijuana. Trials will focus on HIV-related cachexia, neuropathic pain, nausea and vomiting associated with cancer chemotherapy, and muscle spasticity associated with MS and other diseases.

430

40.4.8.3 Legal Status of Medical Marijuana.

Eleven states have passed laws that legalize (or at least decriminalize) medical use of marijuana. However, in 2005, the U.S. Supreme Court ruled that federal DEA legislation trumps these state laws, and hence people who use or provide medical marijuana are still subject to federal prosecution, even in states where medical marijuana has been legalized. In Canada, medical use of marijuana has been legal since 2001. In fact, Canadian patients can purchase the drug directly from the government, at a price 3 to 5 times cheaper than on the street.

40.4.9 Comparison of Marijuana with Alcohol

In several important ways, responses to marijuana and alcohol are quite different. Whereas increased hostility and aggression are common sequelae of alcohol consumption, aggressive behavior is rare among marijuana users. Although loss of judgment and control can occur with either drug, these losses are greater with alcohol. For the marijuana user, increased appetite and food intake are typical. In contrast, heavy drinkers often suffer nutritional deficiencies. Lastly, whereas marijuana can cause toxic psychosis, dissociative phenomena, and paranoia, these severe psychologic reactions rarely occur with alcohol.

40.5 PSYCHEDELICS

The psychedelics are a fascinating drug family for which LSD can be considered the prototype. Other family members include mescaline, dimethyltryptamine (DMT), and psilocin. The psychedelics are so named because of their ability to produce what has been termed a *psychedelic state*. Individuals in this state show an increased awareness of sensory stimuli and are likely to perceive the world around them as beautiful and harmonious; the normally insignificant may assume exceptional meaning, the “self” may seem split into an “observer” and a “doer,” and boundaries between “self” and “nonself” may fade, producing a sense of unity with the cosmos.

Psychedelic drugs are often referred to as *hallucinogens* or *psychotomimetics*. These names reflect an ability to produce hallucinations as well as mental states that resemble psychoses.

Although psychedelics can cause hallucinations and psychotic-like states, these are not their most characteristic effects. The characteristic that truly distinguishes the psychedelics from other agents is their *ability to bring on the same types of alterations in thought, perception, and feeling that otherwise occur only in dreams*. In essence, the psychedelics seem able to activate mechanisms for dreaming without causing unconsciousness.

40.5.1 **d**-Lysergic Acid Diethylamide (LSD)

40.5.1.1 History.

The first person to experience LSD was a Swiss chemist named Albert Hofmann. In 1943, 5 years after LSD was first synthesized, Hofmann accidentally ingested a minute amount of the drug. The result was a dream-like state accompanied by perceptual distortions and vivid hallucinations. The high potency and unusual actions of LSD led to speculation that it might provide a model for studying psychosis. Unfortunately, that speculation did not prove correct: Extensive research has shown that the effects of LSD cannot be equated with idiopathic psychosis. With the realization that LSD did not produce a “model psychosis,” medical interest in the drug declined. Not everyone, however, lost interest; during the 1960s, nonmedical experimentation flourished. This widespread use caused substantial societal concern, and, by 1970, LSD had been classified as a Schedule I substance. Nonetheless, street use of LSD continues.

40.5.1.2 Mechanism of Action.

LSD acts at multiple sites in the brain and spinal cord. However, effects are most prominent in the cerebral cortex and the locus ceruleus. Effects are thought to result from activation of serotonin₂ receptors. This concept has been reinforced by the observation that *ritanserin*, a selective blocker of serotonin₂ receptors, can prevent the effects of LSD in animals.

40.5.1.3 Time Course.

LSD is usually administered orally but can also be injected or smoked. With oral administration, initial effects can be felt in minutes. Over the next few hours, responses become progressively more intense, and then subside 8 to 12 hours later.

40.5.1.4 Subjective and Behavioral Effects.

Responses to LSD can be diverse, complex, and changeable. The drug can alter thinking, feeling, perception, sense of self, and sense of relationship with the environment and other people. LSD-induced experiences may be sublime or terrifying. Just what will be experienced during any particular “trip” cannot be predicted.

Perceptual alterations can be dramatic. Colors may appear iridescent or glowing, kaleidoscopic images may appear, and vivid hallucinations may occur. Sensory experiences may merge so that

colors seem to be heard and sounds seem to be visible. Afterimages may occur, causing current perceptions to overlap with preceding perceptions. The LSD user may feel a sense of wonderment and awe at the beauty of commonplace things.

LSD can have a profound impact on affect. Emotions may range from elation, good humor, and euphoria to sadness, dysphoria, and fear. The intensity of emotion may be overwhelming.

Thoughts may turn inward. Attitudes may be re-evaluated, and old values assigned new priorities. A sense of new and important insight may be felt. However, despite the intensity of these experiences, enduring changes in beliefs, behavior, and personality are rare.

40.5.1.5 Physiologic Effects.

LSD has few physiologic effects. Activation of the sympathetic nervous system can produce tachycardia, elevation of blood pressure, mydriasis, piloerection, and hyperthermia.

Neuromuscular effects (tremor, incoordination, hyperreflexia, and muscular weakness) may also occur.

40.5.1.6 Tolerance and Dependence.

Tolerance to LSD develops rapidly. Substantial tolerance can be seen after just three or four daily doses. Tolerance to subjective and behavioral effects develops to a greater extent than to cardiovascular effects. Cross-tolerance exists with LSD, mescaline, and psilocybin, but not with DMT. Since DMT is similar to LSD, the absence of cross-tolerance is surprising. There is no cross-tolerance with amphetamines or THC. Upon cessation of LSD use, tolerance rapidly fades. Abrupt withdrawal of LSD is not associated with an abstinence syndrome. Hence there is no evidence for physical dependence.

40.5.1.7 Toxicity.

Toxic reactions are primarily psychologic. LSD has never been a direct cause of death, although fatalities have occurred from accidents and suicides.

Acute panic reactions are relatively common and may be associated with a fear of disintegration of the self. Such “bad trips” can usually be managed by a process of “talking down” (providing emotional support and reassurance in a nonthreatening environment). Panic episodes can also be managed with an antianxiety agent, such as diazepam. Neuroleptics (eg, haloperidol, chlorpromazine) may actually intensify the experience, and hence their use is questionable.

431

432

A small percentage of former LSD users experience episodic visual disturbances, referred to as *flashbacks* by users and *hallucinogen persisting perception disorder* (HPPD) by clinicians. These disturbances may manifest as geometric pseudohallucinations, flashes of color, or positive afterimages. Visual disturbances may be precipitated by several factors, including marijuana use, fatigue, stress, and anxiety. Phenothiazines exacerbate these experiences rather than provide relief. HPPD appears to be caused by permanent changes in the visual system.

In addition to panic reactions and visual disturbances, LSD can cause other adverse psychologic effects. Depressive episodes, dissociative reactions, and distortions of body image may occur. When an LSD experience has been intensely terrifying, the user may be left with persistent residual fear. The drug may also cause prolonged psychotic reactions. In contrast to acute effects, which differ substantially from symptoms of schizophrenia, prolonged psychotic reactions mimic schizophrenia faithfully.

40.5.1.8 Potential Therapeutic Uses.

LSD has no recognized therapeutic applications. The drug has been evaluated for possible use in treating alcoholism, opioid addiction, and psychiatric disorders. In addition, LSD has been studied as a possible means of promoting psychologic well-being in patients with terminal cancer. However, for all of these potential uses, LSD proved either ineffective or impractical.

40.5.2 Mescaline, Psilocybin, Psilocin, and Dimethyltryptamine

In addition to LSD, the family of psychedelic drugs includes mescaline, psilocin, psilocybin, dimethyltryptamine (DMT), and several related compounds. Some psychedelics are synthetic and some occur naturally. DMT and LSD represent the synthetic compounds. Mescaline, a constituent of the peyote cactus, and psilocin and psilocybin, constituents of “magic mushrooms,” represent compounds found in nature.

The subjective and behavioral effects of the miscellaneous psychedelic drugs are similar to those of LSD. Like LSD, these drugs can elicit modes of thought, perception, and feeling that are normally restricted to dreams. In addition, they can cause hallucinations and induce mental states that resemble psychosis.

The miscellaneous psychedelics differ from LSD with respect to potency and time course. LSD is the most potent of the psychedelics, producing its full spectrum of effects at doses as low as 0.5 mcg/kg. Psilocin and psilocybin are 100 times less potent than LSD, and mescaline is 4000 times less potent than LSD. Whereas the effects of LSD are prolonged (responses may last 12 or more

hours), the effects of mescaline and DMT are shorter: responses to mescaline usually terminate within 8 to 12 hours, and responses to DMT terminate within 1 to 2 hours.

None of these psychedelics is approved for medical use. The use of psilocybin in patients with terminal cancer and obsessive-compulsive disorder is under investigation.

40.6 DISSOCIATIVE DRUGS

The dissociative drugs—phencyclidine and ketamine—were originally developed as surgical anesthetics. When taken recreationally, these drugs distort perception of sight and sound, and produce feelings of dissociation (detachment) from the environment. High doses can produce sedation, immobility, analgesia, and amnesia.

40.6.1 Phencyclidine

Phencyclidine (“PCP,” “angel dust,” “peace pill”) was originally developed as an anesthetic for animals. The drug was tried briefly as a general anesthetic for humans but was withdrawn owing to severe emergence delirium. Although rejected for therapeutic use, phencyclidine has become widely used as a drug of abuse, largely because it can be synthesized easily by amateur chemists, making it cheap and abundant. The popularity of phencyclidine is disturbing in that the drug causes a high incidence of severe adverse effects, which make phencyclidine one of the most dangerous drugs of abuse.

40.6.1.1 Chemistry and Pharmacokinetics

40.6.1.1.1 Chemistry.

Phencyclidine is a weak organic base with high lipid solubility. The drug is chemically related to ketamine, an unusual general anesthetic (see [Chapter 27](#) and below). The structural formula of phencyclidine appears in [Figure 39-1](#).

40.6.1.1.2 Pharmacokinetics.

Phencyclidine can be administered orally, intranasally, intravenously, and by smoking. For administration by smoking, the drug is usually sprinkled on plant matter (eg, oregano, parsley, tobacco, marijuana). Because of its high lipid solubility, phencyclidine is readily absorbed from all sites.

Once absorbed, phencyclidine undergoes substantial gastroenteric recirculation. Because it is a base, phencyclidine in the blood can be drawn into the acidic environment of the stomach

(by the pH partitioning effect); from the stomach, the drug re-enters the intestine, from which it is reabsorbed into the blood. This cycling from blood to GI tract and back prolongs the drug's sojourn in the body. Elimination occurs eventually through a combination of hepatic metabolism and renal excretion.

40.6.1.2 Mechanism of Action

Phencyclidine acts in the cerebral cortex and limbic system, where it blocks a subset of receptors for glutamate, known as *N*-methyl-D-aspartate (NMDA) receptor complexes. These glutamate receptors are involved in multiple processes, including learning, memory, emotionality, and perception of pain.

40.6.1.3 Subjective and Behavioral Effects

Phencyclidine produces a unique set of effects. Hallucinations are prominent. In addition, the drug can produce CNS depression, CNS excitation, and analgesia.

40.6.1.3.1 Effects of Low to Moderate Doses.

At low doses, phencyclidine produces effects like those of alcohol. Low-dose intoxication is characterized by euphoria, release of inhibitions, and emotional lability. Nystagmus, slurred speech, and motor incoordination may occur too.

As dosage increases, the clinical picture becomes more variable and complex. Symptoms include excitation, disorientation, anxiety, disorganized thoughts, altered body image, and reduced perception of tactile and painful stimuli. Mood may be volatile and hostile. Bizarre behavior may develop. Heart rate and blood pressure are elevated.

432

433

40.6.1.3.2 High-Dose (Toxic) Effects.

High doses can cause severe adverse physiologic and psychologic effects. Death may result from a variety of causes.

Psychologic effects include hallucinations, confusional states, combativeness, and psychosis. The psychosis closely resembles schizophrenia and may persist for weeks. Individuals with pre-existing psychoses are especially vulnerable to psychotogenic effects. Suicide has been attempted.

The physiologic effects of high-dose phencyclidine are varied. Extreme overdose can produce hypertension, coma, seizures, and muscular rigidity associated with severe hyperthermia and rhabdomyolysis.

40.6.1.3.3 Treatment of Toxicity.

Treatment is primarily supportive. Psychotic reactions are best managed by isolation from external stimuli. “Talking down” is not effective, and the benefits of antipsychotic drugs, such as haloperidol, are limited. Physical restraint may be needed to prevent self-inflicted harm and to protect others from assault. If respiration is depressed, mechanical support of ventilation may be needed. Severe hypertension can be managed with diazoxide, a vasodilator. Seizures can be controlled with IV diazepam. If fever is high, external cooling can lower temperature. By promoting muscle relaxation, dantrolene can reduce heat generation and rhabdomyolysis.

Elimination of phencyclidine can be accelerated by continuous gastric lavage and acidification of the urine with ammonium chloride. Continuous lavage is effective because gastroenteric recirculation keeps delivering drug to the stomach. Acidification of urine may promote phencyclidine excretion by reducing tubular reabsorption of this weak base.

40.6.2 Ketamine

Ketamine is a dissociative anesthetic used in animals and humans (see [Chapter 27](#), General Anesthetics). Medicinal ketamine is formulated as an injectable liquid. For recreational use, the liquid is evaporated off, leaving a powder that can be snorted or ingested. Doses typically range from 50 to 200 mg. Much of the ketamine sold on the street was diverted from veterinary offices.

Ketamine is similar to phencyclidine in structure, mechanism, and effects, although its duration of action is shorter. When the drug is snorted, effects begin in 5 to 15 minutes and persist about an hour. Moderate doses produce effects ranging from a dream-like state to a pleasant sensation of floating to a sense of being separated from one's body. Some users experience a state known as the *K-hole*, likened to a near-death experience in which there is a sense of rising above one's body. For some, the K-hole experience is accompanied by a sense of inner peace and radiant light. For others, the K-hole experience is characterized by a terrifying sense of nearly complete sensory detachment. At high doses, ketamine can cause hallucinations, delirium, amnesia, elevation of blood pressure, and potentially fatal disruption of respiration. Even higher doses can produce unconsciousness and fatal cardiovascular collapse.

Because of its depressant and amnesic effects, ketamine has been used to facilitate sexual assault. The drug is colorless, tasteless, and odorless, and hence can be added to a beverage without detection. The use of two other drugs—gamma-hydroxybutyrate (GHB) and Rohypnol—to facilitate sexual assault is discussed in [Box 39-1](#).

^{40.7} DEXTROMETHORPHAN

Dextromethorphan (DXM) is a cough suppressant widely available in over-the-counter cough and cold remedies (see [Chapter 76](#)). At the low doses needed for cough suppression, DXM is devoid of psychologic effects. However, at doses 5 to 10 times higher, DXM can produce euphoria, disorientation, paranoia, and altered sense of time, as well as visual, auditory, and tactile hallucinations. These effects are produced by dextrophan, a metabolite of DXM that blocks receptors for NMDA. Note that this is the same mechanism used by phencyclidine and ketamine. Many of the products that contain DXM also contain other drugs, including acetaminophen, antihistamines, phenylephrine, and pseudoephedrine. Therefore, when excessive doses are taken, users are subject to toxicity from these compounds as well as from DXM itself. The principal users of DXM are adolescents and teenagers. Between 1999 and 2004, reports of DXM abuse in these groups rose 10-fold. Products that contain DXM include Coricidin HBP Cough & Cold, Robitussin, Day Quil Cold, and Theraflu Thin Strips.

^{40.8} 3,4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA, ECSTASY)

MDMA, also known as “ecstasy,” is a complex drug with stimulant and psychedelic properties. The drug is structurally related to methamphetamine (a stimulant) and mescaline (a hallucinogen). Low doses produce mild LSD-like psychedelic effects; higher doses produce amphetamine-like stimulant effects. These effects result from promoting the release of at least three neurotransmitters: serotonin, dopamine, and norepinephrine. Although MDMA can produce effects that are clearly pleasurable, it can also be dangerous; the biggest concerns are neurotoxicity, seizures, hyperthermia and its sequelae, and excessive cardiovascular stimulation. MDMA is classified as a Schedule I drug.

^{40.8.1} Time Course and Dosage.

MDMA is usually administered orally, but may also be snorted, injected, or inserted as a rectal suppository. With oral administration, effects begin in 20 minutes, peak in 2 to 3 hours, and persist 4 to 5 hours. The usual dose is 100 mg or less.

40.8.2 Who Uses MDMA and Why?

MDMA is used primarily by adolescents and young adults, who often take it at nightclubs and all-night dance parties, known as “raves.” The drug is used by young people in cities, in the suburbs, and in the country. According to a survey conducted in 2007, 1.5% of 8th-graders, 3.5% of 10th-graders, and 4.5% of 12th-graders had used MDMA in the past year.

Why do people take MDMA? Because it makes them feel really good. The drug can elevate mood, increase sensory awareness, and heighten sensitivity to music. It can also facilitate interpersonal relationships: Users report a sense of closeness with others, lowering of defenses, reduced anxiety, enhanced communication, and increased sociability.

40.8.3 Adverse Effects.

Unfortunately, MDMA is not free of risks. The drug can injure serotonergic neurons, stimulate the heart, and raise body temperature to a dangerous level. In addition, it can cause neurologic effects (eg, seizures, spasmodic jerking, jaw clenching, teeth grinding) and a host of adverse psychologic effects (eg, confusion, anxiety, paranoia, panic attacks, visual hallucinations, and suicidal thoughts and behavior). Ever year, MDMA is associated with several thousand admissions to emergency departments, mainly because of seizures.

MDMA can damage serotonergic neurons, perhaps irreversibly. When administered to rats and primates in doses only 2 to 4 times greater than those that produce hallucinations in humans, MDMA causes *irreversible destruction of serotonergic neurons*, resulting in passivity and insomnia. At least three lines of evidence suggest that MDMA is also neurotoxic in humans: (1) MDMA causes dose-related impairment of memory, a brain function mediated in part by serotonin. Memory impairment persists long after MDMA was last taken. (2) The cerebrospinal fluid of long-term MDMA users contains abnormally low concentrations of serotonin metabolites, suggesting a loss of serotonergic neurons. (3) Using positron emission tomography to study former MDMA users, researchers demonstrated decreased binding of a ligand selective for the serotonin transporter, indicating damage to serotonergic neurons. In this study, reductions in ligand binding correlated with the extent of MDMA use, and not with the duration of abstinence.

MDMA can cause hyperthermia in association with dehydration, hyponatremia, and rhabdomyolysis (disintegration of muscle tissue). Treatment consists of rapid cooling, rehydration, and administering dantrolene [Dantrium], a drug that relaxes skeletal muscle, thereby reducing heat generation and the risk of rhabdomyolysis. The risk of hyperthermia and

dehydration could be greatly reduced by providing ample fluids at raves and other events where MDMA is likely to be used.

Because of its amphetamine-like actions, MDMA can increase heart rate, blood pressure, and myocardial oxygen consumption. Remarkably, the increases in heart rate and blood pressure equal those produced by maximal doses of dobutamine, a powerful adrenergic agonist (see [Chapter 17](#)). Cardiovascular stimulation poses a special risk to users with heart disease.

40.8.4 Potential Medical Use.

Despite its potential for adverse effects, MDMA also has the potential for therapeutic good, owing largely to its ability to decrease feelings of fear and defensiveness and promote feelings of love, trust, and compassion. In 2004, the FDA approved two small clinical trials of MDMA, one in patients with post-traumatic stress disorder, and the other in patients with severe anxiety related to terminal cancer.

40.9 INHALANTS

The inhalants are a diverse group of drugs that have one characteristic in common: administration by inhalation. These drugs can be divided into three classes: anesthetics, volatile nitrites, and organic solvents.

40.9.1 Anesthetics

Provided that dosage is modest, anesthetics produce subjective effects similar to those of alcohol (euphoria, exhilaration, loss of inhibitions). The anesthetics that have been abused most are *nitrous oxide* (“laughing gas”) and *ether*. One reason for the popularity of these drugs is ease of administration: Both agents can be used without exotic equipment. For nitrous oxide, ready availability also promotes use: Small cylinders of the drug, marketed for aerating whipping cream, can be purchased without restriction.

40.9.2 Volatile Nitrites

Four volatile nitrites—*amyl nitrite*, *butyl nitrite*, *isobutyl nitrite*, and *cyclohexyl nitrite*—are subject to abuse. These drugs are abused by homosexual males because of an ability to relax the anal sphincter, and by males in general because of a reputed ability to prolong and intensify sexual orgasm.

The most pronounced pharmacologic effect of volatile nitrites is *venodilation*, which causes pooling of blood in veins, which in turn causes a profound drop in systolic blood pressure. The

result is dizziness, lightheadedness, palpitations, and possibly pulsatile headache. Effects begin seconds after inhalation and fade rapidly. The primary toxicity is methemoglobinemia, which can be treated with methylene blue and supplemental oxygen.

Nitrites are available from medical and nonmedical sources. Amyl nitrite is used for angina pectoris. Cyclohexyl nitrite is present in room odorizers. Butyl nitrite and isobutyl nitrite are present in products made solely for recreational use. Trade names for butyl nitrite and isobutyl nitrite include Climax, Rush, and Locker Room. On the street, preparations of amyl nitrite are known as “poppers” or “snappers.” These terms reflect the fact that amyl nitrite is packaged in glass ampules that make a popping sound when snapped open to allow inhalation.

40.9.3 Organic Solvents

A wide assortment of solvents have been inhaled to induce intoxication. These compounds include *toluene*, *gasoline*, *lighter fluid*, *paint thinner*, *nail-polish remover*, *benzene*, *acetone*, *chloroform*, and *model-airplane glue*. These agents are used primarily by children and the very poor—people who, because of age or insufficient funds, lack access to more conventional drugs of abuse. In recent years, use of inhalants by young children and teens has been rising.

40.9.3.1 Administration.

Solvents are administered by three processes, referred to as “bagging,” “huffing,” and “sniffing.” Bagging is performed by pouring solvent in a bag and inhaling the vapor. Huffing is performed by pouring the solvent on a rag and inhaling the vapor. Sniffing is performed by inhaling the solvent directly from its container.

40.9.3.2 Acute Pharmacologic Effects.

The acute effects of organic solvents are somewhat like those of alcohol (euphoria, impaired judgment, slurred speech, flushing, CNS depression). In addition, these compounds can cause visual hallucinations and disorientation with respect to time and place. High doses can cause sudden death. Possible causes include anoxia, respiratory depression, vagal stimulation (which slows heart rate), and dysrhythmias.

40.9.3.3 Chronic Toxicity.

Prolonged use is associated with multiple toxicities. For example, chloroform is toxic to the heart, liver, and kidneys; and toluene can cause severe brain damage and bone marrow

depression. Many solvents can damage the heart; fatal dysrhythmias have occurred secondary to drug-induced heart block.

40.9.3.4 Management.

Management of acute toxicity is strictly supportive. The objective is to stabilize vital signs. We have no antidotes for volatile solvents.

434

40... NICOTINE AND SMOKING

435

Cigarette smoking remains the greatest single cause of preventable illness and premature death. In the United States, smoking kills nearly 400,000 adults each year—over 242,000 males and 155,000 females. Around the world, tobacco kills 5 million people each year. On average, male smokers die 13.2 years prematurely, and females die 14.5 years prematurely. As shown in [Table 39-3](#), most deaths result from lung cancer (123,836), heart disease (107,774), and chronic airway obstruction (75,074). Not only do cigarettes kill the people who smoke them, every year they also kill thousands of nonsmokers who inhaled secondhand smoke. The direct medical costs of smoking exceed \$95 billion a year. Indirect costs, including lost time from work and disability, add up to an additional \$97 billion.

Although tobacco smoke contains many dangerous compounds, nicotine is of greatest concern. Other hazardous components in tobacco smoke include carbon monoxide, hydrogen cyanide, ammonia, nitrosamines, and tar. Tar is composed of various polycyclic hydrocarbons, some of which are proven carcinogens.

What is the regulatory status of cigarettes? Good question, given that cigarettes are the single most dangerous product available to U.S. consumers. Until recently, cigarettes had avoided virtually all federal regulation. However, strong regulations are now in place. Under the *Family Smoking Prevention and Tobacco Control Act*, passed in June 2009, the FDA now has the authority to

- Strengthen advertising restrictions, including the prohibition on marketing to youth.
- Require revised and more prominent warning labels.
- Require disclosure of all ingredients in tobacco products and restrict harmful additives.
- Monitor nicotine yields, and mandate gradual nicotine reduction to nonaddictive levels.

40.10.1 Basic Pharmacology of Nicotine

40.10.1.1 Mechanism of Action

The effects of nicotine result from actions at nicotinic receptors. Whether these receptors are activated or inhibited depends on nicotine dosage. *Low* doses *activate* nicotinic receptors; *high* doses *block* them. The amount of nicotine received from cigarettes is relatively low. Accordingly, cigarette smoking causes receptor *activation*.

Nicotine can activate nicotinic receptors at several locations. Most effects result from activating nicotinic receptors in autonomic ganglia and the adrenal medulla. In addition, nicotine can activate nicotinic receptors in the carotid body, aortic arch, and CNS. As discussed below, actions in the CNS mimic those of cocaine and other highly addictive substances. When present at the levels produced by smoking, nicotine has no significant effect on nicotinic receptors of the neuromuscular junction.

40.10.1.2 Pharmacokinetics

Absorption of nicotine depends on whether the delivery system is a cigarette, a cigar, or smokeless tobacco. Nicotine in cigarette smoke is absorbed primarily from the lungs. When cigarette smoke is inhaled, between 90% and 98% of nicotine in the lungs enters the blood. Unlike nicotine in cigarette smoke, nicotine in cigar smoke is absorbed primarily from the mouth, as is nicotine in smokeless tobacco.

TABLE 39-3 Average Annual Smoking-Attributable Mortality (United States, 2000–2004)*

Disease Category	Smoking-Related Deaths	
	Male	Female
Malignant Neoplasms		
Lip, oral cavity, pharynx	3,749	1,144
Esophagus	6,961	1,631
Stomach	1,900	584
Pancreas	3,147	3,536
Larynx	2,446	563
Trachea, lung, bronchus	78,680	46,842
Cervix uteri	0	447
Kidney and renal pelvis	2,827	216
Urinary bladder	3,907	1,076
Acute myeloid leukemia	855	337
<i>Subtotal</i>	104,472	56,376
Cardiovascular Diseases		
Ischemic heart disease	50,884	29,121
Other heart disease	12,944	8,060
Cerebrovascular disease	7,896	8,026
Atherosclerosis	1,282	611
Aortic aneurysm	5,628	2,791
Other circulatory diseases	505	749
<i>Subtotal</i>	79,139	49,358
Respiratory Diseases		
Pneumonia, influenza	6,042	4,381
Bronchitis, emphysema	7,536	6,391
Chronic airway obstruction	40,217	38,771
<i>Subtotal</i>	53,795	49,543
AVERAGE ANNUAL TOTAL	237,406	155,277

Data were obtained online at apps.nccd.cdc.gov/sammeec/—web site of the Centers for Disease Control and Prevention: Smoking-Attributable Mortality, Morbidity, and Economic Costs (SAMMEC).

* Data are for adults ages 35 and older, and do not include deaths caused by burns or secondhand smoke.

Nicotine can cross membranes easily and is widely distributed throughout the body. The drug readily enters breast milk, reaching levels that can be toxic to the nursing infant. Nicotine also crosses the placental barrier and can cause fetal harm. When inhaled in cigarette smoke, nicotine reaches the brain in just 10 seconds.

Nicotine is rapidly metabolized to inactive products. Nicotine and its metabolites are excreted by the kidney. The drug's half-life is 1 to 2 hours.

40.10.1.3 Pharmacologic Effects

The pharmacologic effects discussed in this section are associated with *low* doses of nicotine. These are the effects caused by smoking cigarettes. Responses to *high* doses are discussed under *Acute Poisoning*.

40.10.1.3.1 Cardiovascular Effects.

The cardiovascular effects of nicotine result primarily from activating nicotinic receptors in *sympathetic ganglia* and the *adrenal medulla*. Activation of these receptors promotes release of norepinephrine from sympathetic nerves and release of epinephrine (and some norepinephrine) from the adrenals. Norepinephrine and epinephrine act on the cardiovascular system to constrict blood vessels, accelerate the heart, and increase the force of ventricular contraction. The net result is elevation of blood pressure and increased cardiac work. These effects underlie cardiovascular deaths.

435

436

40.10.1.3.2 GI Effects.

Nicotine influences GI function primarily by activating nicotinic receptors in *parasympathetic ganglia*. The result is increased secretion of gastric acid and increased tone and motility of GI smooth muscle. In addition, nicotine can promote vomiting. Nicotine-induced vomiting results from a complex process that involves nicotinic receptors in the aortic arch, the carotid sinus, and the CNS.

40.10.1.3.3 CNS Effects.

Nicotine is a CNS stimulant. The drug stimulates respiration and produces an arousal pattern on the electroencephalogram. Moderate doses can cause tremors, and high doses can cause convulsions.

Nicotine has multiple psychologic effects. The drug increases alertness, facilitates memory, improves cognition, reduces aggression, and suppresses appetite. In addition, by promoting release of dopamine, nicotine activates the brain's "pleasure system" located in the mesolimbic area. The effects of nicotine on the pleasure system are identical to those of other highly addictive drugs, including cocaine, amphetamines, and opioids.

40.10.1.3.4 Effects During Pregnancy and Lactation.

Exposure to nicotine can harm the fetus. Nicotine in breast milk can harm the nursing infant. Accordingly, therapeutic formulations of nicotine (eg, nicotine chewing gum, nicotine transdermal patches, nicotine nasal spray) are contraindicated during pregnancy, and their use by nursing mothers is not recommended.

40.10.1.4 Tolerance and Dependence

40.10.1.4.1 Tolerance.

Tolerance develops to some effects of nicotine but not to others. Tolerance does develop to nausea and dizziness, which are common in the unseasoned smoker. In contrast, *very little tolerance develops to the cardiovascular actions of nicotine*: Veteran smokers continue to experience increased blood pressure and increased cardiac work whenever they smoke.

40.10.1.4.2 Dependence.

Chronic cigarette smoking results in dependence. By definition, this means that individuals who discontinue smoking will experience an abstinence syndrome. Prominent symptoms are craving, nervousness, restlessness, irritability, impatience, increased hostility, insomnia, impaired concentration, increased appetite, and weight gain. Symptoms begin about 24 hours after smoking has ceased, and can last for weeks to months. Women report more discomfort than men. Experience has shown that abrupt discontinuation may be preferable to gradual reduction. (All that gradual reduction seems to do is prolong suffering.)

40.10.1.5 Acute Poisoning

Nicotine is highly toxic. Doses as low as 40 mg can be fatal. Toxicity is underscored by the use of nicotine as an insecticide. Common causes of nicotine poisoning include ingestion of tobacco by children and exposure to nicotine-containing insecticides.

40.10.1.5.1 Symptoms.

The most prominent symptoms involve the cardiovascular, GI, and central nervous systems. Specific symptoms include nausea, salivation, vomiting, diarrhea, cold sweat, disturbed hearing and vision, confusion, and faintness; pulses may be rapid, weak, and irregular. Death results from respiratory paralysis, which is caused by direct effects of nicotine on the muscles of respiration, as well as by effects in the CNS.

40.10.1.5.2 Treatment.

Management centers on reducing nicotine absorption and supporting respiration; there is no specific antidote to nicotine poisoning. Absorption of ingested nicotine can be reduced by giving activated charcoal. If respiration is depressed, ventilatory assistance should be provided. Since nicotine undergoes rapid metabolic inactivation, recovery from the acute phase of poisoning can occur within hours.

40.10.1.6 Chronic Toxicity from Smoking

According to a 2004 report from the U.S. Surgeon General, the adverse consequences of smoking are more extensive than previously understood. It is now clear that chronic smoking can injure nearly every organ of the body. We already knew that smoking could cause cardiovascular disease, chronic lung disease, and cancers of the larynx, lung, esophagus, oral cavity, and bladder. New additions to the list include leukemia, cataracts, pneumonia, periodontal disease, type 2 diabetes, abdominal aortic aneurysm, and cancers of the cervix, kidney, pancreas, and stomach. Smoking during pregnancy increases the risk of low birth weight, preterm labor, stillbirth, miscarriage, spontaneous abortion, perinatal mortality, and sudden infant death. As shown in [Table 39-3](#), the leading causes of smoking-related death are lung cancer, ischemic heart disease, and chronic airway obstruction.

40.10.2 Pharmacologic Aids to Smoking Cessation

Cigarettes are highly addictive, and hence giving them up is very hard. Nonetheless, abstinence *can* be achieved. Every year, about 41% of Americans who smoke make one or more attempts to

quit. Of those who try to quit *without formal help*, only 3% to 5% achieve long-term success. In contrast, when a combination of counseling and drugs is employed, the 1-year abstinence rate approaches 30%. However, even with the aid of counseling and drugs, the first attempt usually fails. In fact, most people try quitting 5 to 7 times before they ultimately succeed. As time without a cigarette increases, the chances of relapse get progressively smaller: Of those who quit for a year, only 15% smoke again; and of those who quit for 5 years, only 3% smoke again.

Long-term smokers should be assured that quitting offers important health benefits. Regardless of how long one has smoked, quitting can reduce the risk of developing a tobacco-related disease, slow the progression of an established tobacco-related disease, and increase life expectancy. These benefits apply not only to people who quit while they are young and healthy, but also to people who quit after age 65 and to those with established tobacco-related disease. Data from the Nurses' Health Study indicate that former smokers eventually achieve the same disease-risk status as never smokers, even with respect to lung cancer. The risk of chronic obstructive pulmonary disease or death from a heart attack declines to that of never smokers in 20 years, and the risk of lung cancer reaches that of never smokers in 30 years.

Nine drug products have been shown to aid smoking cessation ([Table 39-4](#)). Of these, seven are specifically approved by the FDA for this use, and are considered first-line treatments. The other two—nortriptyline and clonidine—are considered second-line treatments. Of the seven first-line products, five contain nicotine and two do not. The nicotine-based products—nicotine gum, nicotine lozenge, nicotine patch, nicotine inhaler, and nicotine nasal spray—are employed as nicotine replacement therapy (NRT). The nicotine-free products—sustained-release bupropion (bupropion SR) [Zyban] and varenicline [Chantix]—are taken to decrease nicotine craving and suppress symptoms of withdrawal. The most effective drug therapies for smoking cessation are varenicline alone and the nicotine patch combined with a short-acting nicotine product (ie, nasal spray or gum).

436

437

TABLE 39-4 Pharmacologic Aids for Smoking Cessation

Product	Common Side Effects	Advantages	Disadvantages
FIRST-LINE AGENTS			
Nicotine-Based Products			
Nicotine patch [Nicotrol, Nicoderm CQ]	Transient itching, burning, and redness under the patch; insomnia	Nonprescription; provides a steady level of nicotine; easy to use; unobtrusive	User cannot adjust dose if craving occurs; nicotine released more slowly than in other products
Nicotine gum [Nicorette]	Mouth and throat irritation, aching jaw muscles, dyspepsia	Nonprescription; user controls dose	Unpleasant taste; requires proper chewing technique; cannot eat or drink while chewing the gum; can damage dental work and is difficult for denture wearers to use
Nicotine lozenge [Commit]	Hiccups, dyspepsia, mouth irritation, nausea	Nonprescription; user controls dose; easier to use than nicotine gum	Cannot eat or drink while the lozenge is in the mouth
Nicotine nasal spray [Nicotrol NS]	During 1st week: mouth and throat irritation, rhinitis, sneezing, coughing, teary eyes	User controls dose; fastest nicotine delivery and highest nicotine levels of all nicotine-based products	Prescription required; most irritating nicotine-based product; device visible when used
Nicotine inhaler [Nicotrol Inhaler]	Mouth and throat irritation, cough	User controls dose; mimics hand-to-mouth motion of smoking	Prescription required; slow onset and low nicotine levels; frequent puffing needed; device visible when used
Nicotine-Free Products			
Varenicline [Chantix]	Nausea, sleep disturbances, headaches, abnormal dreams	Easy to use (pill); no nicotine; most effective pharmacologic aid to smoking cessation	Prescription required; does not counter weight gain associated with smoking cessation; may cause neuropsychiatric disturbances, including suicidal thoughts and actions

Pharmacology for Nursing Care, 7th Edition

Bupropion [Zyban]	Insomnia, dry mouth, agitation	Easy to use (pill); no nicotine; promotes weight loss, which may limit cessation-related weight gain; first-choice drug for smokers with depression	Prescription required; carries a small risk of seizures
SECOND-LINE AGENTS			
Nortriptyline* [Aventyl, Pamelor]	Dry mouth, sedation, dizziness	Easy to use (pill); no nicotine	Prescription required; side effects are common; caution required in patients with heart disease
Clonidine* [Catapres]	Dry mouth, sedation, dizziness	Easy to use (pill); no nicotine	Prescription required; side effects limit use

* Not FDA-approved for use as a smoking cessation aid.

At this time, we cannot predict who will respond best to a particular product. Accordingly, selection among the first-line drugs should be based on patient preference, success with a particular product in the past, and side effects. The second-line drugs should be reserved for patients who cannot use the first-line drugs or who failed to quit while using them.

Interventions for smoking cessation can be found in *Treating Tobacco Use and Dependence: 2008 Update*, a clinical practice guideline issued by the U.S. Public Health Service. As stated in the guideline, tobacco dependence is a chronic condition that warrants repeated intervention until long-term abstinence is achieved. This is the same philosophy that guides treatment of dependence on other highly addictive substances, including cocaine and heroin. Tobacco dependence can be treated with two methods: counseling and drugs. Both methods are effective, but the combination of both is more effective than either one alone. Accordingly, the guidelines recommend that all patients who want to quit be offered counseling—either individual, group, or by phone (available in all states by dialing 1-800-QUITNOW)—along with at least one first-line drug: bupropion, varenicline, or a nicotine-based product. The overall intervention strategy is summarized in the “5 A’s” model for treating tobacco use and dependence:

Ask (screen all patients for tobacco use).

Advise tobacco users to quit.

Assess willingness to make a quit attempt.

Assist with quitting (offer medication and provide or refer to counseling).

Arrange follow-up contacts, beginning within the first week after the quit date.

437

40.10.2.1 Nicotine Replacement Therapy (NRT)

438

NRT allows smokers to substitute a pharmaceutical source of nicotine for the nicotine in cigarettes—and then gradually withdraw the replacement nicotine. This is analogous to using methadone to wean addicts from heroin.

Five formulations of nicotine are available: chewing gum, lozenges, transdermal patches, a nasal spray, and an inhaler (see [Table 39-4](#)). With the gum, lozenges, patches, and inhaler, blood levels of nicotine rise slowly and remain relatively steady. Because nicotine levels rise slowly, these delivery systems produce less pleasure than cigarettes, but nonetheless do relieve symptoms of withdrawal. With the nasal spray, blood levels of nicotine rise rapidly, much as they do with smoking. Hence the nasal spray provides some of the subjective pleasure that smoking does.

Long-term quitting rates are significantly greater with NRT than with placebo—although absolute success rates remain low. For example, the 1-year success with nicotine patches is about 25%, compared with 9% for placebo. Success rates are highest when replacement therapy is combined with counseling.

40.10.2.1.1 Nicotine Chewing Gum (Nicotine Polacrilex).

Nicotine chewing gum [Nicorette] is composed of a gum base plus nicotine polacrilex, an ion exchange resin to which nicotine is bound. The gum must be chewed to release the nicotine. Following release, nicotine is absorbed across the oral mucosa into the systemic circulation. Like other forms of NRT, nicotine gum doubles the cessation success rate.

The most common adverse effects are mouth and throat soreness, jaw muscle ache, eructation (belching), and hiccups. Using optimal chewing technique minimizes these problems. Nicotine gum and all other nicotine-containing products should be avoided during pregnancy and lactation.

Patients should be advised to chew the gum slowly and intermittently for about 30 minutes. Rapid chewing can release too much nicotine at one time, resulting in effects similar to those of excessive smoking (eg, nausea, throat irritation, hiccups). Since foods and beverages can reduce nicotine absorption, patients should not eat or drink while chewing or for 15 minutes before chewing.

Nicotine gum is available in two strengths: 2 mg/piece and 4 mg/piece. Dosing is individualized and based on the degree of nicotine dependence. For initial therapy, patients with low to moderate nicotine dependence should use the 2-mg strength; highly dependent patients (those who smoke more than 25 cigarettes a day) should use the 4-mg strength. The average adult dosage is 9 to 12 pieces/day. The maximum daily dosage is 30 pieces of the 2-mg strength or 20 pieces of the 4-mg strength. Experience indicates that dosing on a fixed schedule (one piece every 2 to 3 hours) is more effective than PRN dosing for achieving abstinence.

After 3 months without cigarettes, patients should discontinue nicotine use. Withdrawal should be done gradually. Use of nicotine gum beyond 6 months is not recommended.

40.10.2.1.2 Nicotine Lozenges (Nicotine Polacrilex).

The pharmacology of nicotine lozenges [Commit] is very similar to that of nicotine gum. Both products contain nicotine bound to polacrilex. Sucking on the lozenge releases nicotine, which is then absorbed across the oral mucosa into the systemic circulation. As with nicotine gum and other forms of NRT, nicotine lozenges double the cessation success rate.

The most common adverse effects are mouth irritation, dyspepsia, nausea, and hiccups—all of which can be increased by taking two lozenges at once or by taking several lozenges in immediate succession. Like all other nicotine-containing products, the lozenges should be avoided during pregnancy and lactation.

Administration consists of placing the lozenge in the mouth and allowing it to dissolve, which takes 20 to 30 minutes. Users should not eat or drink for 15 minutes before dosing and while the lozenge is in the mouth. Also, they should not chew or swallow the lozenge, and they should minimize swallowing saliva.

Like nicotine gum, nicotine lozenges are available in two strengths: 2 mg and 4 mg. However, in contrast to nicotine gum, which is dosed on the basis of total cigarettes smoked per day, dosing with the lozenges is based on *when* the first cigarette of the day is smoked: The 2-mg

strength is indicated for people who start smoking 30 minutes or more after waking; the 4-mg strength is indicated for those who smoke sooner. Users should consume no more than 5 lozenges every 6 hours, and no more than 20 lozenges per day. The recommended dosing schedule is 1 lozenge every 1 to 2 hours for the first 6 weeks; 1 every 2 to 4 hours for the next 3 weeks; and 1 every 4 to 8 hours for the next 3 weeks, after which dosing should stop.

40.10.2.1.3 Nicotine Transdermal Systems (Patches).

Nicotine transdermal systems are nicotine-containing adhesive patches that, after application to the skin, slowly release their nicotine content. The nicotine is absorbed into the skin and then into the blood, producing steady blood levels. Use of the patch about doubles the cessation success rate.

Two systems are available: Nicoderm CQ and Nicotrol. Both can be purchased without a prescription. As indicated in [Table 39-4](#), the patches come in different sizes. The larger patches release more nicotine.

Nicotine patches are applied once a day to clean, dry, non-hairy skin of the upper body or upper arm. The site should be changed daily and not reused for at least 1 week. Nicoderm CQ patches are left in place for 24 hours and then immediately replaced with a fresh one. In contrast, Nicotrol patches are applied in the morning and removed 16 hours later at bedtime. This pattern is intended to simulate nicotine dosing produced by smoking.

Most patients begin treatment with a large patch and then progress to smaller patches over several weeks ([Table 39-5](#)). Certain patients (those with cardiovascular disease, those who weigh less than 100 pounds, or those who smoke less than one-half pack of cigarettes a day) should begin with a smaller patch.

Adverse effects are generally mild. Short-lived erythema, itching, and burning occur under the patch in 35% to 50% of users. In 14% to 17% of users, persistent erythema occurs, lasting up to 24 hours after patch removal. Patients who experience severe, persistent local reactions (eg, severe erythema, itching, edema) should discontinue the patch and contact a physician or nurse practitioner. Nicotine patches and all other nicotine-containing products should be avoided during pregnancy and lactation.

40.10.2.1.4 Nicotine Inhaler.

The nicotine inhaler [Nicotrol Inhaler] differs from other NRT products in that it looks much like a cigarette. Puffing on it delivers the nicotine. Because of this delivery method, using the

inhaler can substitute for the hand-to-mouth behavior of smoking. In addition to nicotine, the inhaler contains menthol, whose purpose is to create a sensation in the back of the throat reminiscent of that caused by smoke. Like other forms of NRT, the inhaler doubles cessation success rates.

TABLE 39-5 Nicotine Transdermal Systems (Patches)

Trade Name	Surface Area (cm ²)	Hours/Day in Place	Dose Absorbed	Duration of Use	
				Per Patch Size	Total
Nicoderm CQ Step 1	30	24	21 mg over 24 hr	First 4–6 wk	8–10 wk
Nicoderm CQ Step 2	20	24	14 mg over 24 hr	Next 2 wk	
Nicoderm CQ Step 3	10	24	7 mg over 24 hr	Next 2 wk	
Nicotrol Step 1	30	16	15 mg over 16 hr	First 6 wk	10 wk
Nicotrol Step 2	20	16	10 mg over 16 hr	Next 2 wk	
Nicotrol Step 3	10	16	5 mg over 16 hr	Next 2 wk	

The nicotine inhaler consists of a mouthpiece and a sealed, tubular cartridge. Inside the cartridge is a porous plug containing 10 mg of nicotine. Inserting the cartridge into the mouthpiece breaks the seal. Puffing on the mouthpiece draws air over the plug, and thereby draws nicotine vapor into the mouth. Most of the nicotine is absorbed through the *oral mucosa*—not in the lungs. As a result, blood levels rise slowly, and peak 10 to 15 minutes after puffing stops. Blood levels are less than half those achieved with cigarettes. Each cartridge can deliver 300 to 400 puffs. Benefits are greatest with frequent puffing over 20 minutes, after which the cartridge is discarded. Patients generally use 6 to 16 cartridges a day for 3 months, and then taper off over 2 to 3 months.

Adverse effects are mild. The most frequent are dyspepsia, coughing, throat irritation, oral burning, and rhinitis. The inhaler should not be used by patients with asthma. Because the cartridges contain dangerous amounts of nicotine, they should be kept away from children and pets.

40.10.2.1.5 Nicotine Nasal Spray.

Nicotine nasal spray [Nicotrol NS] differs from other NRT formulations in that blood levels of nicotine rise *rapidly* after each administration, thereby closely simulating smoking. Because nicotine levels rise rapidly, the spray provides some of the subjective pleasure associated with cigarettes. As with other forms of NRT, the spray doubles smoking cessation rates.

The spray device delivers 0.5 mg of nicotine per activation. Two sprays (one in each nostril) constitute one dose and are equivalent to the amount of nicotine absorbed from one cigarette. Treatment should be started with 1 or 2 doses per hour—and never more than 5 doses per hour, or 40 doses a day. After 4 to 6 weeks, dosing should be gradually reduced and then stopped.

Quitting success with the spray has been good news and bad news. The good news, as reported in one study, is that 27% of users avoided smoking for 1 year—about twice the abstinence rate achieved with placebo. The bad news is that many patients continued to use the spray, being unwilling or unable to give it up. Nonetheless, since the spray delivers nicotine without the additional hazards in cigarettes, using the spray is clearly preferable to smoking.

Adverse effects are mild and temporary. At first, most users experience rhinitis, sneezing, coughing, watering eyes, and nasal and throat irritation. Fortunately, these effects abate in a few days. Nicotine nasal spray should be avoided by patients with sinus problems, allergies, or asthma.

40.10.2.2 Bupropion SR

Bupropion SR [Zyban], an atypical antidepressant, was the first non-nicotine drug approved as an aid to quit smoking. The drug is structurally similar to amphetamine and, like amphetamine, causes CNS stimulation and suppresses appetite. In people trying to quit cigarettes, bupropion reduces the urge to smoke and reduces some symptoms of nicotine withdrawal (eg, irritability, anxiety). The drug is effective in the presence and absence of depression. Although the mechanism of action is uncertain, benefits may derive from blocking uptake of norepinephrine and dopamine. For use in depression, bupropion is sold under the trade name Wellbutrin.

Like the NRT products, bupropion SR doubles the cessation success rate. In one trial, patients were given bupropion SR (100, 150, or 300 mg/day) or placebo. At 7 weeks, abstinence rates

were 19% with placebo, and 29%, 39%, and 44% with increasing dosages of bupropion SR. At 12 weeks, abstinence rates were lower: 12% with placebo and 20%, 23%, and 23% with increasing dosages of bupropion SR. Combining a nicotine patch with bupropion SR is somewhat more effective than either treatment alone.

Adverse effects are generally mild. The most common are dry mouth and insomnia. High doses (above 450 mg/day) are associated with a 0.4% risk of seizures. However, at the doses employed for smoking cessation (300 mg/day), seizures have not been reported. Nonetheless, bupropion SR should be avoided in patients with seizure risk factors, such as head trauma, history of seizures, anorexia nervosa, cocaine use, and alcohol withdrawal. Because it suppresses appetite, bupropion SR can cause weight loss. However, since weight gain is common among ex-smokers, appetite reduction may be an added benefit rather than a drawback. Bupropion SR should not be combined with a monoamine oxidase inhibitor. Nor should it be given to patients taking Wellbutrin, which is just another name for bupropion itself.

The usual regimen is 150 mg in the morning for 3 days, followed by 150 mg twice a day for 7 to 12 weeks. To minimize interference with sleep, the second dose should be taken as early in the day as possible—but at least 8 hours after the morning dose. Because onset of effects is delayed, dosing should begin 1 to 2 weeks before attempting to give up cigarettes.

The basic pharmacology of bupropion is discussed in [Chapter 32](#).

40.10.2.3 Varenicline

Varenicline [Chantix], a partial agonist at nicotinic receptors, is our most effective aid to smoking cessation. In clinical trials, more patients achieved abstinence with varenicline than with bupropion SR or the nicotine patch. Estimated abstinence rates after 6 months were 33.2% with varenicline, 24.2% with bupropion SR, and 23.4% with the nicotine patch. The most common side effect is nausea. Unlike bupropion SR and NRT, varenicline does *not* reduce weight gain that occurs with smoking cessation. Since being approved in 2006, varenicline has been used by more than 5 million people.

439

440

40.10.2.3.1 Mechanism of Action.

Varenicline acts as a *partial agonist* at a subset of nicotinic receptors—known as $\alpha_4\beta_2$ nicotinic receptors—whose activation promotes release of dopamine, the compound that mediates the pleasurable effects of nicotine. Compared with nicotine, varenicline binds $\alpha_4\beta_2$ receptors with greater affinity. Hence, when varenicline is present, access of nicotine to these receptors is blocked. Because varenicline is a partial agonist, receptor

binding results in mild activation, which promotes some dopamine release, and thereby helps reduce both nicotine craving and the intensity of withdrawal symptoms. At the same time, the presence of varenicline prevents intense receptor activation by nicotine itself, and thereby blocks the reward that nicotine can provide.

40.10.2.3.2 Pharmacokinetics.

Varenicline is readily absorbed from the GI tract, both in the presence and absence of food. Plasma levels peak about 4 hours after dosing. Binding to plasma proteins is low (20%). Metabolism is minimal, and hence most of each dose (92%) is excreted unchanged in the urine. The plasma half-life is 17 to 24 hours. Moderate to severe renal impairment delays excretion and increases varenicline blood levels.

40.10.2.3.3 Adverse Effects.

In clinical trials, dose-dependent *nausea* was the most common adverse effect, occurring in 30% to 40% of users. Nausea is mild to moderate initially, and becomes less severe over time. Other common reactions include sleep disturbances (18%), headaches (15%), abnormal dreams (13%), constipation (8%), dry mouth (6%), flatulence (6%), vomiting (5%), and altered sense of taste (5% to 8%). Mild physical dependence develops, but there have been no reports of abuse or addictive behavior.

Postmarketing reports indicate that varenicline can cause serious *neuropsychiatric effects*, including mood changes, erratic behavior, and suicidality. As of February 2008, there were 391 reports of suicidal thoughts and 39 successful suicides—out of more than 5 million people using the drug. At this time, we don't know if varenicline was the cause of suicidality, or if these patients had an underlying psychiatric illness. All patients should be advised to contact their prescriber if they experience a significant change in behavior or mental status. Varenicline should be used with caution in patients with a history of psychiatric disease.

Most recently, varenicline has been associated with rare reports of heart attacks, dysrhythmias, seizures, diabetes, dizziness, disturbed vision, and moderate and severe skin reactions. However, a causal relationship has not been established.

40.10.2.3.4 Drug Interactions.

Varenicline does not affect the major components of the cytochrome P450 system. Studies with bupropion, transdermal nicotine, digoxin, warfarin, cimetidine, and metformin have

shown no significant interactions. To date, no clinically significant interactions with other drugs have been reported.

40.10.2.3.5 Preparations, Dosage, and Administration.

Varenicline is formulated in 0.5- and 1-mg tablets. To reduce nausea, each dose should be taken after eating and with a full glass of water. Dosage should be titrated as follows: days 1 to 3, 0.5 mg once daily; days 4 to 7, 0.5 mg twice daily; day 8 to the end of treatment, 1 mg twice daily. Dosing should begin 1 week before smoking is scheduled to stop, and should continue for 12 weeks. If abstinence has been achieved, an additional 12 weeks of treatment is recommended. Patients who fail to stop smoking after the initial 12 weeks, or who relapse after a full course of treatment, should be encouraged to try again when conditions are deemed favorable. Patients with severe renal impairment should begin therapy at 0.5 mg once daily and increase to 0.5 mg twice daily, if tolerated. Patients with end-stage renal disease undergoing dialysis should take a maximum of 0.5 mg once daily. Dosage adjustment is unnecessary in patients with mild to moderate renal impairment.

40.10.2.4 Nortriptyline and Clonidine

Nortriptyline [Aventyl, Pamelor] and clonidine [Catapres] are second-line drugs for helping people quit smoking. Neither agent is FDA approved for this use. Nortriptyline is a tricyclic antidepressant (see [Chapter 32](#)). Clonidine is a centrally acting α_2 agonist used primarily for hypertension (see [Chapter 19](#)). Both drugs cause dry mouth, sedation, and dizziness—but the intensity is greater with clonidine. For nortriptyline, dosing is initiated at 25 mg/day starting 10 to 28 days before the quitting date, and then gradually increased to 75 to 100 mg/day. For clonidine, the dosage is 0.1 to 0.3 mg twice a day.

40.10.2.5 Drugs That Are Not Recommended

According to *Treating Tobacco Use and Dependence: 2008 Update*, there is insufficient proof to recommend the following drugs as aids to smoking cessation: naltrexone, mecamylamine, silver acetate, beta blockers, benzodiazepines, and antidepressants other than bupropion SR and nortriptyline, including the selective serotonin reuptake inhibitors.

40... ANABOLIC STEROIDS

Many athletes take anabolic steroids (androgens) to enhance athletic performance. The principal benefit is increased muscle mass and strength. Because of the massive doses that are employed, the risk of adverse effects is substantial. With long-term steroid use, an addiction syndrome develops.

Pharmacology for Nursing Care, 7th Edition

Because of their abuse potential, most androgens are now classified as Schedule III drugs (see [Table 37-3](#)). The basic pharmacology of androgens and their abuse by athletes are discussed in [Chapter 64](#).

40.11.1

KEY POINTS

- Because heroin is very lipid soluble, initial effects are more intense and occur faster than with other opioids. As a result, heroin is the opioid of choice among abusers.
- Among healthcare providers who abuse opioids, meperidine [Demerol] is a drug of choice. Why? Because meperidine is orally active, causes minimal pupillary constriction, and causes less constipation and urinary retention than other opioids.
- With opioids, tolerance to respiratory depression develops in parallel with tolerance to euphoria. As a result, respiratory depression does not increase as higher doses are taken to produce desired subjective effects.

440

- Persons tolerant to one opioid are cross-tolerant to all other opioids.
- Although the opioid withdrawal syndrome can be extremely unpleasant, it is rarely dangerous.
- Opioid overdose produces a classic triad of symptoms: respiratory depression, coma, and pinpoint pupils. Death can result.
- Naloxone, an opioid antagonist, is the treatment of choice for opioid overdose.
- Naloxone dosage must be titrated carefully, because too much naloxone will transport the patient from a state of intoxication to one of withdrawal. Also, since the half-life of naloxone is shorter than the half-lives of the opioids, naloxone must be administered repeatedly until the crisis is over.
- Because of cross-dependence, methadone can ease withdrawal symptoms in opioid-dependent individuals. To ease withdrawal, methadone is substituted for the abused opioid and then gradually tapered.
- In opioid abusers who are not ready for withdrawal, methadone can be used for maintenance therapy or suppressive therapy. In maintenance therapy, the methadone dosage is equivalent to the dosage of the abused opioid, thereby preventing withdrawal. In suppressive therapy, the abuser is rendered opioid tolerant with very high doses of methadone; as a result, use of street opioids can no longer produce subjective effects.

441

- Buprenorphine is an alternative to methadone for detoxification and maintenance of opioid addicts.
- In contrast to methadone, which is available only through approved treatment facilities, buprenorphine can be prescribed by any physician or nurse practitioner who has (1) received at least 8 hours of approved training and (2) registered with the Substance Abuse and Mental Health Services Administration.
- With barbiturates, tolerance develops to subjective effects but not to respiratory depression. As a result, as increasingly large doses are taken to produce subjective effects, the risk of serious respiratory depression increases. (Note that this differs from the situation with opioids.)
- Individuals who are tolerant to barbiturates show cross-tolerance with other CNS depressants (eg, alcohol, benzodiazepines, general anesthetics) but not with opioids.
- Individuals who are physically dependent on barbiturates show cross-dependence with other CNS depressants, but not with opioids.
- When physical dependence on barbiturates (and other CNS depressants) is great, the associated abstinence syndrome can be severe—sometimes fatal. (Note that this differs from the situation with opioids.)
- Overdose with barbiturates produces the same triad of symptoms seen with opioids: respiratory depression, coma, and pinpoint pupils. Death can result.
- In contrast to opioid overdose, barbiturate overdose has no antidote, and hence treatment is only supportive.
- In contrast to overdose with opioids or barbiturates, overdose with benzodiazepines alone is rarely fatal.
- If necessary, benzodiazepine overdose can be treated with flumazenil, a benzodiazepine antagonist.
- The psychologic effects of cocaine result from activation of dopamine receptors secondary to cocaine-induced blockade of dopamine reuptake.

- Severe overdose with cocaine can produce hyperpyrexia, convulsions, ventricular dysrhythmias, and hemorrhagic stroke; death has occurred. Psychologic effects of overdose include severe anxiety, paranoid ideation, and hallucinations.
- There is no specific antidote to cocaine overdose. Intravenous diazepam can suppress anxiety, seizures, hypertension, and dysrhythmias. Intravenous nitroprusside or phen-tolamine can treat severe hypertension.
- In animals, regular use of cocaine produces sensitization—not tolerance. Whether this is true for humans is unclear.
- Whether cocaine causes significant physical dependence is in dispute.
- Psychosocial therapy is considered the cornerstone of cocaine addiction treatment. Adding disulfiram may also help.
- In addition to CNS stimulation, amphetamines cause vasoconstriction and stimulate the heart. Cardiovascular stimulation may result in hypertension, angina, and dysrhythmias.
- Regular use of amphetamines can produce a state that closely resembles paranoid schizophrenia.
- Although physical dependence on amphetamines is only moderate, psychologic dependence can be intense. Withdrawal can produce dysphoria and a strong sense of craving.
- The major psychoactive substance in marijuana is delta-9-tetrahydrocannabinol (THC).
- THC acts through specific receptors in the brain.
- Marijuana has three principal subjective effects: euphoria, sedation, and hallucinations.
- Physiologic effects of marijuana, as well as tolerance and physical dependence, are minimal.
- Marijuana has no approved medical uses, although its major active component—THC—does.
- Psychedelic drugs produce alterations in thought, perception, and feeling that otherwise occur only in dreams.

- Psychedelic drugs are also known as hallucinogens or psychotomimetics—names that reflect their ability to produce hallucinations and mental states that resemble psychosis.
- Lysergic acid diethylamide (LSD) can be considered the prototype of the psychedelic drugs.
- LSD produces its effects by activating serotonin₂ receptors in the brain.
- Although tolerance develops to LSD, physiologic effects and physical dependence are minimal.
- Acute panic reactions to LSD can be managed by “talking down” and by treatment with benzodiazepines. Neuroleptic drugs (eg, haloperidol) may intensify the reaction.
- LSD users may experience episodic visual disturbances after discontinuing the drug. In many cases, the underlying cause is a permanent change in the visual system.
- Some LSD users experience prolonged psychotic reactions that closely resemble schizophrenia.
- Phencyclidine (PCP) is a dissociative anesthetic that produces alcohol-like effects at low doses and hallucinations and psychotic reactions at high doses.
- Extreme overdose with phencyclidine can produce hypertension, coma, and seizures, as well as muscular rigidity associated with severe hyperthermia and rhabdomyolysis.

441

- There is no specific antidote to phencyclidine overdose. “Talking down” is not effective, and antipsychotic drugs are of limited help.
- Ecstasy (MDMA) produces psychedelic effects at low doses and amphetamine-like stimulation at higher doses.
- Ecstasy can cause irreversible destruction of serotonergic neurons.
- Cigarette smoking kills nearly 400,000 American adults each year, making smoking the largest preventable cause of premature death.
- The principal cause of death among smokers is lung cancer, followed closely by heart disease.

442

- Nicotine in cigarette smoke is absorbed from the lungs, whereas nicotine in cigar smoke and smokeless tobacco is absorbed from the mouth.
- By activating nicotinic receptors in sympathetic ganglia and the adrenal medulla, nicotine promotes vasoconstriction, acceleration of heart rate, and increased force of ventricular contraction, thereby elevating blood pressure and increasing cardiac work. These effects underlie cardiovascular deaths.
- Through actions in the CNS, nicotine increases alertness, facilitates memory, improves cognitive function, reduces aggression, and suppresses appetite. In addition, by promoting release of dopamine, nicotine activates the same pleasure circuit involved in addiction to cocaine, amphetamines, and opioids.
- Although tolerance develops to some effects of nicotine, very little tolerance develops to cardiovascular effects: Veteran smokers continue to experience an increase in blood pressure and cardiac work whenever they light up.
- Nicotine causes physical dependence. Withdrawal is characterized by craving, nervousness, restlessness, irritability, impatience, increased hostility, insomnia, impaired concentration, increased appetite, and weight gain.
- Nicotine for replacement therapy is available in five delivery systems: chewing gum, lozenges, transdermal patches, nasal spray, and an inhaler.
- Bupropion SR [Zyban], which blocks reuptake of norepinephrine and dopamine, helps smokers quit by reducing nicotine craving and withdrawal symptoms.
- Varenicline [Chantix] acts as a partial agonist at specific nicotine receptors, and thereby reduces nicotine craving and withdrawal symptoms. In addition, the drug blocks access of nicotine itself to nicotine receptors, and thereby prevents nicotine from producing pleasurable effects.
- The most effective drug/therapies for smoking cessation are varenicline alone and the nicotine patch combined with PRN nicotine nasal spray or nicotine gum.
- With the aid of counseling and pharmacotherapy, about 30% of smokers who attempt to quit can expect to achieve long-term abstinence.

⁴¹CHAPTER 40 Diuretics

Diuretics are drugs that increase the output of urine. These agents have two major applications: (1) treatment of hypertension and (2) mobilization of edematous fluid (associated with heart failure, cirrhosis, and kidney disease). In addition, because of their ability to maintain urine flow, diuretics are used to prevent renal failure.

^{41.1}REVIEW OF RENAL ANATOMY AND PHYSIOLOGY

Understanding the diuretic drugs requires a basic knowledge of the anatomy and physiology of the kidney. Accordingly, we review these topics before discussing the diuretics themselves.

^{41.1.1} Anatomy

The basic functional unit of the kidney is the *nephron*. As indicated in [Figure 40-1](#), the nephron has four functionally distinct regions: (1) the *glomerulus*, (2) the *proximal convoluted tubule*, (3) the *loop of Henle*, and (4a, 4b) the *distal convoluted tubule*. All nephrons are oriented within the kidney such that the upper portion of Henle's loop is located within the renal cortex and the lower end of the loop descends toward the renal *medulla*. Without this orientation, the kidney could not produce concentrated urine.

In addition to the nephrons, the *collecting ducts* (the tubules into which the nephrons pour their contents) play a critical role in kidney function. As suggested by [Figure 40-1](#), the final segment of the distal convoluted tubule (4b) plus the collecting duct into which it empties (5) can be considered a single functional unit: the *distal nephron*.

^{41.1.2} Physiology

^{41.1.2.1} Overview of Kidney Functions

The kidney serves three basic functions: (1) cleansing of extracellular fluid (ECF) and maintenance of ECF volume and composition; (2) maintenance of acid-base balance; and (3) excretion of metabolic wastes and foreign substances (eg, drugs, toxins). Of the three, maintenance of ECF volume and composition is the one that diuretics affect most.

^{41.1.2.2} The Three Basic Renal Processes

Effects of the kidney on ECF are the net result of three basic processes: (1) *filtration*, (2) *reabsorption*, and (3) *active secretion*. In order to cleanse the entire ECF, huge volumes of plasma must be filtered. Furthermore, in order to maintain homeostasis, practically everything

that has been filtered must be reabsorbed—leaving behind only a small volume of urine for excretion.

41.1.2.2.1 Filtration.

Filtration occurs at the *glomerulus* and is the first step in urine formation. Virtually all small molecules (electrolytes, amino acids, glucose, drugs, metabolic wastes) present in plasma undergo filtration. In contrast, cells and large molecules (lipids, proteins) remain behind in the blood. The most prevalent constituents of the filtrate are sodium ions and chloride ions. Bicarbonate ions and potassium ions are also present, but in smaller amounts.

The filtration capacity of the kidney is very large. Each minute the kidney produces 125 mL of filtrate, which adds up to 180 L/day. Since the total volume of ECF is only 12.5 L, the kidney can process the equivalent of all the ECF in the body every 100 minutes. Hence, the ECF undergoes complete cleansing many times each day.

Be aware that filtration is a *nonselective process*, and therefore cannot regulate the composition of urine. Reabsorption and secretion—processes that display a significant degree of selectivity—are the primary determinants of what the urine ultimately contains. Of the two, reabsorption is by far the more important.

41.1.2.2.2 Reabsorption.

Greater than 99% of the water, electrolytes, and nutrients that are filtered at the glomerulus undergo reabsorption. This conserves valuable constituents of the filtrate while allowing wastes to undergo excretion. Reabsorption of solutes (eg, electrolytes, amino acids, glucose) takes place by way of *active transport*. Water then follows passively along the osmotic gradient created by solute reuptake. Specific

443

444

Figure 40-1 Schematic representation of a nephron and collecting duct.

sites along the nephron at which reabsorption takes place are discussed below. Diuretics work primarily by interfering with reabsorption.

41.1.2.2.3 Active Tubular Secretion.

The kidney has two major kinds of “pumps” for active secretion. These pumps transport compounds from the plasma into the lumen of the nephron. One pump transports *organic acids* and the other transports *organic bases*. Together, these pumps can promote the excretion of a wide assortment of molecules, including metabolic wastes, drugs, and toxins. The pumps for active secretion are located in the *proximal convoluted tubule*.

41.1.2.3 Processes of Reabsorption That Occur at Specific Sites Along the Nephron

Because most diuretics act by disrupting solute reabsorption, to understand the diuretics, we must first understand the major processes by which nephrons reabsorb filtered solutes. Because sodium and chloride ions are the predominant solutes in the filtrate, reabsorption of these ions is of greatest interest. As we discuss reabsorption, numeric values are given for the percentage of solute reabsorbed at specific sites along the nephron. Bear in mind that these values are only approximate. [Figure 40-2](#) provides a summary of the sites of sodium and chloride reabsorption, indicating the amount of reabsorption that occurs at each site.

41.1.2.3.1 Proximal Convoluted Tubule.

The proximal convoluted tubule (PCT) has a high reabsorptive capacity. As indicated in [Figure 40-2](#), a large fraction (about 65%) of filtered sodium and chloride is reabsorbed at the PCT. In addition, essentially all of the bicarbonate and potassium in the filtrate is reabsorbed here. As sodium, chloride, and other solutes are actively reabsorbed, water follows passively. Since solutes and water are reabsorbed to an equal extent, the tubular urine remains isotonic (300 mOsm/L). By the time the filtrate leaves the PCT, sodium and chloride are the only solutes that remain in significant amounts.

41.1.2.3.2 Loop of Henle.

The *descending limb* of the loop of Henle is freely permeable to water. Hence, as tubular urine moves down the loop and passes through the hypertonic environment of the renal medulla, water is drawn from the loop into the interstitial space. This process decreases the volume of the tubular urine and causes the urine to become concentrated (tonicity increases to about 1200 mOsm/L).

Within the thick segment of the *ascending limb* of the loop of Henle, about *20% of filtered sodium and chloride is reabsorbed* (see [Fig. 40-2](#)). Since, unlike the descending limb, the ascending limb is not permeable to water, water must remain in the loop as reabsorption of sodium and chloride takes place. This process causes the tonicity of the tubular urine to return to that of the original filtrate (300 mOsm/L).

444

445

Figure 40-2 Schematic diagram of a nephron showing sites of sodium absorption and diuretic action. The percentages indicate how much of the filtered sodium and chloride is reabsorbed at each site.

41.1.2.3.3 Distal Convoluted Tubule (Early Segment).

About 10% of filtered sodium and chloride is reabsorbed in the early segment of the distal convoluted tubule. Water follows passively.

41.1.2.3.4 Late Distal Convoluted Tubule and Collecting Duct (Distal Nephron).

The distal nephron is the site of two important processes. The first involves exchange of sodium for potassium and is under the influence of aldosterone. The second determines the final concentration of the urine and is regulated by antidiuretic hormone (ADH).

41.1.2.3.4.1 Sodium-Potassium Exchange.

Aldosterone, the principal mineralocorticoid of the adrenal cortex, stimulates reabsorption of sodium from the distal nephron. At the same time, aldosterone causes potassium to be secreted. Although not directly coupled, these two processes—sodium retention and potassium excretion—can be viewed as an exchange mechanism. This exchange is shown schematically in [Figure 40-2](#). Aldosterone promotes sodium-potassium exchange by stimulating cells of the distal nephron to synthesize more of the pumps responsible for sodium and potassium transport.

41.1.2.3.4.2 Regulation of Urine Concentration by ADH.

Although of great physiologic significance, ADH has little to do with the actions of diuretics. Hence, discussion of this physiologically important topic is presented in small type.

ADH acts on the collecting duct to regulate conservation of water. To understand the effects of ADH, we need to know four facts:

- In the absence of ADH, the collecting duct is impermeable to water.
- The collecting duct is oriented such that it begins in the cortex of the kidney and then passes down through the hypertonic renal medulla (see [Fig. 40-2](#)).
- Tubular urine entering the collecting duct is isotonic (300 mOsm/L).
- ADH acts on the collecting duct to increase its permeability to water.

By rendering the collecting duct permeable to water, ADH allows water to be drawn from the duct as it passes through the hypertonic renal medulla. Because of this water reabsorption, urine that entered the duct in a relatively dilute state becomes concentrated and reduced in volume.

In the absence of ADH, water cannot be reabsorbed in the collecting duct. As a result, large volumes of dilute urine are produced. The clinical syndrome resulting from ADH deficiency is known as *diabetes insipidus*.

41.2 INTRODUCTION TO DIURETICS

41.2.1 How Diuretics Work

Most diuretics share the same basic mechanism of action: blockade of sodium and chloride reabsorption. By blocking the reabsorption of these prominent solutes, diuretics create osmotic pressure within the nephron that prevents the passive reabsorption of water. Hence, diuretics cause water and solutes to be retained within the nephron, and thereby promote the excretion of both. 445
446

The increase in urine flow that a diuretic produces is directly related to the amount of sodium and chloride reabsorption that it blocks. Accordingly, drugs that block solute reabsorption to the greatest degree produce the most profound diuresis. Since the amount of solute in the nephron becomes progressively smaller as filtrate flows from the proximal tubule to the collecting duct, *drugs that act early in the nephron have the opportunity to block the greatest amount of solute reabsorption. Accordingly, these agents produce the greatest diuresis.* Conversely, since most of the filtered solute has already been reabsorbed by the time the filtrate reaches the distal parts of the nephron, diuretics that act at distal sites have very little reabsorption available to block. Consequently, such agents produce relatively scant diuresis.

It is instructive to look at the quantitative relationship between blockade of solute reabsorption and production of diuresis. Recall that the kidney produces 180 L of filtrate a day, practically all of which is normally reabsorbed. With filtrate production at this volume, a diuretic will increase daily urine output by 1.8 L for each 1% of solute reabsorption that is blocked. A 3% blockade of solute reabsorption will produce 5.4 L of urine a day—a rate of fluid loss that would reduce body weight by 12 pounds in 24 hours. Clearly, with only a small blockade of reabsorption, diuretics can produce a profound effect on the fluid and electrolyte composition of the body.

41.2.2 Adverse Impact on Extracellular Fluid

In order to promote excretion of water, diuretics must interfere with the normal operation of the kidney. By doing so, diuretics can cause *hypovolemia* (from excessive fluid loss), *acid-base imbalance*, and *disturbance of electrolyte levels*. These adverse effects can be minimized by using shortacting diuretics and by timing drug administration such that the kidney is allowed to operate in a drug-free manner between periods of diuresis. Both measures will give the kidney periodic

opportunities to readjust the ECF so as to compensate for any undesired alterations produced under the influence of diuretics.

41.2.3 Classification of Diuretics

There are four major categories of diuretic drugs: (1) *high-ceiling (loop) diuretics* (eg, furosemide); (2) *thiazide diuretics* (eg, hydrochlorothiazide); (3) *osmotic diuretics* (eg, mannitol); and (4) *potassium-sparing diuretics*. The last group, the potassium-sparing agents, can be subdivided into *aldosterone antagonists* (eg, spironolactone) and *nonaldosterone antagonists* (eg, triamterene).

In addition to the four major categories of diuretics, there is a fifth group: the *carbonic anhydrase inhibitors*. Although the carbonic anhydrase inhibitors are classified as diuretics, these drugs are employed primarily to lower intraocular pressure (IOP) and not to increase urine production.

Consequently, the carbonic anhydrase inhibitors are discussed in [Chapter 103](#) (Drugs for the Eye) rather than here.

41.3 HIGH-CEILING (LOOP) DIURETICS

The high-ceiling agents are the most effective diuretics available. These drugs produce more loss of fluid and electrolytes than any other diuretics. Because their site of action is in the loop of Henle, the high-ceiling agents are also known as *loop diuretics*.

41.3.1 Furosemide

Furosemide [Lasix] is the most frequently prescribed loop diuretic and will serve as our prototype for the group.

41.3.1.1 Mechanism of Action

Furosemide acts in the thick segment of the ascending limb of Henle's loop to block reabsorption of sodium and chloride (see [Fig. 40-2](#)). By blocking solute reabsorption, furosemide prevents passive reabsorption of water. Since a substantial amount (20%) of filtered NaCl is normally reabsorbed in the loop of Henle, interference with reabsorption here can produce profound diuresis.

41.3.1.2 Pharmacokinetics

Furosemide can be administered orally, IV, and IM. With oral administration, diuresis begins in 60 minutes and persists for 8 hours. Oral therapy is used when rapid onset is not required. Effects of intravenous furosemide begin within 5 minutes and last for 2 hours. Intravenous

therapy is used in critical situations (eg, pulmonary edema) that demand immediate mobilization of fluid. Furosemide undergoes hepatic metabolism followed by renal excretion.

41.3.1.3 Therapeutic Uses

Furosemide is a powerful drug that is generally reserved for situations that require rapid or massive mobilization of fluid. This drug should be avoided when less efficacious diuretics (thiazides) will suffice. Conditions that justify use of furosemide include (1) pulmonary edema associated with congestive heart failure (CHF); (2) edema of hepatic, cardiac, or renal origin that has been unresponsive to less efficacious diuretics; and (3) hypertension that cannot be controlled with other diuretics. Furosemide is especially useful in patients with severe renal impairment, since, unlike the thiazides (see below), the drug can promote diuresis even when renal blood flow and glomerular filtration rate (GFR) are low. If treatment with furosemide alone is insufficient, a thiazide diuretic may be added to the regimen. There is no benefit to combining furosemide with another high-ceiling agent.

41.3.1.4 Adverse Effects

41.3.1.4.1 Hyponatremia, Hypochloremia, and Dehydration.

Furosemide can produce excessive loss of sodium, chloride, and water. Severe dehydration can result. Signs of evolving dehydration include dry mouth, unusual thirst, and oliguria (scanty urine output). Impending dehydration can also be anticipated from excessive loss of weight. If dehydration occurs, furosemide should be withheld.

Dehydration can promote thrombosis and embolism. Symptoms include headache and pain in the chest, calves, or pelvis. The prescriber should be notified if these develop.

446

The risk of dehydration and its sequelae can be minimized by initiating therapy with low doses, adjusting the dosage carefully, monitoring weight loss every day, and administering furosemide on an intermittent schedule.

447

41.3.1.4.2 Hypotension.

Furosemide can cause a substantial drop in blood pressure. At least two mechanisms are involved: (1) loss of volume and (2) relaxation of venous smooth muscle, which reduces venous return to the heart. Signs of hypotension include dizziness, lightheadedness, and fainting. If blood pressure falls precipitously, furosemide should be discontinued. Because of the risk of hypotension, blood pressure should be monitored routinely.

Outpatients should be taught to monitor their blood pressure and instructed to notify the prescriber if it drops substantially. Also, patients should be informed about symptoms of postural hypotension (dizziness, lightheadedness) and advised to sit or lie down if these occur. Patients should be taught that postural hypotension can be minimized by getting up slowly.

41.3.1.4.3 Hypokalemia.

Potassium is lost through increased secretion in the distal nephron. If serum potassium falls below 3.5 mEq/L, fatal dysrhythmias may result. As discussed below under *Drug Interactions*, loss of potassium is of special concern for patients taking digoxin, a drug used for heart failure. Hypokalemia can be minimized by consuming potassium-rich foods (eg, dried fruits, nuts, spinach, citrus fruits, potatoes, bananas), taking potassium supplements, or using a potassium-sparing diuretic.

41.3.1.4.4 Ototoxicity.

Rarely, loop diuretics cause hearing impairment. With furosemide, deafness is transient. With ethacrynic acid (another loop diuretic), irreversible hearing loss has occurred. The ability to impair hearing is unique to the high-ceiling agents; diuretics in other classes are not ototoxic. Because of the risk of hearing loss, caution is needed when high-ceiling diuretics are used in combination with other ototoxic drugs (eg, aminoglycoside antibiotics).

41.3.1.4.5 Hyperglycemia.

Elevation of plasma glucose is a potential, albeit uncommon, complication of furosemide therapy. Hyperglycemia appears to result from inhibition of insulin release. Increased glycogenolysis and decreased glycogen synthesis may also contribute. When furosemide is taken by a diabetic patient, he or she should be especially diligent about monitoring blood glucose content.

41.3.1.4.6 Hyperuricemia.

Elevation of plasma uric acid is a frequent side effect of treatment. For most patients, furosemide-induced hyperuricemia is asymptomatic. However, for patients predisposed to gout, elevation of uric acid may precipitate a gouty attack. Patients should be informed about symptoms of gout (tenderness or swelling in joints) and instructed to notify the prescriber if these develop.

41.3.1.4.7 Use in Pregnancy.

When administered to pregnant laboratory animals, high-ceiling diuretics have caused maternal death, abortion, fetal resorption, and other adverse effects. There are no definitive studies on loop diuretics during human pregnancy. However, given the toxicity displayed in animals, prudence dictates that pregnant women use these drugs only if absolutely required.

41.3.1.4.8 Impact on Lipids, Calcium, and Magnesium.

Furosemide reduces high-density lipoprotein (HDL) cholesterol and raises low-density lipoprotein (LDL) cholesterol and triglycerides. Although these undesirable effects by themselves can increase the risk of coronary heart disease, they are more than balanced by the beneficial effects of the diuretic therapy on the heart. That is, despite adverse effects on lipids, high-ceiling diuretics reduce the risk of coronary mortality by 25%.

Furosemide increases urinary excretion of magnesium, posing a risk of magnesium deficiency. Symptoms include muscle weakness, tremor, twitching, and dysrhythmias.

Furosemide increases urinary excretion of calcium. This action has been exploited to treat hypercalcemia.

41.3.1.5 Drug Interactions

41.3.1.5.1 Digoxin.

Digoxin is used for heart failure (see [Chapter 47](#)) and cardiac dysrhythmias (see [Chapter 48](#)). In the presence of low potassium, the risk of serious digoxin-induced toxicity (ventricular dysrhythmias) is greatly increased. Since high-ceiling diuretics promote potassium loss, use of these drugs in combination with digoxin can increase the risk of dysrhythmias. This interaction is unfortunate in that most patients who take digoxin for heart failure must also take a diuretic as part of their therapy. To reduce the risk of toxicity, potassium levels should be monitored routinely, and, when indicated, potassium supplements or a potassium-sparing diuretic should be given.

41.3.1.5.2 Ototoxic Drugs.

The risk of furosemide-induced hearing loss is increased by concurrent use of other ototoxic drugs—especially aminoglycoside antibiotics (eg, gentamicin). Accordingly, combined use of these drugs should be avoided.

41.3.1.5.3 Potassium-Sparing Diuretics.

The potassium-sparing diuretics (eg, spironolactone, triamterene) can help counterbalance the potassium-wasting effects of furosemide, thereby reducing the risk of hypokalemia.

41.3.1.5.4 Lithium.

Lithium is used to treat bipolar disorder (see [Chapter 33](#)). In patients with low sodium, excretion of lithium is reduced. Hence, by lowering sodium levels, furosemide can cause lithium to accumulate to toxic levels. Accordingly, lithium levels should be monitored, and, if they climb too high, lithium dosage should be reduced.

41.3.1.5.5 Antihypertensive Agents.

The hypotensive effects of furosemide add with those of other hypotensive drugs. To avoid excessive reduction of blood pressure, patients may need to reduce or eliminate use of other hypotensive medications.

41.3.1.5.6 Nonsteroidal Anti-inflammatory Drugs.

The nonsteroidal anti-inflammatory drugs (NSAIDs; eg, aspirin) can attenuate the diuretic effects of furosemide. The mechanism appears to be inhibition of prostaglandin synthesis in the kidney. (Part of the diuretic effect of furosemide results from increasing renal blood flow, which is thought to occur through a prostaglandin-mediated process. By inhibiting prostaglandin synthesis, NSAIDs prevent the increase in renal blood flow, and thereby partially blunt diuretic effects.)

41.3.1.6 Preparations, Dosage, and Administration

41.3.1.6.1 Oral.

Furosemide [Lasix] is available in tablets (20, 40, and 80 mg) and in solution (8 and 10 mg/mL) for oral use. The initial dosage for adults is 20 to 80 mg/day as a single dose. The maximum daily dosage is 600 mg. Twice-daily dosing (8:00 AM and 2:00 PM) is common. Administration late in the day produces nocturia and should be avoided.

41.3.1.6.2 Parenteral.

Furosemide is available in solution (10 mg/mL) for IV and IM administration. The usual dosage for adults is 20 to 40 mg, repeated in 1 or 2 hours if needed. Intravenous

administration should be done slowly (over 1 to 2 minutes). For high-dose therapy, furosemide can be administered by continuous infusion at a rate of 4 mg/min or slower.

41.3.2 Other High-Ceiling Diuretics

In addition to furosemide, three other high-ceiling agents are available: *ethacrynic acid* [Edecrin], *bumetanide* [Bumex], and *torsemide* [Demadex]. All three are much like furosemide. They all promote diuresis by inhibiting sodium and chloride reabsorption in the thick ascending limb of the loop of Henle. All are approved for edema caused by heart failure, chronic renal disease, and cirrhosis, but only torsemide, like furosemide, is also approved for hypertension. All can cause ototoxicity, hypovolemia, hypotension, hypokalemia, hyperuricemia, hyperglycemia, and disruption of lipid metabolism (ie, reduction of HDL cholesterol and elevation of LDL cholesterol and triglycerides). Lastly, they all share the same drug interactions: their effects can be blunted by NSAIDs, they can intensify ototoxicity caused by aminoglycosides, they can increase cardiotoxicity caused by digoxin, and they can cause lithium to accumulate to toxic levels. Routes, dosages, and time courses are summarized in [Table 40-1](#).

447

448

TABLE 40-1 High-Ceiling (Loop) Diuretics: Routes, Time Course, and Dosage

Drug	Route	Onset (min)	Duration (hr)	Dosage (mg)	Doses/Day
Furosemide [Lasix]	Oral	Within 60	6–8	20–80	1–2
	IV or IM	Within 5	2	20–40	
Ethacrynic acid [Edecrin]	Oral	Within 30	6–8	50–100	1–2
	IV	Within 5	2	50	1–2
Bumetanide [Bumex]	Oral	30–60	4–6	0.5–2	1
	IV	Within a few	0.5–1	0.5–1	1–3
Torsemide [Demadex]	Oral	Within 60	6–8	5–20	1
	IV	Within 10	6–8	5–20	1

41.4 THIAZIDES AND RELATED DIURETICS

The thiazide diuretics (also known as benzothiadiazides) have effects similar to those of the loop diuretics. Like the loop diuretics, thiazides increase renal excretion of sodium, chloride, potassium, and water. In addition, thiazides elevate plasma levels of uric acid and glucose. The principal difference between the thiazides and high-ceiling agents is that the maximum diuresis produced by the thiazides is considerably lower than the maximum diuresis produced by the high-ceiling drugs. In addition, whereas loop diuretics can be effective even when urine flow is scant, thiazides cannot.

41.4.1 Hydrochlorothiazide

Hydrochlorothiazide [HydroDIURIL, others] is the most widely used thiazide diuretic and will serve as our prototype for the group. Because of its use in hypertension, a very common disorder, hydrochlorothiazide is one of our most widely used drugs.

41.4.1.1 Mechanism of Action

Hydrochlorothiazide promotes urine production by blocking the reabsorption of sodium and chloride in the *early segment of the distal convoluted tubule* (see [Fig. 40-2](#)). Retention of sodium and chloride in the nephron causes water to be retained as well, thereby producing an increased flow of urine. Since only 10% of filtered sodium and chloride is normally reabsorbed at the site where thiazides act, the maximum urine flow these drugs can produce is lower than with the high-ceiling drugs.

The ability of thiazides to promote diuresis is dependent on adequate kidney function. These drugs are ineffective when GFR is low (less than 15 to 20 mL/min). Hence, in contrast to the high-ceiling agents, thiazides cannot be used to promote fluid loss in patients with severe renal impairment.

41.4.1.2 Pharmacokinetics

Diuresis begins about 2 hours after oral administration. Effects peak within 4 to 6 hours, and may persist up to 12 hours. Most of the drug is excreted unchanged in the urine.

41.4.1.3 Therapeutic Uses

41.4.1.3.1 Essential Hypertension.

The primary indication for hydrochlorothiazide is hypertension, a condition for which thiazides are often drugs of first choice. For many hypertensive patients, blood pressure can be controlled with a thiazide alone, although many other patients require multiple-drug therapy. The role of thiazides in hypertension is discussed in [Chapter 46](#).

41.4.1.3.2 Edema.

Thiazides are preferred drugs for mobilizing edema associated with mild to moderate heart failure. They are also given to mobilize edema associated with hepatic or renal disease.

41.4.1.3.3 Diabetes Insipidus.

Diabetes insipidus is a rare condition characterized by excessive production of urine. In patients with this disorder, thiazides reduce urine production by 30% to 50%. The mechanism of this paradoxical effect is unclear.

41.4.1.4 Adverse Effects

The adverse effects of thiazide diuretics are similar to those of the high-ceiling agents. In fact, with the exception that thiazides lack ototoxic actions, the adverse effects of the thiazides and loop diuretics are nearly identical.

41.4.1.4.1 Hyponatremia, Hypochloremia, and Dehydration.

Loss of sodium, chloride, and water can lead to hyponatremia, hypochloremia, and dehydration. It should be noted, however, that since the diuresis produced by thiazides is moderate, these drugs have a smaller impact on sodium, chloride, and water than do the loop diuretics. To evaluate fluid and electrolyte status, electrolyte levels should be determined periodically, and the patient should be weighed on a regular basis.

41.4.1.4.2 Hypokalemia.

Like the high-ceiling diuretics, the thiazides can cause hypokalemia from excessive potassium excretion. As noted, potassium loss is of particular concern for patients taking digoxin. Potassium levels should be measured periodically, and, if serum potassium falls below 3.5 mEq/L, treatment with potassium supplements or a potassium-sparing diuretic should be instituted. Hypokalemia can be minimized by eating potassium-rich foods.

41.4.1.4.3 Use in Pregnancy and Lactation.

The thiazides have direct and indirect effects on the developing fetus. By reducing blood volume, thiazides can decrease placental perfusion, and may thereby compromise fetal nutrition and growth. Furthermore, thiazides can cross the placental barrier to produce fetal harm directly. Potential effects include electrolyte imbalance, hypoglycemia, jaundice, and hemolytic anemia. Because of the potential for fetal harm, *thiazides should not be used routinely during pregnancy*. Edema of pregnancy is not an indication for diuretic therapy, except when severe. In contrast, edema from pathologic causes (eg, heart failure, cirrhosis) does constitute a legitimate indication for thiazide use.

Thiazides enter breast milk and can be hazardous to the nursing infant. Women taking thiazides should be cautioned against breast-feeding.

448

41.4.1.4.4 Hyperglycemia.

449

Like the loop diuretics, the thiazides can elevate plasma levels of glucose. Significant hyperglycemia develops only in diabetic patients, who should be especially diligent about monitoring blood glucose. To maintain normal glucose levels, the diabetic patient may require larger doses of insulin or an oral hypoglycemic drug.

41.4.1.4.5 Hyperuricemia.

The thiazides, like the loop diuretics, can cause retention of uric acid, thereby elevating plasma uric acid levels. Although hyperuricemia is usually asymptomatic, it may precipitate gouty arthritis in patients with a history of the disorder. Plasma levels of uric acid should be measured periodically.

41.4.1.4.6 Impact on Lipids, Calcium, and Magnesium.

Thiazides can increase levels of LDL cholesterol, total cholesterol, and triglycerides. Thiazides reduce urinary excretion of calcium, an effect that has been used to treat calcium-related kidney stones. Thiazides increase excretion of magnesium, sometimes causing magnesium deficiency. Symptoms include muscle weakness, tremor, twitching, and dysrhythmias.

41.4.1.5 Drug Interactions

The important drug interactions of the thiazides are nearly identical to those of the loop diuretics. By promoting potassium loss, thiazides can increase the risk of toxicity from *digoxin*. By counterbalancing the potassium-wasting effects of the thiazides, the *potassium-sparing diuretics* can help prevent excessive potassium loss. By lowering blood pressure, thiazides can augment the effects of other *antihypertensive drugs*. By promoting sodium loss, thiazides can reduce renal excretion of *lithium*, thereby causing the drug to accumulate, possibly to toxic levels. *NSAIDs* may blunt the diuretic effects of thiazides. In contrast to the loop diuretics, the thiazides can be combined with *ototoxic agents* without an increased risk of hearing loss.

41.4.1.6 Preparations, Dosage, and Administration

Hydrochlorothiazide [HydroDIURIL, others] is supplied in capsules (12.5 mg) and tablets (12.5, 25, 50, and 100 mg). Like most other thiazides, hydrochlorothiazide is administered only by

mouth. The usual adult dosage is 25 to 50 mg once or twice daily. To minimize nocturia, the drug should not be administered late in the day. To minimize electrolyte imbalance, the drug should be administered on an intermittent basis (eg, every other day). In addition to being marketed alone, hydrochlorothiazide is available in fixed-dose combinations with potassium-sparing diuretics and a long list of other drugs: beta blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, calcium channel blockers, reserpine, hydralazine, clonidine, methyldopa, and prazosin (see [Table 46-6](#)).

41.4.2 Other Thiazide-Type Diuretics

In addition to hydrochlorothiazide, five other thiazides (and related drugs) are approved for use in the United States ([Table 40-2](#)). All have pharmacologic properties similar to those of hydrochlorothiazide. With the exception of chlorothiazide, these drugs are administered only by mouth. Chlorothiazide can be administered IV as well as PO. Although the thiazides differ from one another in milligram potency (see [Table 40-2](#)), at therapeutically equivalent doses, all elicit the same degree of diuresis. Although most have the same onset time (1 to 2 hours), these drugs differ significantly with respect to duration of action. As with hydrochlorothiazide, disturbance of electrolyte balance can be minimized through alternate-day dosing. Nocturia can be minimized by avoiding dosing in the late afternoon. [Table 40-2](#) lists three drugs—chlorthalidone, indapamide, and metolazone—that are not true thiazides. However, these agents are very similar to thiazides both in structure and function, hence their inclusion in this group.

41.5 POTASSIUM-SPARING DIURETICS

The potassium-sparing diuretics can elicit two potentially useful responses. First, they produce a modest increase in urine production. Second, they produce a substantial *decrease in potassium excretion*. Because their diuretic effects are limited, the potassium-sparing drugs are rarely employed alone to promote diuresis. However, because of their marked ability to decrease potassium excretion, these drugs are often used to counteract potassium loss caused by thiazide and loop diuretics.

There are two subcategories of potassium-sparing diuretics: *aldosterone antagonists* and *nonaldosterone antagonists*. In the United States, only one aldosterone antagonist—spironolactone—is used for diuresis.* Two nonaldosterone antagonists—triamterene and amiloride—are currently employed.

41.5.1 Spironolactone

41.5.1.1 Mechanism of Action

Spironolactone [Aldactone] blocks the actions of aldosterone in the distal nephron. Since aldosterone acts to promote sodium uptake in exchange for potassium secretion (see [Fig. 40-2](#)), inhibition of aldosterone has the opposite effect: *retention of potassium and increased excretion of sodium*. The diuresis caused by spironolactone is scanty because most of the filtered sodium load has already been reabsorbed by the time the filtrate reaches the distal nephron. (Recall that the degree of diuresis a drug produces is directly proportional to the amount of sodium reuptake that it blocks.)

As indicated in [Table 40-3](#), the effects of spironolactone are delayed, taking up to 48 hours to develop. Why the delay? Recall that aldosterone acts by stimulating cells of the distal nephron to synthesize the proteins required for sodium and potassium transport. By preventing aldosterone's action, spironolactone blocks the synthesis of *new* proteins, but does not stop existing transport proteins from doing their job. Hence, effects are not visible until the existing proteins complete their normal life cycle—a process that takes 1 or 2 days.

449

450

TABLE 40-2 Thiazides and Related Diuretics: Dosages and Time Course of Effects

		Time Course		Optimal Oral Adult Dosage (mg/day)
Generic Name	Trade Name	Onset (hr)	Duration (hr)	
Thiazides				
Chlorothiazide	Diuril	1–2	6–12	500–1000
Hydrochlorothiazide	HydroDIURIL, Hydro-Par, Ezide, Microzide	2	6–12	12.5–25
Methyclothiazide	Enduron	2	24	2.5–5
Related Drugs				
Chlorthalidone	Hygroton, Thalitone	2	24–72	50–100
Indapamide	Lozol	1–2	Up to 36	2.5–5
Metolazone	Zaroxolyn	1	12–24	2.5–20

* Another aldosterone antagonist—*eplerenone*—is available, but the drug is not considered a diuretic. The basic pharmacology of eplerenone and its main use (heart failure) are discussed in [Chapters 43](#) and [47](#), respectively.

TABLE 40-3 Potassium-Sparing Diuretics: Names, Dosages and Time Course of Effects

Generic Name	Trade Name	Time Course		Usual Adult Dosage (mg/day)
		Onset (hr)	Duration (hr)	
Spironolactone	Aldactone	24–48	48–72	25–200
Triamterene	Dyrenium	2–4	12–16	200–300
Amiloride	Midamor	2	24	5–20

41.5.1.2 Therapeutic Uses

41.5.1.2.1 Hypertension and Edema.

Spironolactone is used primarily for hypertension and edema. Although it can be employed alone, the drug is used most commonly in combination with a thiazide or loop diuretic. The purpose of spironolactone in these combinations is to counteract the potassium-wasting effects of the more powerful diuretics. Spironolactone also makes a small contribution to diuresis.

41.5.1.2.2 Heart Failure.

In patients with severe heart failure, spironolactone greatly reduces mortality and hospital admissions. Benefits derive from protective effects of aldosterone blockade in the heart and blood vessels (see [Chapter 47](#)).

41.5.1.2.3 Other Uses.

In addition to the applications discussed above, spironolactone can be used for primary hyperaldosteronism ([Chapter 59](#)), premenstrual syndrome ([Chapter 60](#)), polycystic ovary syndrome ([Chapter 62](#)), and acne in young women ([Chapter 104](#)).

41.5.1.3 Adverse Effects

41.5.1.3.1 Hyperkalemia.

The potassium-sparing effects of spironolactone can result in hyperkalemia, a condition that can produce fatal dysrhythmias. Although hyperkalemia is most likely when spironolactone is used alone, it can also develop when spironolactone is used in conjunction with potassium-wasting agents (thiazides and high-ceiling diuretics). If serum potassium rises above 5 mEq/L, or if signs of hyperkalemia develop (eg, abnormal cardiac rhythm), spironolactone should be discontinued and potassium intake restricted. Injection of insulin can help lower potassium levels by promoting potassium uptake into cells.

41.5.1.3.2 Benign and Malignant Tumors.

When given long term to rats in doses 25 to 250 times those used in humans, spironolactone caused benign adenomas of the thyroid and testes, malignant mammary tumors, and proliferative changes in the liver. The risk of tumors in humans from use of normal doses is unknown.

41.5.1.3.3 Endocrine Effects.

Spironolactone is a steroid derivative with a structure similar to that of steroid hormones (eg, progesterone, estradiol, testosterone). As a result, spironolactone can cause a variety of endocrine effects, including *gynecomastia*, *menstrual irregularities*, *impotence*, *hirsutism*, and *deepening of the voice*.

41.5.1.4 Drug Interactions

41.5.1.4.1 Thiazide and Loop Diuretics.

Spironolactone is frequently combined with thiazide and loop diuretics. The goal is to counteract the potassium-wasting effects of the more powerful diuretic.

41.5.1.4.2 Agents That Raise Potassium Levels.

Because of the risk of hyperkalemia, *spironolactone must never be combined with potassium supplements, salt substitutes (which contain potassium chloride), or another potassium-sparing diuretic*. In addition, three groups of drugs—*angiotensin-converting enzyme (ACE) inhibitors*, *angiotensin receptor blockers*, and *direct renin inhibitors*—can elevate potassium

levels (by suppressing aldosterone secretion), and hence should be combined with spironolactone only when clearly necessary.

41.5.1.5 Preparations, Dosage, and Administration

Spironolactone [Aldactone] is dispensed in tablets (25, 50, and 100 mg) for oral administration. The usual adult dosage is 25 to 100 mg/day. Spironolactone is also marketed in a fixed-dose combination with hydrochlorothiazide under the trade name Aldactazide.

41.5.2 Triamterene

41.5.2.1 Mechanism of Action

Like spironolactone, triamterene [Dyrenium] disrupts sodium-potassium exchange in the distal nephron. However, in contrast to spironolactone, which reduces ion transport *indirectly* through blockade of aldosterone, triamterene is a *direct inhibitor of the exchange mechanism itself*. The net effect of inhibition is a decrease in sodium reuptake and a reduction in potassium secretion. Hence, sodium excretion is increased, while potassium is conserved. Because it inhibits ion transport directly, triamterene acts much more quickly than spironolactone. As indicated in [Table 40-3](#), initial responses develop in hours, compared with days for spironolactone. As with spironolactone, diuresis with triamterene is scant.

41.5.2.2 Therapeutic Uses

Triamterene can be used alone or in combination with other diuretics to treat *hypertension* and *edema*. When used alone, triamterene produces mild diuresis. When combined with other diuretics (eg, furosemide, hydrochlorothiazide), triamterene augments diuresis and helps counteract the potassium-wasting effects of the more powerful diuretic. It is the latter effect for which triamterene is principally employed.

41.5.2.3 Adverse Effects

41.5.2.3.1 Hyperkalemia.

Excessive potassium accumulation is the most significant adverse effect. Hyperkalemia is most likely when triamterene is used alone, but can also occur when the drug is combined with thiazides or high-ceiling agents. Triamterene should never be used in conjunction with another potassium-sparing diuretic or with potassium supplements or salt substitutes. In addition, caution is needed if the drug is combined with an ACE inhibitor, angiotensin receptor blocker, or direct renin inhibitor.

41.5.2.3.2 Other Adverse Effects.

Relatively common side effects include *nausea, vomiting, leg cramps, and dizziness*. Blood dyscrasias occur rarely.

41.5.2.4 Preparations, Dosage, and Administration

Triamterene [Dyrenium] is available in 50- and 100-mg capsules for oral use. The usual initial dosage is 100 mg twice a day. The maximum daily dosage is 300 mg. Triamterene is also marketed in fixed-dose combinations with hydrochlorothiazide under the trade names Dyazide and Maxzide.

41.5.3 Amiloride

41.5.3.1 Pharmacologic Properties.

Amiloride [Midamor] has actions similar to those of triamterene. Both drugs inhibit potassium loss by direct blockade of sodium-potassium exchange in the distal nephron. Also, both drugs produce only modest diuresis. Although it can be employed alone as a diuretic, amiloride is used primarily to counteract potassium loss caused by more powerful diuretics (thiazides, high-ceiling agents). The major adverse effect is hyperkalemia. Accordingly, concurrent use of other potassium-sparing diuretics or potassium supplements must be avoided. Caution is needed if the drug is combined with an ACE inhibitor, angiotensin receptor blocker, or direct renin inhibitor.

41.5.3.2 Preparations, Dosage, and Administration.

Amiloride [Midamor] is supplied in 5-mg tablets for oral use. Dosing is begun at 5 mg/day and may be increased to a maximum of 20 mg/day. Amiloride is available in a fixed-dose combination with hydrochlorothiazide under the trade name Moduretic.

41.6 OSMOTIC DIURETICS

Four compounds—mannitol, urea, glycerin, and isosorbide—are classified as osmotic diuretics. However, of the four, only mannitol is used for its diuretic actions. The osmotic agents differ from other diuretics in both mechanism and indications.

41.6.1 Mannitol

Mannitol [Osmitrol] is a simple six-carbon sugar that possesses the four properties characteristic of an osmotic diuretic:

- It is freely filtered at the glomerulus.
- It undergoes minimal reabsorption.
- It is not metabolized to a significant degree.
- It is pharmacologically inert (ie, it has no direct effects on the biochemistry or physiology of cells).

41.6.1.1 Mechanism of Diuretic Action

Mannitol promotes diuresis by creating an osmotic force within the lumen of the nephron. Unlike other solutes, mannitol undergoes minimal reabsorption after filtration. As a result, most of the drug remains within the nephron, creating an osmotic force that inhibits passive reabsorption of water. Hence, urine flow increases. The degree of diuresis produced is directly related to the concentration of mannitol in the filtrate; the more mannitol present, the greater the diuresis. Mannitol has no significant effect on the excretion of potassium and other electrolytes.

41.6.1.2 Pharmacokinetics

Mannitol does not diffuse across the GI epithelium and cannot be transported by the uptake systems that absorb dietary sugars. Accordingly, in order to reach the circulation, the drug must be given parenterally. Following IV injection, mannitol distributes freely to extracellular water. Diuresis begins in 30 to 60 minutes and persists 6 to 8 hours. Most of the drug is excreted intact in the urine.

41.6.1.3 Therapeutic Uses

41.6.1.3.1 Prophylaxis of Renal Failure.

Under certain conditions (eg, dehydration, severe hypotension, hypovolemic shock), blood flow to the kidney is decreased, causing a great reduction in filtrate volume. When the volume of filtrate is this low, transport mechanisms of the nephron are able to reabsorb virtually all of the sodium and chloride present, causing complete reabsorption of water as well. As a result, urine production ceases, and kidney failure ensues. The risk of renal failure can be reduced with mannitol. Because filtered mannitol is not reabsorbed—even when filtrate volume is small—filtered mannitol will remain in the nephron, drawing water with it. Hence, mannitol can preserve urine flow and may thereby prevent renal failure. Thiazides and loop diuretics are not as effective for this application because, under conditions of low filtrate production,

there is such an excess of reabsorptive capacity (relative to the amount of filtrate) that these drugs are unable to produce sufficient blockade of reabsorption to promote diuresis.

41.6.1.3.2 Reduction of Intracranial Pressure.

Intracranial pressure (ICP) that has been elevated by cerebral edema can be reduced with mannitol. The drug lowers ICP because its presence in the cerebral vasculature creates an osmotic force that draws edematous fluid out of the brain. There is no risk of increasing cerebral edema because mannitol cannot exit the capillary beds of the brain.

41.6.1.3.3 Reduction of Intraocular Pressure.

Mannitol and other osmotic agents can lower IOP. Mannitol reduces IOP by rendering the plasma hyperosmotic with respect to intraocular fluids, thereby creating an osmotic force that draws ocular fluid into the blood. Use of mannitol to lower IOP is reserved for patients who have not responded to more conventional treatment.

41.6.1.4 Adverse Effects

41.6.1.4.1 Edema.

Mannitol can leave the vascular system at all capillary beds except those of the brain. When the drug exits capillaries, it draws water along, causing edema. Mannitol must be used with extreme caution in patients with heart disease, since it may precipitate CHF and pulmonary edema. If signs of pulmonary congestion or CHF develop, use of the drug must cease immediately. Mannitol must also be discontinued if patients with heart failure or pulmonary edema develop renal failure, because the resultant accumulation of mannitol would increase the risk of cardiac or pulmonary injury.

41.6.1.4.2 Other Adverse Effects.

Common responses include headache, nausea, and vomiting. Fluid and electrolyte imbalance may also occur.

41.6.1.5 Preparations, Dosage, and Administration

Mannitol [Osmitrol] is administered by IV infusion. Solutions for IV use range in concentration from 5% to 25%. Dosing is complex and varies with the objective of therapy (prevention of renal failure, lowering of ICP, lowering of IOP). The usual adult dosage for preventing renal failure is 50 to 100 gm over 24 hours. The infusion rate should be set to elicit a urine flow of at least 30 to 50 mL/hr. It should be noted that mannitol may crystallize out of solution if exposed

to low temperature. Accordingly, preparations should be observed for crystals prior to use. Preparations that contain crystals should be warmed (to redissolve the mannitol) and then cooled to body temperature for administration. A filter needle is employed to withdraw mannitol from the vial, and an in-line filter is used to prevent crystals from entering the circulation. If urine flow declines to a very low rate or ceases entirely, the infusion should be stopped.

41.6.2 Urea, Glycerin, and Isosorbide

In addition to mannitol, three other drugs—urea, glycerin, and isosorbide—are classified as osmotic diuretics. Like mannitol, these agents are freely filtered at the glomerulus and undergo limited reabsorption. These properties promote osmotic diuresis. It must be noted, however, that although urea, glycerin, and isosorbide can produce diuresis, they are not actually used for this purpose. Rather, they are used only to reduce IOP and ICP. Urea [Ureaphil] is administered intravenously. Glycerin [Osmoglyn] and isosorbide [Ismotic] are administered by mouth.

41.6.2.1

<p>KEY POINTS</p> <ul style="list-style-type: none">▪ More than 99% of the water, electrolytes, and nutrients that are filtered at the glomerulus undergo reabsorption.▪ Most diuretics block active reabsorption of sodium and chloride, and thereby prevent passive reabsorption of water.▪ The amount of diuresis produced is directly related to the amount of sodium and chloride reabsorption blocked.▪ Drugs that act early in the nephron are in a position to block the greatest amount of solute reabsorption, and hence produce the greatest diuresis.▪ High-ceiling diuretics (loop diuretics) block sodium and chloride reabsorption in the loop of Henle.	451
<ul style="list-style-type: none">▪ High-ceiling diuretics produce the greatest diuresis.▪ In contrast to thiazide diuretics, high-ceiling diuretics are effective even when the glomerular filtration rate is low.▪ High-ceiling diuretics can cause dehydration through excessive fluid loss.▪ High-ceiling diuretics can cause hypotension by decreasing blood volume and relaxing venous smooth muscle.	452

- High-ceiling diuretics can cause hearing loss, which is usually reversible.
- Hypokalemia caused by high-ceiling diuretics is a special problem for patients taking digoxin.
- Thiazide diuretics block sodium and water reabsorption in the early distal convoluted tubule.
- Thiazide diuretics produce less diuresis than high-ceiling diuretics.
- Thiazide diuretics are ineffective when glomerular filtration rate is low.
- Like the high-ceiling diuretics, thiazide diuretics can cause dehydration and hypokalemia. However, thiazides do not cause hearing loss.
- Thiazide-induced hypokalemia is a special problem for patients taking digoxin.
- Potassium-sparing diuretics act by directly or indirectly blocking sodium-potassium “exchange” in the distal convoluted tubule.
- Potassium-sparing diuretics cause only modest diuresis.
- Potassium-sparing diuretics are used primarily to counteract potassium loss in patients taking high-ceiling diuretics or thiazides.
- The principal adverse effect of potassium-sparing diuretics is hyperkalemia.
- Because of the risk of hyperkalemia, potassium-sparing diuretics should not be combined with one another or with potassium supplements, and they should be used cautiously in patients taking ACE inhibitors, angiotensin receptor blockers, or direct renin inhibitors.
- High-ceiling diuretics and thiazides are used to treat hypertension and edema associated with heart failure, cirrhosis, and kidney disease.

41.6.2.2

Summary of Major Nursing Implications*

41.6.2.2.1

HIGH-CEILING (LOOP) DIURETICS

Bumetanide

Ethacrynic acid

Furosemide

Torsemide

41.6.2.2...

Preadministration Assessment

41.6.2.2...

Therapeutic Goal

High-ceiling diuretics are indicated for patients with (1) pulmonary edema associated with congestive heart failure; (2) edema of hepatic, cardiac, or renal origin that has been unresponsive to less effective diuretics; (3) hypertension that cannot be controlled with thiazide and potassium-sparing diuretics; and (4) all patients who need diuretic therapy but have low renal blood flow.

41.6.2.2...

Baseline Data

For all patients, obtain baseline values for weight, blood pressure (sitting and supine), pulse, respiration, and electrolytes (sodium, potassium, chloride). For patients with edema, record sites and extent of edema. For patients with ascites, measure abdominal girth. For acutely ill patients (eg, severe CHF), assess lung sounds.

41.6.2.2...

Identifying High-Risk Patients

Use with *caution* in patients with cardiovascular disease, renal impairment, diabetes mellitus, or a history of gout, and in patients who are pregnant or taking digoxin, lithium, ototoxic drugs, NSAIDs, or antihypertensive drugs.

41.6.2.2...

Implementation: Administration

41.6.2.2...

Routes

Furosemide and Bumetanide. Oral, IV, IM.

Ethacrynic Acid and Torsemide. Oral, IV.

41.6.2.2...	Administration	
41.6.2.2...	Oral.	
	Dosing may be done once daily, twice daily, or on alternate days. Instruct patients who are using once-a-day or alternate-day dosing to take their medication in the morning. Instruct patients using twice-a-day dosing to take their medication at 8:00 AM and 2:00 PM (to minimize nocturia).	
	Advise patients to administer furosemide with food if GI upset occurs.	
41.6.2.2...	Parenteral.	
	Administer IV injections slowly (over 1 to 2 minutes). For high-dose therapy, administer by continuous infusion. Discard discolored solutions.	
41.6.2.2...	Promoting Adherence	
	Increased frequency of urination is inconvenient and can discourage adherence. To promote adherence, inform patients that treatment will increase urine volume and frequency of voiding, and that these effects will subside 6 to 8 hours after dosing. Inform patients that nighttime diuresis can be minimized by avoiding dosing late in the day.	
41.6.2.2...	Ongoing Evaluation and Interventions	
41.6.2.2...	Evaluating Therapeutic Effects	
	Monitor blood pressure and pulse rate, weigh the patient daily, and evaluate for decreased edema.	452
	Monitor intake and output. Notify the prescriber if oliguria (urine output less than 25 mL/hr) or anuria (no urine output) develops.	453
	Instruct outpatients to weigh themselves daily (using the same scale), preferably in the morning before eating. Also, instruct them to maintain a weight record, and to report excessive weight gain or weight loss.	
	In acute conditions requiring rapid diuresis and careful monitoring, a Foley catheter may be used. The catheter should be emptied prior to drug injection, and output should be monitored hourly and recorded.	

41.6.2.2...

Minimizing Adverse Effects

41.6.2.2...

Hyponatremia, Hypochloremia, and Dehydration.

Loss of sodium, chloride, and water can cause hyponatremia, hypochloremia, and severe dehydration. Signs of dehydration include dry mouth, unusual thirst, and oliguria. Withhold the drug if these appear.

Dehydration can promote thromboembolism. Monitor the patient for symptoms (headache; pain in the chest, calves, or pelvis), and notify the prescriber if these develop.

The risk of dehydration and its sequelae can be minimized by (1) initiating therapy with low doses, (2) adjusting the dosage carefully, (3) monitoring weight loss daily, and (4) using an intermittent dosing schedule.

41.6.2.2...

Hypotension.

Monitor blood pressure. If it falls precipitously, withhold medication and notify the prescriber.

Teach patients to monitor their blood pressure and instruct them to notify the prescriber if it drops substantially.

Inform patients about signs of postural hypotension (dizziness, lightheadedness), and advise them to sit or lie down if these occur. Inform patients that postural hypotension can be minimized by getting up slowly, and by dangling legs off the bed before standing.

41.6.2.2...

Hypokalemia.

If serum potassium falls below 3.5 mEq/L, fatal dysrhythmias may result.

Hypokalemia can be minimized by consuming potassium-rich foods (eg, nuts, dried fruits, spinach, citrus fruits, potatoes, bananas), taking potassium supplements, or using a potassium-sparing diuretic. **Teach patients the signs and symptoms of hypokalemia (eg, irregular heartbeat, muscle weakness, cramping, flaccid paralysis, leg discomfort, extreme thirst, confusion), and stress the importance of showing up for regular blood tests.**

41.6.2.2...

Ototoxicity.

Inform patients about possible hearing loss and instruct them to notify the prescriber if a hearing deficit develops. Exercise caution when high-ceiling diuretics are used concurrently with other ototoxic drugs, especially aminoglycosides.

41.6.2.2...

Hyperglycemia.

High-ceiling diuretics may elevate blood glucose levels in diabetic patients. **Advise these patients to be especially diligent about monitoring blood glucose.**

41.6.2.2...

Hyperuricemia.

High-ceiling diuretics frequently cause *asymptomatic* hyperuricemia, although gout-prone patients may experience a gouty attack. **Inform patients about signs of gout (tenderness or swelling in joints), and instruct them to notify the prescriber if these occur.**

41.6.2.2...

Minimizing Adverse Interactions

41.6.2.2...

Digoxin.

By lowering potassium levels, high-ceiling diuretics increase the risk of fatal dysrhythmias from digoxin. Serum potassium levels must be monitored and maintained above 3.5 mEq/L.

41.6.2.2...

Lithium.

High-ceiling diuretics can suppress lithium excretion, thereby causing the drug to accumulate, possibly to toxic levels. Plasma lithium should be monitored routinely. If drug levels become elevated, lithium dosage should be reduced.

41.6.2.2...

Ototoxic Drugs.

The risk of hearing loss from high-ceiling diuretics is increased in the presence of other ototoxic drugs, especially aminoglycosides. Exercise caution when such combinations are employed.

41.6.2.2.2

THIAZIDES AND RELATED DIURETICS

Chlorothiazide

Chlorthalidone

Hydrochlorothiazide

Indapamide

Methyclothiazide

Metolazone

Thiazide diuretics have actions much like those of the high-ceiling diuretics. Hence, nursing implications for the thiazides are nearly identical to those of the high-ceiling agents.

41.6.2.2...

Preadministration Assessment

41.6.2.2...

Therapeutic Goal

Thiazide diuretics are used to treat hypertension and edema.

41.6.2.2...

Baseline Data

For all patients, obtain baseline values for weight, blood pressure (sitting and supine), pulse, respiration, and electrolytes (sodium, chloride, potassium). For patients with edema, record sites and extent of edema.

41.6.2.2...

Identifying High-Risk Patients

Use with *caution* in patients with cardiovascular disease, renal impairment, diabetes mellitus, or a history of gout and in patients taking digoxin, lithium, or antihypertensive drugs. *Generally avoid* in women who are pregnant or breast-feeding.

41.6.2.2...

Implementation: Administration

41.6.2.2...

Routes

Oral. All thiazide-type diuretics.

Intravenous. Chlorothiazide.

41.6.2.2...	<p>Administration</p> <p>Dosing may be done once daily, twice daily, or on alternate days. When once-a-day dosing is employed, instruct patients to take their medicine early in the day to minimize nocturia. Caution women not to breast-feed.</p>	
41.6.2.2...	<p>Minimizing Adverse Interactions</p> <p>Like high-ceiling diuretics, thiazides can interact adversely with <i>digoxin</i> and <i>lithium</i>. For implications regarding these interactions, see nursing implications for <i>High-Ceiling (Loop) Diuretics</i>.</p>	
41.6.2.2.3	<p>POTASSIUM-SPARING DIURETICS</p> <p>Amiloride</p> <p>Spironolactone</p>	

Triamterene

Preadministration Assessment

Therapeutic Goal

Potassium-sparing diuretics are given primarily to counterbalance the potassium-losing effects of thiazides and high-ceiling diuretics.

Baseline Data

Obtain baseline values for serum potassium, along with baseline values for weight, blood pressure (sitting and supine), pulse, respiration, sodium, and chloride. For patients with edema, record sites and extent of edema.

Identifying High-Risk Patients

Potassium-sparing diuretics are *contraindicated* for patients with hyperkalemia and for patients taking potassium supplements or another potassium-sparing diuretic. Use with *caution* in patients taking ACE inhibitors, angiotensin receptor blockers, and direct renin inhibitors.

Implementation: Administration

Route

Oral.

Administration

Advise patients to take these drugs with or after meals if GI upset occurs.

Ongoing Evaluation and Interventions

Evaluating Therapeutic Effects

Monitor serum potassium levels on a regular basis. The objective is to maintain serum potassium levels between 3.5 and 5 mEq/L.

41.6.2.2...

Minimizing Adverse Effects

41.6.2.2...

Hyperkalemia.

Hyperkalemia is the principal adverse effect. **Instruct patients to restrict intake of potassium-rich foods (eg, nuts, dried fruits, spinach, citrus fruits, potatoes, bananas).** If serum potassium levels rise above 5 mEq/L, or if signs of hyperkalemia develop (eg, abnormal cardiac rhythm), withhold medication and notify the prescriber. Insulin can be given to (temporarily) drive potassium levels down.

41.6.2.2...

Endocrine Effects.

Spironolactone may cause *menstrual irregularities* and *impotence*. **Inform patients about these effects, and instruct them to notify the prescriber if they occur.**

41.6.2.2...

Minimizing Adverse Interactions

41.6.2.2...

Drugs That Raise Potassium Levels.

Because of the risk of hyperkalemia, don't combine a potassium-sparing diuretic with potassium supplements, salt substitutes, or with another potassium-sparing diuretic. Generally avoid combined use with ACE inhibitors, angiotensin receptor blockers, and direct renin inhibitors.

* Patient education information is highlighted as **blue text**.

⁴²CHAPTER 41 Agents Affecting the Volume and Ion Content of Body Fluids

The drugs discussed in this chapter are used to correct disturbances in the volume and ionic composition of body fluids. Three groups of agents are considered: (1) drugs used to correct disorders of fluid volume and osmolality, (2) drugs used to correct disturbances of hydrogen ion concentration (acid-base status), and (3) drugs used to correct electrolyte imbalances.

^{42.1}DISORDERS OF FLUID VOLUME AND OSMOLALITY

Good health requires that both the volume and osmolality of extracellular and intracellular fluids remain within a normal range. If a substantial alteration in either the volume or osmolality of these fluids develops, significant harm can result.

Maintenance of fluid volume and osmolality is primarily the job of the kidneys, and, even under adverse conditions, renal mechanisms usually succeed in keeping the volume and composition of body fluids within acceptable limits. However, circumstances can arise in which the regulatory capacity of the kidneys is exceeded. When this occurs, disruption of fluid volume, osmolality, or both can result.

Abnormal states of hydration can be divided into two major categories: volume contraction and volume expansion. *Volume contraction* is defined as a *decrease* in total body water; conversely, *volume expansion* is defined as an *increase* in total body water. States of volume contraction and volume expansion have three subclassifications based on alterations in extracellular osmolality. For volume contraction, the subcategories are *isotonic contraction*, *hypertonic contraction*, and *hypotonic contraction*. Volume expansion may also be subclassified as *isotonic*, *hypertonic*, or *hypotonic*. Descriptions and causes of these abnormal states are discussed below.

In the clinical setting, changes in osmolality are described in terms of the sodium content of plasma. Sodium is used as the reference for classification because this ion is the principal extracellular solute. (Recall that plasma sodium content ranges from 135 to 145 mEq/L.) In most cases, the total osmolality of plasma is equal to approximately twice the osmolality of sodium. That is, total plasma osmolality usually ranges from 280 to 300 mOsm/kg water.

42.1.1 Volume Contraction

42.1.1.1 Isotonic Contraction

42.1.1.1.1 Definition and Causes.

Isotonic contraction is defined as volume contraction in which *sodium and water are lost in isotonic proportions*. Hence, although there is a decrease in the total volume of extracellular fluid, there is no change in osmolality. Causes of isotonic contraction include vomiting, diarrhea, kidney disease, and misuse of diuretics. Isotonic contraction is characteristic of cholera, an infection that produces vomiting and severe diarrhea.

42.1.1.1.2 Treatment.

Lost volume should be replaced with fluids that are isotonic to plasma. This can be accomplished by infusing isotonic (0.9%) sodium chloride in sterile water, a solution in which both sodium and chloride are present at a concentration of 145 mEq/L. Volume should be replenished slowly to avoid pulmonary edema.

42.1.1.2 Hypertonic Contraction

42.1.1.2.1 Definition and Causes.

Hypertonic contraction is defined as volume contraction in which *loss of water exceeds loss of sodium*. Hence, there is a reduction in extracellular fluid volume coupled with an increase in osmolality. Because of extracellular hypertonicity, water is drawn out of cells, thereby producing intracellular dehydration and partial compensation for lost extracellular volume.

Causes of hypertonic contraction include excessive sweating, osmotic diuresis, and feeding excessively concentrated foods to infants. Hypertonic contraction may also develop secondary to extensive burns or disorders of the central nervous system (CNS) that render the patient unable to experience or report thirst.

42.1.1.2.2 Treatment.

Volume replacement in hypertonic contraction should be accomplished with hypotonic fluids (eg, 0.11% sodium chloride) or with fluids that contain no solutes at all. Initial therapy may consist simply of drinking water. Alternatively, 5% dextrose can be infused intravenously. (Since dextrose is rapidly metabolized to carbon dioxide and water, dextrose solutions can be

455

456

viewed as the osmotic equivalent of water alone.) Volume replenishment should be done in stages. About 50% of the estimated loss should be replaced during the first few hours of treatment. The remainder should be replenished over 1 to 2 days.

42.1.1.3 Hypotonic Contraction

42.1.1.3.1 Definition and Causes.

Hypotonic contraction is defined as volume contraction in which *loss of sodium exceeds loss of water*. Hence, both the volume and osmolality of extracellular fluid are reduced. Because intracellular osmolality now exceeds extracellular osmolality, extracellular volume becomes diminished further by movement of water into cells.

The principal cause of hypotonic contraction is excessive loss of sodium through the kidneys. This may occur because of diuretic therapy, chronic renal insufficiency, or lack of aldosterone (the adrenocortical hormone that promotes renal retention of sodium).

42.1.1.3.2 Treatment.

If hyponatremia is mild, and if renal function is adequate, hypotonic contraction can be corrected by infusing *isotonic* sodium chloride solution for injection. When this is done, plasma tonicity will be adjusted by the kidneys. However, if the sodium loss is severe, a *hypertonic* (eg, 3%) solution of sodium chloride should be infused. Administration should continue until plasma sodium concentration has been raised to about 130 mEq/L. Patients should be monitored for signs of fluid overload (distention of neck veins, peripheral or pulmonary edema). When hypotonic contraction is due to aldosterone insufficiency, patients should receive hormone replacement therapy along with intravenous infusion of isotonic sodium chloride.

42.1.2 Volume Expansion

Volume expansion is defined as an *increase in the total volume of body fluid*. As with volume contraction, volume expansion may be *isotonic*, *hypertonic*, or *hypotonic*. Volume expansion may result from an overdose with therapeutic fluids (eg, sodium chloride infusion) or may be associated with disease states, such as heart failure, nephrotic syndrome, or cirrhosis of the liver with ascites. The principal drugs employed to correct volume expansion are *diuretics* and the *agents used for heart failure*. These drugs are discussed in [Chapters 40](#) and [47](#), respectively.

42.2 ACID-BASE DISTURBANCES

Maintenance of acid-base balance is a complex process, the full discussion of which is beyond the scope of this text. Hence, discussion here is condensed.

Acid-base status is regulated by multiple systems. The most important are (1) the bicarbonate–carbonic acid buffer system, (2) the respiratory system, and (3) the kidneys. The respiratory system influences pH through control of CO₂ exhalation. Because CO₂ represents volatile carbonic acid, exhalation of CO₂ tends to elevate pH (reduce acidity), whereas retention of CO₂ (secondary to respiratory slowing) tends to lower pH. The kidneys influence pH by regulating bicarbonate excretion. By *retaining* bicarbonate, the kidneys can raise pH. Conversely, by increasing bicarbonate *excretion*, the kidneys can lower pH, and thereby compensate for alkalosis.

There are four principal types of acid-base imbalance: (1) respiratory alkalosis, (2) respiratory acidosis, (3) metabolic alkalosis, and (4) metabolic acidosis. Causes and treatments are discussed below.

42.2.1 Respiratory Alkalosis

42.2.1.1 Causes.

Respiratory alkalosis is produced by hyperventilation. Deep and rapid breathing increases CO₂ loss, which in turn lowers the pCO₂* of blood, and thereby increases pH. Mild hyperventilation may result from a number of causes, including hypoxia, pulmonary disease, and drugs (especially aspirin and other salicylates). Severe hyperventilation can be caused by CNS injury and hysteria.

* pCO₂ is the partial pressure of carbon dioxide in blood.

42.2.1.2 Treatment.

Management of respiratory alkalosis is dictated by the severity of pH elevation. When alkalosis is mild, no specific treatment is indicated. Severe respiratory alkalosis resulting from hysteria can be controlled by having the patient rebreathe his or her CO₂-laden expired breath. This can be accomplished by holding a paper bag over the nose and mouth. A similar effect can be achieved by having the patient inhale a gas mixture containing 5% CO₂. A sedative (eg, diazepam [Valium]) can help suppress the hysteria.

42.2.2 Respiratory Acidosis

42.2.2.1 Causes.

Respiratory acidosis results from retention of CO₂ secondary to hypoventilation. Reduced CO₂ exhalation raises plasma pCO₂, which in turn causes plasma pH to fall. Primary causes of impaired ventilation are (1) depression of the medullary respiratory center, and (2) pathologic changes in the lungs (eg, status asthmaticus, airway obstruction). Over time, the kidneys compensate for respiratory acidosis by excreting less bicarbonate.

42.2.2.2 Treatment.

Primary treatment of respiratory acidosis is directed at correcting respiratory impairment. The patient may also need oxygen and ventilatory assistance. Infusion of sodium bicarbonate may be indicated if acidosis is severe.

42.2.3 Metabolic Alkalosis

42.2.3.1 Causes.

Metabolic alkalosis is characterized by increases in both the pH and bicarbonate content of plasma. Causes include excessive loss of gastric acid (through vomiting or suctioning) and administration of alkalinizing salts (eg, sodium bicarbonate). The body compensates for metabolic alkalosis by (1) hypoventilation (which causes retention of CO₂), (2) increased renal excretion of bicarbonate, and (3) accumulation of organic acids.

42.2.3.2 Treatment.

In most cases, metabolic alkalosis can be corrected by infusing a solution of *sodium chloride plus potassium chloride*. This facilitates renal excretion of bicarbonate, and thereby promotes normalization of plasma pH. When alkalosis is severe, direct correction of pH is indicated. This can be accomplished by infusing dilute (0.1 N) *hydrochloric acid* through a central venous catheter or by administering an acid-forming salt, such as *ammonium chloride*. However, ammonium chloride must not be given to patients with liver failure, because the drug is likely to cause hepatic encephalopathy in these patients.

456

457

42.2.4 Metabolic Acidosis

42.2.4.1 Causes.

Principal causes of metabolic acidosis are chronic renal failure, loss of bicarbonate during severe diarrhea, and metabolic disorders that result in overproduction of lactic acid (lactic acidosis) or ketoacids (ketoacidosis). Metabolic acidosis may also result from poisoning by methanol and certain medications (eg, aspirin and other salicylates).

42.2.4.2 Treatment.

Treatment consists of correcting the underlying cause of acidosis, and, if the acidosis is severe, administering an alkalinizing salt (eg, sodium bicarbonate, sodium carbonate).

When an alkalinizing salt is indicated, *sodium bicarbonate* is generally preferred.

Administration may be oral or intravenous. If acidosis is mild, oral administration is preferred. Intravenous infusion is usually reserved for severe reductions of pH. When sodium bicarbonate is given IV to treat acute, severe acidosis, caution must be exercised to avoid excessive elevation of plasma pH. Why? Because rapid conversion from acidosis to alkalosis can be hazardous. Also, because of the sodium content of sodium bicarbonate, care should be taken to avoid hypernatremia.

42.3 POTASSIUM IMBALANCES

Potassium is the most abundant *intracellular* cation, having a concentration within cells of about 150 mEq/L. In contrast, *extracellular* concentrations are low (4 to 5 mEq/L). Potassium plays a major role in conducting nerve impulses and maintaining the electrical excitability of muscle. Potassium also helps regulate acid-base balance.

42.3.1 Regulation of Potassium Levels

Serum levels of potassium are regulated primarily by the kidneys. Under steady-state conditions, urinary output of potassium equals intake. Renal excretion of potassium is increased by aldosterone, an adrenal steroid that promotes conservation of sodium while increasing potassium loss. Potassium excretion is also increased by most diuretics. Potassium-sparing diuretics (eg, spironolactone) are the exception.

Potassium levels are influenced by extracellular pH. In the presence of extracellular *alkalosis*, potassium uptake by cells is *enhanced*, causing a *reduction* in extracellular potassium levels.

Conversely, extracellular *acidosis* promotes the exit of potassium from cells, thereby causing extracellular *hyperkalemia*.

Insulin has a profound effect on potassium: In high doses, insulin stimulates potassium uptake by cells—an ability that has been exploited to treat hyperkalemia.

42.3.2 Hypokalemia

42.3.2.1 Causes and Consequences

Hypokalemia is defined as a deficiency of potassium in the blood. By definition, hypokalemia exists when serum potassium levels fall below 3.5 mEq/L. The most common cause is treatment with a thiazide or loop diuretic (see [Chapter 40](#)). Other causes include insufficient potassium intake; alkalosis and excessive insulin (both of which decrease extracellular potassium levels by driving potassium into cells); increased renal excretion of potassium (eg, as caused by aldosterone); and potassium loss associated with vomiting, diarrhea, and abuse of laxatives. Hypokalemia may also occur because of excessive potassium loss in sweat. As a rule, potassium depletion is accompanied by loss of chloride. Insufficiency of both ions produces *hypokalemic alkalosis*.

Hypokalemia has adverse effects on skeletal muscle, smooth muscle, blood pressure, and the heart. Symptoms include weakness or paralysis of skeletal muscle, a risk of fatal dysrhythmias, and intestinal dilation and ileus. In patients taking digoxin (a cardiac drug), hypokalemia is the principal cause of digoxin toxicity. For all people, hypokalemia increases the risk of hypertension and stroke.

42.3.2.2 Prevention and Treatment

Potassium depletion can be treated with three potassium salts: potassium chloride, potassium phosphate, and potassium bicarbonate. These may also be used for prophylaxis against potassium insufficiency. For either treatment or prophylaxis, the preferred salt is *potassium chloride*. Why? Because chloride deficiency frequently coexists with potassium deficiency.

Potassium chloride may be administered PO or IV. Oral therapy is preferred for prophylaxis and for treating mild deficiency. Intravenous therapy is reserved for severe deficiency and for patients who cannot take potassium by mouth.

42.3.2.2.1 Oral Potassium Chloride.

42.3.2.2.1.1 Uses, Dosage, and Preparations.

Oral potassium chloride may be used for both prevention and treatment of potassium deficiency. Dosages for prevention range from 16 to 24 mEq/day. Dosages for deficiency range from 40 to 100 mEq/day.

Oral potassium chloride is available in solution and in solid formulations: immediate-release tablets, sustained-release tablets, effervescent tablets, and powders. *The sustained-release tablets (eg, K-Dur, Micro-K) are preferred.* Why? Because they are more convenient and better tolerated than the other formulations, and hence offer the best chance of patient adherence.

42.3.2.2.1.2 Adverse Effects.

Potassium chloride irritates the GI tract, frequently causing abdominal discomfort, nausea, vomiting, and diarrhea. With the exception of the sustained-release tablets, solid formulations can produce high local concentrations of potassium, resulting in severe intestinal injury (ulcerative lesions, bleeding, perforation); death has occurred. To minimize GI effects, oral potassium chloride should be taken with meals or a full glass of water. If symptoms of irritation occur, administration should be discontinued. Rarely, oral potassium chloride produces hyperkalemia. This dangerous development is much more likely with IV therapy.

42.3.2.2.2 Intravenous Potassium Chloride.

Intravenous potassium chloride is indicated for prevention and treatment of hypokalemia. Intravenous solutions must be diluted (preferably to 40 mEq/L or less) and infused slowly (generally no faster than 10 mEq/hr in adults).

The principal complication is *hyperkalemia*, which can prove fatal. To reduce the risk of hyperkalemia, serum potassium levels should be measured prior to the infusion and periodically throughout the treatment interval. Also, renal function should be assessed before and during treatment to ensure adequate output of urine. If renal failure develops, the infusion should be stopped immediately. Changes in the electrocardiogram (ECG) can be an early indication that potassium toxicity is developing.

457

458

42.3.2.2.3 Contraindications to Potassium Use.

Potassium should be avoided under conditions that predispose the patient to hyperkalemia (eg, severe renal impairment, use of potassium-sparing diuretics, hypoaldosteronism). Potassium must also be avoided when hyperkalemia already exists.

42.3.3 Hyperkalemia

42.3.3.1 Causes.

Hyperkalemia (excessive elevation of serum potassium) can result from a number of causes. These include severe tissue trauma, untreated Addison's disease, acute acidosis (which draws potassium out of cells), misuse of potassium-sparing diuretics, and overdose with IV potassium.

42.3.3.2 Consequences.

The most serious consequence of hyperkalemia is disruption of the electrical activity of the heart. Because hyperkalemia alters the generation and conduction of cardiac impulses, alterations in the ECG and cardiac rhythm are usually the earliest signs that potassium levels are growing dangerously high. With mild elevation of serum potassium (5 to 7 mEq/L), the T wave heightens and the PR interval becomes prolonged. When serum potassium reaches 8 to 9 mEq/L, cardiac arrest can occur, possibly preceded by ventricular tachycardia or fibrillation.

Effects of hyperkalemia are not limited to the heart. Noncardiac effects include confusion, anxiety, dyspnea, weakness or heaviness of the legs, and numbness or tingling of the hands, feet, and lips.

42.3.3.3 Treatment.

Treatment is begun by withholding any foods that contain potassium and any medicines that promote potassium accumulation (eg, potassium-sparing diuretics, potassium supplements). After this, management consists of measures that (1) counteract potassium-induced cardiotoxicity and (2) lower extracellular levels of potassium. Specific steps include (1) infusion of a *calcium salt* (eg, calcium gluconate) to offset effects of hyperkalemia on the heart; (2) infusion of *glucose* and *insulin* to promote uptake of potassium by cells and thereby decrease extracellular potassium levels; and (3) if acidosis is present (which is likely), infusion of *sodium bicarbonate* to move pH toward alkalinity, and thereby increase cellular uptake of potassium. If these measures prove inadequate, steps can be taken to remove potassium. These include (1)

oral or rectal administration of *sodium polystyrene sulfonate* [Kayexalate], an exchange resin that absorbs potassium; and (2) peritoneal or extracorporeal dialysis.

42.4 MAGNESIUM IMBALANCES

Magnesium is required for the activity of many enzymes and for binding of messenger RNA to ribosomes. In addition, magnesium helps regulate neurochemical transmission and the excitability of muscle. The concentration of magnesium within cells is about 40 mEq/L, much higher than its concentration outside cells (about 2 mEq/L).

42.4.1 Hypomagnesemia

42.4.1.1 Causes and Consequences

Low levels of magnesium may result from a variety of causes, including diarrhea, hemodialysis, kidney disease, and prolonged intravenous feeding with magnesium-free solutions.

Hypomagnesemia may also be seen in chronic alcoholics and in people with diabetes or pancreatitis. Frequently, patients with magnesium deficiency also present with hypocalcemia and hypokalemia.

Prominent symptoms of hypomagnesemia involve cardiac and skeletal muscle. In the presence of low levels of magnesium, release of acetylcholine at the neuromuscular junction is enhanced. This can increase muscle excitability to the point of tetany. Hypomagnesemia also increases excitability of neurons in the CNS, causing disorientation, psychoses, and seizures.

In the kidneys, hypomagnesemia may lead to nephrocalcinosis (formation of minuscule calcium stones within nephrons). Renal injury occurs when the stones become large enough to block the flow of tubular urine.

42.4.1.2 Prevention and Treatment

Frank hypomagnesemia is treated with parenteral magnesium sulfate. For prophylaxis against magnesium deficiency, an oral preparation (magnesium gluconate, magnesium hydroxide) may be used.

42.4.1.2.1 Magnesium Gluconate and Magnesium Hydroxide.

Tablets of magnesium gluconate or magnesium hydroxide may be taken as supplements to dietary magnesium to help prevent hypomagnesemia. Milk of magnesia (a liquid formulation of magnesium hydroxide) may also be used for prophylaxis. With any oral magnesium

preparation, excessive doses may cause diarrhea. The adult and pediatric dosage for preventing deficiency is 5 mg/kg/day.

42.4.1.2.2 Magnesium Sulfate.

42.4.1.2.2.1 Uses, Administration, and Dosage.

Magnesium sulfate (IM or IV) is the preferred treatment for severe hypomagnesemia. The IM dosage is 0.5 to 1 gm 4 times a day. For IV therapy, a 10% solution can be used, infused at a rate of 1.5 mL/min or less.

42.4.1.2.2.2 Adverse Effects.

Excessive levels of magnesium cause *neuromuscular blockade*. Paralysis of the respiratory muscles is of particular concern. By suppressing neuromuscular transmission, magnesium excess can intensify the effects of neuromuscular blocking agents (eg, tubocurarine, succinylcholine). Hence, caution must be exercised in patients receiving these drugs. The neuromuscular blocking actions of magnesium can be counteracted with calcium. Accordingly, when parenteral magnesium is being employed, an injectable form of calcium (eg, calcium gluconate) should be immediately available.

In the heart, excessive magnesium can suppress impulse conduction through the atrioventricular (AV) node. Accordingly, magnesium sulfate is contraindicated for patients with AV heart block.

To minimize the risk of toxicity, serum magnesium levels should be monitored. Respiratory paralysis occurs at 12 to 15 mEq/L. When magnesium levels exceed 25 mEq/L, cardiac arrest may set in.

458

42.4.2 Hypermagnesemia

459

Toxic elevation of magnesium levels is most common in patients with renal insufficiency, especially when magnesium-containing antacids or cathartics are being used. Symptoms of mild intoxication include muscle weakness (resulting from inhibition of acetylcholine release), hypotension, sedation, and ECG changes. As noted, respiratory paralysis is likely when plasma levels reach 12 to 15 mEq/L. At higher magnesium concentrations, there is a risk of cardiac arrest. Muscle weakness and paralysis can be counteracted with intravenous calcium.

42.4.2.1

KEY POINTS

- Treat isotonic volume contraction with isotonic (0.9%) sodium chloride.
- Treat hypertonic volume contraction with hypotonic (eg, 0.11%) sodium chloride.
- Treat hypotonic volume contraction with hypertonic (eg, 3%) sodium chloride.
- Treat volume expansion with diuretics.
- Treat respiratory or metabolic acidosis with sodium bicarbonate.
- Treat respiratory alkalosis by having patients inhale 5% CO₂ or rebreathe their expired air.
- Treat metabolic alkalosis with an infusion of sodium chloride plus potassium chloride. For severe cases, infuse 0.1% hydrochloric acid or ammonium chloride.
- Treat moderate hypokalemia with potassium chloride in sustained-release tablets.
- Treat severe hypokalemia with IV potassium chloride.
- To treat hyperkalemia, begin by withdrawing potassium-containing foods and drugs that promote potassium accumulation (eg, potassium supplements, potassium-sparing diuretics). Subsequent measures include (1) infusing a calcium salt to offset the cardiac effects of potassium, (2) infusing glucose and insulin to promote potassium uptake by cells, and (3) infusing sodium bicarbonate if acidosis is present.
- Treat hypomagnesemia with IM or IV magnesium sulfate. For prophylaxis, give oral magnesium (eg, magnesium gluconate).

⁴³CHAPTER 42 Review of Hemodynamics

Hemodynamics is the study of the movement of blood throughout the circulatory system, along with the regulatory mechanisms and driving forces involved. Concepts introduced here reappear throughout the chapters on cardiovascular drugs. Accordingly, I urge you to review these now. Because this is a pharmacology text, and not a physiology text, discussion is limited to hemodynamic factors that have particular relevance to the actions of drugs.

^{43.1}OVERVIEW OF THE CIRCULATORY SYSTEM

The circulatory system has two primary functions: (1) delivery of oxygen, nutrients, hormones, electrolytes, and other essentials to cells; and (2) removal of carbon dioxide, metabolic wastes, and other detritus from cells. In addition, the system helps fight infection.

The circulatory system has two major divisions: the *pulmonary circulation* and the *systemic circulation*. The pulmonary circulation delivers blood to the lungs. The systemic circulation delivers blood to all other tissues. The systemic circulation is also known as the *greater circulation* or *peripheral circulation*.

^{43.1.1}Components of the Circulatory System

The circulatory system is composed of the *heart* and *blood vessels*. The heart is the pump that moves blood through the arterial tree. The blood vessels have several functions:

- *Arteries* transport blood under high pressure to tissues.
- *Arterioles* are control valves that regulate local blood flow.
- *Capillaries* are the sites for exchange of fluid, oxygen, carbon dioxide, nutrients, hormones, wastes, and so forth.
- *Venules* collect blood from the capillaries.
- *Veins* transport blood back to the heart. In addition, veins serve as a major reservoir for blood.

Arteries and veins differ with respect to distensibility (elasticity). Arteries are very muscular, and hence do not readily stretch. As a result, large increases in arterial pressure (AP) cause only small increases in arterial diameter. Veins are much less muscular, and hence are 6 to 10 times more distensible. As a result, small increases in venous pressure cause large increases in vessel diameter, which produces a large increase in venous volume.

43.1.2 Distribution of Blood

The adult circulatory system contains about 5 L of blood, which is distributed throughout the system. As indicated in [Figure 42-1](#), 9% is in the pulmonary circulation, 7% is in the heart, and 84% is in the systemic circulation. Within the systemic circulation, however, distribution is uneven: most (64%) of the blood is in veins, venules, and venous sinuses; the remaining 20% is in arteries (13%) and arterioles or capillaries (7%). The large volume of blood in the venous system serves as a reservoir.

43.1.3 What Makes Blood Flow?

Blood moves within vessels because the force that drives flow is greater than the resistance to flow. As indicated in [Figure 42-2](#), the force that drives blood flow is the pressure gradient between two points in a vessel. Obviously, blood will flow from the point where pressure is higher toward the point where pressure is lower. Resistance to flow is determined by the diameter and length of the vessel, and by blood viscosity. From a pharmacologic viewpoint, the most important determinant of resistance is vessel diameter: the larger the vessel, the smaller the resistance, and vice versa. Accordingly, when vessels dilate, resistance declines, causing blood flow to increase—and when vessels constrict, resistance rises, causing blood flow to decline. In order to maintain adequate flow when resistance rises, blood pressure must rise as well.

460

Figure 42-1 **Distribution of blood in the circulatory system.** Note that a large percentage of the blood resides in the venous system.

43.1.4 How Does Blood Get Back to the Heart?

As indicated in [Figure 42-3](#), pressure falls progressively as blood moves through the systemic circulation. Pressure is 120 mm Hg when blood enters the aorta, 30 mm Hg when blood enters capillaries, and only 18 mm Hg when blood leaves capillaries, and then drops to negative values (0 to –5 mm Hg) in the right atrium. (Negative atrial pressure is generated by expansion of the chest during inspiration.)

Given that pressure is only 18 mm Hg when blood leaves capillaries, we must ask, “How does blood get back to the heart? After all, a pressure of 18 mm Hg does not seem adequate to move blood from the feet all the way up to the thorax.” The answer is that, in addition to the small pressure head in venules, three mechanisms help ensure venous return. First, negative pressure in the right atrium helps “suck” blood toward the heart. Second, constriction of smooth muscle in the venous wall increases venous pressure, which helps drive blood toward the heart. Third, and most important, the combination of venous valves and skeletal muscle contraction constitutes an auxiliary “venous pump.” As indicated in [Figure 42-4A](#), the veins are equipped with a system of one-way valves. When skeletal muscles contract ([Fig. 42-4B](#)), venous

Figure 42-2 Forces that promote and impede flow of blood. Blood flows from the point of higher pressure toward the point of lower pressure. Resistance to flow is determined by vessel diameter, vessel length, and blood viscosity.

Figure 42-3 **Distribution of pressure within the systemic circulation.** Note that pressure is highest when blood leaves the left ventricle, falls to only 18 mm Hg as blood exits capillaries, and reaches negative values within the right atrium.

blood is squeezed toward the heart—the only direction the valves will permit.

43.2 REGULATION OF CARDIAC OUTPUT

In the average adult, cardiac output is about 5 L/min. Hence, every minute the heart pumps the equivalent of all the blood in the body. In this section, we consider the major factors that determine how much blood the heart pumps.

43.2.1 Determinants of Cardiac Output

The basic equation for cardiac output is

$CO = HR \times SV$ where CO is cardiac output, HR is heart rate, and SV is stroke volume.

According to the equation, an increase in HR or SV will increase CO, whereas a decrease in HR or SV will decrease

461

462

Figure 42-4 Venous valves and the auxiliary venous “pump.”**A,** Veins and their one-way valves in the leg. Note that the arrangement of valves ensures that blood will move toward the heart. **B,** Contraction of skeletal muscle pumps venous blood toward the heart.

CO. For the average person, heart rate is about 70 beats/min and stroke volume is about 70 mL. Multiplying these, we get 4.9 L/min—the average value for CO.

43.2.1.1 Heart Rate.

Heart rate is controlled primarily by the autonomic nervous system (ANS). Rate is increased by the sympathetic branch acting through β_1 -adrenergic receptors in the sinoatrial (SA) node. Rate is decreased by the parasympathetic branch acting through muscarinic receptors in the SA node. Parasympathetic impulses reach the heart via the vagus nerve.

43.2.1.2 Stroke Volume.

Stroke volume is determined largely by three factors: (1) myocardial contractility, (2) cardiac afterload, and (3) cardiac preload. *Myocardial contractility* is defined as the force with which the ventricles contract. Contractility is determined primarily by the degree of cardiac dilation, which in turn is determined by the amount of venous return. The importance of venous return in regulating contractility and stroke volume is discussed separately below. In addition to regulation by venous return, contractility can be increased by the sympathetic nervous system, acting through β_1 -adrenergic receptors in the myocardium.

43.2.1.3 Preload.

Preload is formally defined as the amount of tension (stretch) applied to a muscle prior to contraction. In the heart, stretch is determined by ventricular filling pressure, that is, the *force of venous return*: the greater filling pressure is, the more the ventricles will stretch. Cardiac preload can be expressed as either *end-diastolic volume* or *end-diastolic pressure*. As discussed below, an increase in preload will increase stroke volume, whereas a decrease in preload will reduce stroke volume. Frequently, the terms *preload* and *force of venous return* are used interchangeably—although they are not truly equivalent.

43.2.1.4 Afterload.

Afterload is formally defined as the load against which a muscle exerts its force (ie, the load a muscle must overcome in order to contract). For the heart, afterload is the *arterial pressure* that the left ventricle must overcome to eject blood. Common sense tells us that, if afterload increases, stroke volume will decrease. Conversely, if afterload falls, stroke volume will rise. Cardiac afterload is determined primarily by the degree of peripheral resistance, which in turn is determined by constriction and dilation of arterioles. That is, when arterioles constrict, peripheral resistance rises, causing AP (afterload) to rise as well. Conversely, when arterioles dilate, peripheral resistance falls, causing AP to decline.

43.2.2 Control of Stroke Volume by Venous Return

Q: How much blood does the heart pump with each stroke?

A: Exactly the amount delivered to it by the veins!

43.2.2.1 Starling's Law of the Heart

Starling's law states that the force of ventricular contraction is proportional to muscle fiber length (up to a point). Accordingly, as fiber length (ventricular diameter) increases, there is a corresponding increase in contractile force ([Fig. 42-5](#)). Because of this built-in mechanism, when more blood enters the heart, more is pumped out. As a result, the healthy heart is able to precisely match its output with the volume of blood delivered by the veins. That is, when venous return increases, cardiac output increases correspondingly. Conversely, when venous return declines, cardiac output declines to precisely the same extent. Hence, under normal, nonstressed conditions, stroke volume is determined by factors that regulate venous return.

Why does contractile force change as a function of fiber length (ventricular diameter)? Recall that muscle contraction results from the interaction of two proteins: actin and myosin. As the heart stretches in response to increased ventricular filling, actin and myosin are brought into a more optimal alignment with each other, which allows them to interact with greater force.

43.2.2.2 Factors That Determine Venous Return

Having established that venous return is the primary determinant of stroke volume (and hence cardiac output), we need to understand the factors that determine venous return. With regard to pharmacology, the most important factor is *systemic filling pressure*

462

Figure 42-5 **The Starling relationship between myocardial fiber length and contractile force.** Note that an increase in fiber length produces a corresponding increase in contractile force. Fiber length increases as the ventricles enlarge during filling. Increased contractile force is reflected by increased stroke volume.

(ie, the force that returns blood to the heart). The normal value for filling pressure is 7 mm Hg. This value can be raised to 17 mm Hg by constriction of veins. Filling pressure can also be raised by an increase in blood volume. Conversely, filling pressure, and hence venous return, can be lowered by venodilation or by reducing blood volume. Blood volume and venous tone can both be altered with drugs.

In addition to systemic filling pressure, three other factors influence venous return: (1) the auxiliary muscle pumps discussed above, (2) resistance to flow between peripheral vessels and the right atrium, and (3) right atrial pressure, elevation of which will impede venous return. None of these factors can be directly influenced with drugs.

43.2.3 Starling's Law and Maintenance of Systemic-Pulmonary Balance

Because the myocardium operates in accord with Starling's law, the right and left ventricles always pump exactly the same amount of blood. When venous return increases, stroke volume of the right ventricle increases, thereby increasing delivery of blood to the pulmonary circulation, which in turn delivers more blood to the left ventricle; this increases filling of the left ventricle, which causes *its* stroke volume to increase. Because an increase in venous return causes the output of *both* ventricles to increase, blood flow through the systemic and pulmonary circulations is always in balance, as long as the heart is healthy.

In the failing heart, Starling's law breaks down. That is, force of contraction no longer increases in proportion to increased ventricular filling. As a result, blood backs up behind the failing ventricle. The deadly consequence is illustrated in [Figure 42-6](#). In this example, output of the left ventricle is 1% less than the output of the right ventricle, which causes blood to back up in the pulmonary circulation. In only 20 minutes, this small imbalance between left and right ventricular output shifts a liter of blood from the systemic circulation to the pulmonary circulation. In less than 40 minutes, death from pulmonary congestion would ensue. This example underscores the importance of systemicpulmonary balance, and the critical role of Starling's mechanism in maintaining it.

43.3 REGULATION OF ARTERIAL PRESSURE

AP is the driving force that moves blood through the arterial side of the systemic circulation. The general formula for AP is $AP = PR \times CO$ where AP is arterial pressure, PR is peripheral resistance, and CO is cardiac output. Accordingly, an increase in PR or CO will increase AP, whereas a decrease in PR or CO will decrease AP. Peripheral resistance is regulated primarily through constriction and dilation of arterioles. Cardiac output is regulated by the mechanisms discussed above. Regulation of AP through processes that alter PR and CO is discussed below.

43.3.1 Overview of Control Systems

Under normal circumstances, AP is regulated primarily by three systems: the ANS, the renin-angiotensin-aldosterone system (RAAS), and the kidneys. These systems differ greatly with regard to time frame of response. The ANS acts in two ways: (1) it responds rapidly (in seconds or minutes) to acute changes in blood pressure, and (2) it provides steady-state control. The RAAS responds more slowly, taking hours or days to influence AP. The kidneys are responsible for long-term control, and hence may take days or weeks to adjust AP.

Arterial pressure is also regulated by a fourth system: a family of natriuretic peptides. These peptides come into play primarily under conditions of volume overload.

43.3.2 Steady-State Control by the ANS

The ANS regulates AP by adjusting CO and peripheral resistance. Sympathetic tone to the heart increases heart rate and contractility, thereby increasing CO. In contrast, parasympathetic tone slows the heart, and thereby reduces CO. As discussed in [Chapter 13](#), constriction of blood vessels is regulated exclusively by the sympathetic branch of the ANS; blood vessels have no parasympathetic innervation. Steady-state sympathetic tone provides a moderate level of vasoconstriction. The resultant resistance to blood flow maintains AP. Complete elimination of sympathetic tone would cause AP to fall by 50%.

43.3.3 Rapid Control by the ANS: The Baroreceptor Reflex

The baroreceptor reflex serves to maintain AP at a predetermined level. When AP changes, the reflex immediately attempts to restore AP to the preset value.

The reflex works as follows. Baroreceptors in the aortic arch and carotid sinus sense AP and relay this information to the vasoconstrictor center of the medulla. When AP changes, the vasoconstrictor center compensates by sending appropriate instructions to arterioles, veins, and the heart. For example, when AP drops, the vasoconstrictor center causes (1) constriction of nearly all arterioles, thereby increasing peripheral resistance; (2) constriction of veins, thereby increasing venous return; and (3) acceleration of heart rate (by increasing sympathetic impulses to the heart and decreasing parasympathetic impulses). The combined effect of these responses is to restore AP to the preset level. When AP rises too high, opposite responses occur: The reflex dilates arterioles and veins, and slows the heart.

463

Figure 42-6 **Systemic-pulmonary imbalance that develops when the output of the left and right ventricles is not identical.** In this example, the output of the left ventricle is 1% less than the output of the right ventricle. Hence, while the right ventricle pumps 5000 mL/min, the left pumps only 4950 mL/min—50 mL/min less than the right side. This causes blood to back up in the pulmonary circulation. After 20 minutes, 1000 mL of blood has shifted from the systemic circulation to the pulmonary circulation. Death would ensue in less than 40 minutes. (The 2 days are an allowance for the undertaker and clergy.) Numbers in the pulmonary and systemic circulations indicate volume of blood in liters.

(Adapted from Burton AC: Physiology and Biophysics of the Circulation. Chicago: Year Book Medical Publishers, 1968:144.)

The baroreceptor reflex is poised for rapid action—but not for sustained action. When AP falls or rises, the reflex acts within seconds to restore the preset pressure. However, when AP *remains* elevated or lowered, the system resets to the new pressure within 1 to 2 days. After this, the

system perceives the new (elevated or reduced) pressure as “normal,” and hence ceases to respond.

Drugs that lower AP will trigger the baroreceptor reflex. For example, if we administer a drug that dilates arterioles, the resultant drop in peripheral resistance will reduce AP, causing the baroreceptor reflex to activate. The most noticeable response is *reflex tachycardia*. The baroreceptor reflex can temporarily negate efforts to lower AP with drugs.

43.3.4 The Renin-Angiotensin-Aldosterone System

The RAAS supports AP by causing (1) constriction of arterioles and veins, and (2) retention of water by the kidney. Vasoconstriction is mediated by a hormone named *angiotensin II*. Water retention is mediated in part by *aldosterone*. Responses develop in hours (vasoconstriction) to days (water retention). The RAAS and its role in controlling blood pressure are discussed at length in [Chapter 43](#).

43.3.5 Renal Retention of Water

When AP remains low for a long time, the kidney responds by retaining water, which in turn causes AP to rise. Pressure rises because fluid retention increases blood volume, which increases venous pressure, which increases venous return, which increases CO, which increases AP. Water retention is a mechanism for maintaining AP over long periods (weeks, months, years).

Why does a reduction in AP cause the kidney to retain water? First, low AP reduces renal blood flow (RBF), which in turn reduces glomerular filtration rate (GFR). Because less fluid is filtered, less urine is produced, and therefore more water is retained. Second, low AP activates the RAAS, causing levels of angiotensin II and aldosterone to rise. Angiotensin II causes constriction of renal blood vessels, and thereby further decreases RBF and GFR. Aldosterone promotes renal retention of sodium, which causes water to be retained along with it.

43.3.6 Postural Hypotension

Postural hypotension, also known as *orthostatic hypotension*, is a reduction in AP that can occur when we move from a supine or seated position to an upright position. The cause of hypotension is pooling of blood in veins, which decreases venous return, which in turn decreases CO. Between 300 and 800 mL of blood can pool in veins when we stand, causing CO to drop by as much as 2 L/min. Why does blood collect in veins? When we stand, gravity increases the pressure that blood exerts on veins. Since veins are not very muscular, they are unable to retain their shape when pressure increases, and hence they stretch. The resultant increase in venous volume allows blood to pool.

Two mechanisms help overcome postural hypotension. One is the system of auxiliary venous pumps, which promote venous return. In fact, in healthy individuals, these auxiliary pumps usually prevent postural hypotension from occurring in the first place. When postural hypotension does occur, the baroreceptor reflex can restore AP by (1) constricting veins and arterioles and (2) increasing heart rate.

What would happen if we gave a drug that promoted dilation of veins (or prevented them from constricting)? In patients taking drugs that interfere with venoconstriction, postural hypotension is more intense and more prolonged. Hypotension is more intense because venous pooling is greater.

464

Hypotension is more prolonged because there is no venoconstriction to help reverse venous pooling. As with drugs that reduce AP by dilating arterioles, drugs that reduce AP by relaxing veins can trigger the baroreceptor reflex, and can thereby cause reflex tachycardia.

465

43.3.7 Natriuretic Peptides

Natriuretic peptides serve to protect the cardiovascular system in the event of volume overload, a condition that increases preload, and thereby increases CO and AP. Volume overload is caused by excessive retention of sodium and water. Natriuretic peptides work primarily by (1) reducing blood volume and (2) promoting dilation of arterioles and veins. Both actions lower AP.

The family of natriuretic peptides has three principal members: *atrial natriuretic peptide* (ANP), *B- or brain natriuretic peptide* (BNP), and *C-natriuretic peptide* (CNP). ANP is produced by myocytes of the atria; BNP is produced by myocytes of the ventricles (and to a lesser extent by cells in the brain, where BNP was discovered); and CNP is produced by cells of the vascular endothelium. When blood volume is excessive, all three peptides are released. (Release of ANP and BNP is triggered by stretching of the atria and ventricles, which occurs because of increased preload.)

ANP and BNP have similar actions. Both peptides reduce blood volume and increase venous capacitance, and thereby reduce cardiac preload. Three processes are involved. First, ANP and BNP shift fluid from the vascular system to the extravascular compartment; the underlying mechanism is increased vascular permeability. Second, they act on the kidney to cause diuresis (loss of water) and natriuresis (loss of sodium). Third, they promote dilation of arterioles and veins, in part by suppressing sympathetic outflow from the central nervous system. In addition to these actions, ANP and BNP help protect the heart during the early phase of heart failure. How? By suppressing both the RAAS and sympathetic outflow, and by inhibiting proliferation of myocytes. Although CNP shares some actions of ANP and BNP, its primary action is to promote vasodilation.

43.3.7.1

KEY POINTS*

- Arterioles serve as control valves to regulate local blood flow.
- Veins are a reservoir for blood.
- Arteries are not very distensible. As a result, large increases in AP cause only small increases in arterial diameter.
- Veins are highly distensible. As a result, small increases in venous pressure cause large increases in venous diameter.
- The adult circulatory system contains 5 L of blood, 64% of which is in systemic veins.
- Vasodilation reduces resistance to blood flow, whereas vasoconstriction increases resistance to flow.
- In addition to the small pressure head in venules, three mechanisms help ensure venous return: (1) negative pressure in the right atrium sucks blood toward the heart; (2) constriction of veins increases venous pressure, and thereby drives blood toward the heart; and (3) contraction of skeletal muscles, in conjunction with one-way venous valves, pumps blood toward the heart.
- Heart rate is increased by sympathetic nerve impulses and decreased by parasympathetic impulses.
- Stroke volume is determined by myocardial contractility, cardiac preload, and cardiac afterload.
- Preload is defined as the amount of tension (stretch) applied to a muscle prior to contraction. In the heart, preload is determined by the force of venous return.
- Afterload is defined as the load against which a muscle exerts its force. For the heart, afterload is the arterial pressure (AP) that the left ventricle must overcome to eject blood.
- Cardiac afterload is determined primarily by peripheral resistance, which in turn is determined by the degree of constriction in arterioles.
- Starling's law states that the force of ventricular contraction is proportional to myocardial fiber length. Because of this relationship, when more blood enters the heart,

more is pumped out. As a result, the healthy heart is able to precisely match output with venous return.

- The most important determinant of venous return is systemic filling pressure, which can be raised by constricting veins and increasing blood volume.
- Because cardiac muscle operates under Starling's law, the right and left ventricles always pump exactly the same amount of blood (assuming the heart is healthy). Hence, balance between the pulmonary and systemic circulations is maintained.
- Arterial pressure is regulated by the ANS, the RAAS, the kidneys, and natriuretic peptides.
- The ANS regulates AP (1) through tonic control of heart rate and peripheral resistance and (2) through the baroreceptor reflex.
- The baroreceptor reflex is only useful for short-term control of AP. When pressure remains elevated or lowered, the system resets to the new pressure within 1 to 2 days, and hence ceases to respond.
- Drugs that lower AP trigger the baroreceptor reflex, and thereby cause reflex tachycardia. Hence, the baroreceptor reflex can temporarily negate efforts to lower AP with drugs.
- The RAAS supports AP by causing (1) constriction of arterioles and veins and (2) retention of water by the kidneys. Vasoconstriction is mediated by angiotensin II; water retention is mediated in part by aldosterone.
- The kidneys provide long-term control of blood pressure by regulating blood volume.
- Postural (orthostatic) hypotension is caused by decreased venous return secondary to pooling of blood in veins, which can occur when we assume an erect posture.
- Drugs that dilate veins intensify and prolong postural hypotension. As with other drugs that reduce AP, venodilators can trigger the baroreceptor reflex, and can thereby cause reflex tachycardia.
- Natriuretic peptides defend the cardiovascular system from volume overload—primarily by reducing blood volume and promoting vasodilation.

* Key points are limited to concepts that might not have been stressed when you studied physiology (eg, veins serve as a blood reservoir). Important but obvious

concepts (eg, the heart is a pump; arteries deliver blood to tissues under pressure) are not included in this summary.

⁴⁴CHAPTER 43 Drugs Acting on the Renin-Angiotensin-Aldosterone System

In this chapter we consider four families of drugs: angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), direct renin inhibitors (DRIs), and aldosterone antagonists. With all four groups, effects result from interfering with the renin-angiotensin-aldosterone system (RAAS). The ACE inhibitors, available for more than two decades, have established roles in the treatment of hypertension, heart failure, and diabetic nephropathy; in addition, these drugs are indicated for myocardial infarction and prevention of cardiovascular events in patients at risk. Indications for ARBs are limited to hypertension, heart failure, and diabetic nephropathy. The aldosterone antagonists have only two indications: hypertension and heart failure. Current indications for DRIs are limited to hypertension. We begin the chapter by reviewing the physiology of the RAAS, after which we discuss the drugs that affect it.

^{44.1}PHYSIOLOGY OF THE RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM

The RAAS plays an important role in regulating blood pressure, blood volume, and fluid and electrolyte balance. In addition, the system appears to mediate certain pathophysiologic changes associated with hypertension, heart failure, and myocardial infarction. The RAAS exerts its effects through angiotensin II and aldosterone.

^{44.1.1}Types of Angiotensin

Before considering the physiology of the RAAS, we need to introduce the angiotensin family, which consists of angiotensin I, angiotensin II, and angiotensin III. All three compounds are small polypeptides. Angiotensin I is the precursor of angiotensin II ([Fig. 43-1](#)) and has only weak biologic activity. In contrast, angiotensin II has strong biologic activity. Angiotensin III, which is formed by degradation of angiotensin II, has moderate biologic activity.

^{44.1.2}Actions of Angiotensin II

Angiotensin II participates in all processes regulated by the RAAS. The most prominent actions of angiotensin II are vasoconstriction and stimulation of aldosterone release. Both actions serve to raise blood pressure. In addition, angiotensin II (as well as aldosterone) can act on the heart and blood vessels to cause pathologic changes in their structure and function.

^{44.1.2.1} Vasoconstriction.

Angiotensin II is a powerful vasoconstrictor. The compound acts directly on vascular smooth muscle (VSM) to cause contraction. Vasoconstriction is prominent in arterioles and less so in

veins. As a result of angiotensin-induced vasoconstriction, blood pressure rises. In addition to its direct action on blood vessels, angiotensin II can cause vasoconstriction indirectly by acting on (1) sympathetic neurons to promote norepinephrine release, (2) the adrenal medulla to promote epinephrine release, and (3) the central nervous system to increase sympathetic outflow to blood vessels.

44.1.2.2 Release of Aldosterone.

Angiotensin II acts on the adrenal cortex to promote synthesis and secretion of aldosterone, whose actions are discussed below. The adrenal cortex is highly sensitive to angiotensin II, and hence angiotensin II can stimulate aldosterone release even when angiotensin II levels are too low to induce vasoconstriction. Aldosterone secretion is enhanced when sodium levels are low and when potassium levels are high.

44.1.2.3 Alteration of Cardiac and Vascular Structure.

Angiotensin II may cause pathologic structural changes in the heart and blood vessels. In the heart, the compound may cause *hypertrophy* (increased cardiac mass) and *remodeling* (redistribution of mass within the heart). In hypertension, angiotensin II may be responsible for increasing the thickness of blood vessel walls; in atherosclerosis, it may be responsible for thickening the intimal surface of blood vessels; and in heart failure and myocardial infarction, it may be responsible for causing cardiac hypertrophy and fibrosis.

466

Figure 43-1 **Regulation of blood pressure by the renin-angiotensin-aldosterone system.** In addition to the mechanisms depicted, angiotensin II can raise blood pressure by (1) acting on the distal nephron to promote reabsorption of sodium and (2) increasing vasoconstriction by three mechanisms: promoting release of norepinephrine from sympathetic nerves; promoting release of epinephrine from the adrenal medulla; and acting in the central nervous system to increase sympathetic outflow to blood vessels. (ARBs = angiotensin-receptor blockers.)

Known effects of angiotensin II that could underlie these pathologic changes include

468

- Increased migration, proliferation, and hypertrophy of VSM cells
- Increased production of extracellular matrix by VSM cells
- Hypertrophy of cardiac myocytes
- Increased production of extracellular matrix by cardiac fibroblasts

44.1.3 Actions of Aldosterone

44.1.3.1 Regulation of Blood Volume and Blood Pressure.

After being released from the adrenal cortex, aldosterone acts on distal tubules of the kidney to cause retention of sodium and excretion of potassium and hydrogen. Because retention of sodium causes water to be retained as well, aldosterone increases blood volume, which causes blood pressure to rise.

44.1.3.2 Pathologic Cardiovascular Effects.

Until recently, knowledge of aldosterone's actions was limited to effects on the kidney. Now, however, we know that aldosterone can cause more harmful effects. Like angiotensin II, aldosterone can promote cardiac remodeling and fibrosis. In addition, aldosterone can activate the sympathetic nervous system and suppress uptake of norepinephrine in the heart, thereby predisposing the heart to dysrhythmias. Aldosterone can also promote vascular fibrosis (which decreases arterial compliance) and disrupt the baroreceptor reflex. These adverse effects appear to be limited to states such as heart failure, in which levels of aldosterone can be extremely high.

44.1.4 Formation of Angiotensin II by Renin and Angiotensin-Converting Enzyme

As indicated in [Figure 43-1](#), angiotensin II is formed through two sequential reactions. The first is catalyzed by renin, the second by ACE.

44.1.4.1 Renin

Renin (pronounced “reenin”) catalyzes the formation of *angiotensin I* from *angiotensinogen*. This reaction is the rate-limiting step in angiotensin II formation. Renin is produced by

juxtaglomerular cells of the kidney and undergoes controlled release into the bloodstream, where it cleaves angiotensinogen into angiotensin I.

44.1.4.1.1 Regulation of Renin Release.

Since renin catalyzes the rate-limiting step in angiotensin II formation, and since renin must be released into the blood in order to act, the factors that regulate renin release regulate the rate of angiotensin II formation.

As indicated in [Figure 43-1](#), release of renin can be triggered by multiple factors. Release *increases* in response to a *decline* in blood pressure, blood volume, plasma sodium content, or renal perfusion pressure. Reduced renal perfusion pressure is an especially important stimulus for renin release, and can occur in response to (1) stenosis of the renal arteries, (2) reduced systemic blood pressure, and (3) reduced plasma volume (brought on by dehydration, hemorrhage, or chronic sodium depletion). For the most part, these factors increase renin release through effects exerted locally in the kidney. However, some of these factors may also promote renin release through activation of the sympathetic nervous system. (Sympathetic nerves increase secretion of renin by causing stimulation of beta₁-adrenergic receptors on juxtaglomerular cells.)

Release of renin is *suppressed* by factors opposite to those that cause release. That is, renin secretion is inhibited by elevation of blood pressure, blood volume, and plasma sodium content. Hence, as blood pressure, blood volume, and plasma sodium content increase in response to renin release, further release of renin is suppressed. In this regard, we can view release of renin as being regulated by a classic negative feedback loop.

44.1.4.2 Angiotensin-Converting Enzyme (Kinase II)

ACE catalyzes the conversion of angiotensin I (inactive) into angiotensin II (highly active). ACE is located on the luminal surface of all blood vessels, the vasculature of the lungs being especially rich in the enzyme. Because ACE is abundant, conversion of angiotensin I into angiotensin II occurs almost instantaneously after angiotensin I has been formed. ACE is a relatively nonspecific enzyme that can act on a variety of substrates in addition to angiotensin I.

Nomenclature regarding ACE can be confusing and requires comment. As just noted, ACE can act on several substrates. When the substrate is angiotensin I, we refer to the enzyme as ACE. However, when the enzyme is acting on other substrates, we refer to it by different names. Of importance to us, when the substrate is a hormone known as *bradykinin*, we refer to the enzyme

as *kinase II*. So, please remember, whether we call it ACE or kinase II, we're talking about the same enzyme.

44.1.5 Regulation of Blood Pressure by the Renin-Angiotensin-Aldosterone System

The RAAS is poised to help regulate blood pressure: factors that lower blood pressure turn the system on; factors that raise blood pressure turn it off. However, although the RAAS does indeed contribute to blood pressure control, its role in *normovolemic, sodium-replete* individuals is only modest. In contrast, the system can be a major factor in maintaining blood pressure in the presence of *hemorrhage, dehydration, or sodium depletion*.

As depicted in [Figure 43-1](#), the RAAS, acting through angiotensin II, raises blood pressure through two basic processes: vasoconstriction and renal retention of water and sodium.

Vasoconstriction raises blood pressure by increasing total peripheral resistance; retention of water and sodium raises blood pressure by increasing blood volume. Vasoconstriction occurs within minutes to hours of activating the system, and hence can raise blood pressure quickly. In contrast, days, weeks, or even months are required for the kidney to raise blood pressure by increasing blood volume.

As suggested by [Figure 43-1](#), angiotensin II acts in two ways to promote renal retention of water. First, by constricting renal blood vessels, angiotensin II reduces renal blood flow, and thereby reduces glomerular filtration. Second, angiotensin II stimulates release of aldosterone from the adrenal cortex. Aldosterone then acts on renal tubules to promote retention of sodium and water and excretion of potassium.

468

44.1.6 Tissue (Local) Angiotensin II Production

469

In addition to the traditional RAAS that we've been discussing, in which angiotensin II is produced in the blood and then carried to target tissues, angiotensin II can be produced in individual tissues. This permits discrete, local effects of angiotensin II independent of the main system. Interference with local production of angiotensin II may underlie some effects of the ACE inhibitors.

It is important to note that some angiotensin II is produced by pathways that *do not involve* ACE. As a result, drugs that inhibit ACE cannot completely block angiotensin II production.

44.2 ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

The ACE inhibitors are important drugs for *treating* hypertension, heart failure, diabetic nephropathy, and myocardial infarction (MI). In addition, they are used to *prevent* adverse cardiovascular events in patients at risk. Their most prominent adverse effects are cough, angioedema, first-dose hypotension, and hyperkalemia. For all of these agents, beneficial effects result largely from suppressing formation of angiotensin II. Because the similarities among ACE inhibitors are much more striking than their differences, we will discuss these drugs as a group, rather than selecting a prototype to represent them.

44.2.1 Mechanism of Action and Overview of Pharmacologic Effects

As indicated in [Figure 43-2](#), ACE inhibitors produce their beneficial and adverse effects by (1) reducing levels of angiotensin II (through inhibition of ACE) and (2) increasing levels of bradykinin (through inhibition of kinase II). By reducing levels of angiotensin II, ACE inhibitors can dilate blood vessels (primarily arterioles and to a lesser extent veins), reduce blood volume (through effects on the kidney), and, importantly, prevent or reverse pathologic changes in the heart and blood vessels mediated by angiotensin II and aldosterone. Inhibition of ACE can also cause hyperkalemia and fetal injury. Elevation of bradykinin causes vasodilation (secondary to increased production of prostaglandins and nitric oxide), and can also lead to cough and angioedema.

44.2.2 Pharmacokinetics

Regarding pharmacokinetics, the following generalizations apply:

- Nearly all ACE inhibitors are administered *orally*. The only exception is enalaprilat (the active form of enalapril), which is given IV.
- Except for captopril and moexipril, all oral ACE inhibitors can be administered with food.
- With the exception of captopril, all ACE inhibitors have prolonged half-lives, and hence can be administered just once or twice a day. Captopril is administered 2 or 3 times a day.
- With the exception of lisinopril, all ACE inhibitors are *prodrugs* that must undergo conversion to their active form in the small intestine and liver. Lisinopril is active as given.

- All ACE inhibitors are *excreted by the kidneys*. As a result, nearly all can accumulate to dangerous levels in patients with kidney disease, and hence *dosages must be reduced in these patients*. Only one agent—fosinopril—does not require a dosage reduction.

44.2.3 Therapeutic Uses

When the ACE inhibitors were introduced (over 25 years ago), their only indication was hypertension. Since then, we have learned that their benefits are much broader: In addition to their use in hypertension, these drugs are now used for patients with heart failure, acute MI, left ventricular dysfunction, and diabetic and nondiabetic nephropathy. In addition, they can help prevent MI, stroke, and death in patients at high risk for cardiovascular events. It should be noted that no single ACE inhibitor is approved for all of these conditions ([Table 43-1](#)). However, given that all ACE inhibitors are very similar, it seems likely that all may produce similar benefits.

44.2.3.1 Hypertension.

All ACE inhibitors are approved for hypertension. These drugs are especially effective against malignant hypertension and hypertension secondary to renal arterial stenosis. They are also useful against essential hypertension of mild to moderate intensity—although maximal benefits may take several weeks to develop.

Figure 43-2 **Overview of ACE inhibitor actions and pharmacologic effects.** *Angiotensin-converting enzyme* (ACE) and *kinase II* are two names for the same enzyme. When angiotensin II is the substrate, we call the enzyme ACE; when bradykinin is the substrate, we call it kinase II. Inhibition of this enzyme decreases *production* of angiotensin II (thereby *reducing* angiotensin II levels), and decreases *breakdown* of bradykinin (thereby *increasing* bradykinin levels).

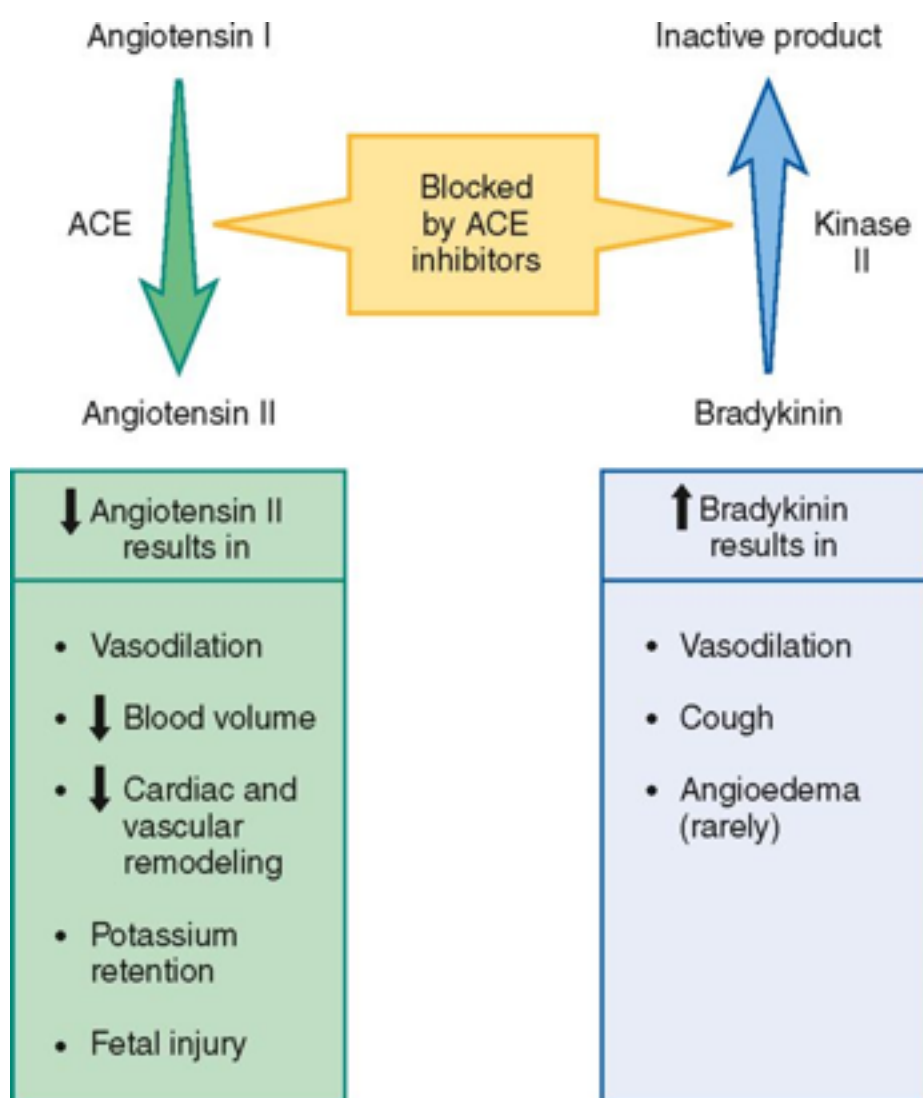

TABLE 43-1 ACE Inhibitors: Approved Indications and Adult Dosages

Generic Name	Trade Name	Approved Indications*	Starting Dosage†	Usual Maintenance Dosage‡
Benazepril	Lotensin	Hypertension	10 mg once/day	20–40 mg/day in 1 or 2 doses
Captopril	Capoten	Hypertension	25 mg 2 or 3 times/day	25–50 mg 2 or 3 times/day
		Heart failure	6.25 mg 3 times/day	50–100 mg 3 times/day
		LVD after MI	12.5 mg 3 times/day	50 mg 3 times/day
		Diabetic nephropathy	25 mg 3 times/day	25 mg 3 times/day
Enalapril	Vasotec	Hypertension	5 mg once/day	10–40 mg/day in 1 or 2 doses
		Heart failure	2.5 mg twice/day	10–20 mg twice/day
		Asymptomatic LVD	2.5 mg twice/day	10 mg twice/day
Enalaprilat	Vasotec	Hypertension	1.25 mg every 6 hr	
Fosinopril	Monopril	Hypertension	10 mg once/day	20–40 mg/day in 1 or 2 doses
		Heart failure	5–10 mg once/day	20–40 mg once/day
Lisinopril	Prinivil, Zestril	Hypertension	10 mg once/day	20–40 mg once/day
		Heart failure	2.5–5 mg once/day	20–40 mg once/day
		Acute MI	5 mg once/day	10 mg once/day
Moexipril	Univasc	Hypertension	7.5 mg once/day	7.5–30 mg/day in 1 or 2 doses
Perindopril	Aceon	Hypertension	4 mg once/day	4–8 mg/day in 1 or 2 doses
		Stable CAD	4 mg once/day	8 mg once/day
Quinapril	Accupril	Hypertension	10–20 mg/day	20–80 mg/day in 1 or 2 doses
		Heart failure	5 mg twice/day	20–40 mg twice/day
Ramipril	Altace	Hypertension	2.5 mg once/day	2.5–20 mg/day in 1 or 2 doses
		Heart failure after MI	1.25–2.5 mg twice/day	5 mg twice/day
		Prevention of MI, stroke, and death in people at high risk for CVD	2.5 mg/day for 1 wk	5 mg once/day for 3 wk

Trandolapril Mavik	Hypertension	1 mg once/day	2–4 mg once/day
	Heart failure after MI	1 mg once/day	4 mg once/day
	LVD after MI	1 mg once/day	4 mg once/day

* CAD = coronary artery disease; CVD = cardiovascular disease; LVD = left ventricular dysfunction; MI = myocardial infarction.

† For all ACE inhibitors except fosinopril, dosage must be reduced in patients with significant renal impairment.

In patients with essential hypertension, the mechanism underlying blood pressure reduction is not fully understood. *Initial* responses are proportional to circulating angiotensin II levels and are clearly related to reduced formation of that compound. (By lowering angiotensin II levels, ACE inhibitors dilate blood vessels and reduce blood volume; both actions help lower blood pressure.) However, with *prolonged* therapy, blood pressure often undergoes additional decline. During this second phase, there is no correspondence between reductions in blood pressure and reductions in *circulating* angiotensin II. It may be that the delayed response is due to reductions in *local* angiotensin II levels—reductions that would not be revealed by measuring angiotensin II in the blood.

ACE inhibitors offer several advantages over most other antihypertensive drugs. In contrast to the sympatholytic agents, ACE inhibitors do not interfere with cardiovascular reflexes. Hence, exercise capacity is not impaired and orthostatic hypotension is minimal. In addition, these drugs can be used safely in patients with bronchial asthma, a condition that precludes the use of beta₂-adrenergic antagonists. ACE inhibitors do not promote hypokalemia, hyperuricemia, or hyperglycemia—side effects seen with thiazide diuretics. Furthermore, they do not induce lethargy, weakness, or sexual dysfunction—responses that are common with other antihypertensive agents. Most importantly, *ACE inhibitors reduce the risk of cardiovascular mortality caused by hypertension*. The only other drugs proved to reduce hypertension-associated mortality are beta blockers and diuretics (see [Chapter 46](#)).

44.2.3.2 Heart Failure.

ACE inhibitors produce multiple benefits in heart failure. By lowering arteriolar tone, these drugs improve regional blood flow, and, by reducing cardiac afterload, they increase cardiac output. By causing venous dilation, they reduce pulmonary congestion and peripheral edema. By dilating blood vessels in the kidney, they increase renal blood flow, and thereby promote excretion of sodium and water. This loss of fluid has two beneficial effects: (1) it helps reduce edema and (2) by lowering blood volume, it decreases venous return to the heart, and thereby

reduces right-heart size. Lastly, by suppressing aldosterone and by reducing local production of angiotensin II in the heart, ACE inhibitors may prevent or reverse pathologic changes in cardiac structure. Although only seven ACE inhibitors are approved for heart failure (see [Table 43-1](#)), both the American Heart Association and the American College of Cardiology have concluded that the ability to improve symptoms and prolong survival is a class effect. The use of ACE inhibitors in heart failure is discussed further in [Chapter 47](#).

44.2.3.3 Myocardial Infarction.

ACE inhibitors can reduce mortality following acute MI (heart attack). In addition, they decrease the chance of developing overt heart failure. Treatment should begin as soon as possible after infarction and should continue for at least 6 weeks. In patients who develop overt heart failure, treatment should continue long term. As for patients who do not develop heart failure, there are no data to indicate whether continued treatment would be beneficial or not. At this time, only three ACE inhibitors—captopril, lisinopril, and trandolapril—are approved for patients with MI.

470

471

44.2.3.4 Diabetic and Nondiabetic Nephropathy.

ACE inhibitors can benefit patients with diabetic nephropathy, the leading cause of end-stage renal disease in the United States. In patients with overt nephropathy, as indicated by proteinuria of more than 500 mg/day, ACE inhibitors can slow progression of renal disease. In patients with less advanced nephropathy (30 to 300 mg proteinuria/day), ACE inhibitors can delay onset of overt nephropathy. These benefits were first demonstrated in patients with type 1 diabetes (insulin-dependent diabetes mellitus) and were later demonstrated in patients with type 2 diabetes (non–insulin-dependent diabetes mellitus). More recently, ACE inhibitors have been shown to provide similar protection in patients with nephropathy unrelated to diabetes.

The principal protective mechanism appears to be reduction of glomerular filtration pressure. ACE inhibitors lower filtration pressure by reducing levels of angiotensin II, a compound that can raise filtration pressure by two mechanisms. First, angiotensin II raises systemic blood pressure, which raises pressure in the afferent arteriole of the glomerulus ([Fig. 43-3](#)). Second, it constricts the efferent arteriole, thereby generating back-pressure in the glomerulus. The resultant increase in filtration pressure promotes injury. By reducing levels of angiotensin II, ACE inhibitors lower glomerular filtration pressure, and thereby slow development of renal injury.

At this time, the only ACE inhibitor approved for nephropathy is captopril. However, the American Diabetes Association considers benefits in diabetic nephropathy to be a class effect, and hence recommends choosing an ACE inhibitor based on its cost and likelihood of patient adherence.

44.2.3.5 Prevention of MI, Stroke, and Death in Patients at High Cardiovascular Risk.

One ACE inhibitor—*ramipril* [Altace]—is approved for reducing the risk of MI, stroke, and death (from cardiovascular causes) in patients at *high* risk for a major cardiovascular event—high risk being defined by (1) a history of stroke, coronary artery disease, peripheral vascular disease, or diabetes, combined with (2) at least one other risk factor, such as hypertension, high LDL cholesterol, low HDL cholesterol, or cigarette smoking. Ramipril was approved for this use based on results of the *Heart Outcomes Prevention Evaluation* (HOPE) trial, a large study in which patients at high

Figure 43-3 Elevation of glomerular filtration pressure by angiotensin II. Angiotensin II increases filtration pressure by (1) increasing pressure in the afferent arteriole (secondary to increasing systemic arterial pressure), and by (2) constricting the efferent arteriole, thereby generating back-pressure in the glomerulus.

cardiovascular risk took either ramipril (10 mg/day) or placebo. Follow-up time was 5 years. The result? The combined endpoint of MI, stroke, or death from cardiovascular causes was significantly lower in the ramipril group (14% vs. 18%)—a 22% reduction in risk. Possible mechanisms underlying benefits include reduced vascular resistance and protection of the heart, blood vessels, and kidneys from the damage that angiotensin II and aldosterone can cause over time.

Like ramipril, *perindopril* [Aceon] can reduce morbidity and mortality in patients at risk for major cardiovascular events. However, the drug is not yet approved for this use. Benefits were demonstrated in the *EUROpean trial On reduction of cardiac events with Perindopril in stable coronary Artery disease* (EUROPA). Patients in EUROPA were at lower risk than those in HOPE.

Can ACE inhibitors other than ramipril and perindopril also reduce cardiovascular risk? Possibly. However, at this time there is insufficient evidence to say for sure.

44.2.4 Adverse Effects

ACE inhibitors are generally well tolerated. Some adverse effects (eg, first-dose hypotension, hyperkalemia) are due to a reduction in angiotensin II, whereas others (cough, angioedema) are due to elevation of bradykinin.

44.2.4.1 First-Dose Hypotension.

A precipitous drop in blood pressure may occur following the first dose of an ACE inhibitor. This reaction is caused by widespread vasodilation secondary to abrupt lowering of angiotensin II levels. First-dose hypotension is most likely in patients with severe hypertension, in patients taking diuretics, and in patients who are sodium depleted or volume depleted. To minimize the first-dose effect, initial doses should be low. Also, diuretics should be temporarily discontinued, starting 2 to 3 days before starting an ACE inhibitor. Blood pressure should be monitored for several hours following the first dose of an ACE inhibitor. If hypotension develops, the patient should assume a supine position. If necessary, blood pressure can be raised with an infusion of normal saline.

44.2.4.2 Cough.

Persistent, dry, irritating, nonproductive cough can develop with all ACE inhibitors. The underlying cause is accumulation of bradykinin secondary to inhibition of kinase II (another name for ACE). Cough occurs in 5% to 10% of patients and is the most common reason for

discontinuing therapy. Factors that increase the risk of cough include advanced age, female sex, and non-black race. Cough begins to subside 3 days after discontinuing an ACE inhibitor and is gone within 10 days.

44.2.4.3 Hyperkalemia.

Inhibition of aldosterone release (secondary to inhibition of angiotensin II production) can cause potassium retention by the kidney. As a rule, significant potassium accumulation is limited to patients taking potassium supplements, salt substitutes (which contain potassium), or a potassium-sparing diuretic. For most other patients, hyperkalemia is rare. Patients should be instructed to avoid potassium supplements and potassium-containing salt substitutes unless they are prescribed.

44.2.4.4 Renal Failure.

ACE inhibitors can cause severe renal insufficiency in patients with *bilateral renal artery stenosis or stenosis in the artery to a single remaining kidney*. In patients with renal artery stenosis, the kidneys release large amounts of renin. The resulting high levels of angiotensin II serve to maintain glomerular filtration by two mechanisms: elevation of blood pressure and constriction of efferent glomerular arterioles (see [Fig. 43-3](#)). When ACE is inhibited, causing angiotensin II levels to fall, the mechanisms that had been supporting glomerular filtration fail, causing urine production to drop precipitously. Not surprisingly, *ACE inhibitors are contraindicated for patients with bilateral renal artery stenosis (or stenosis in the artery to a single remaining kidney)*.

471

472

44.2.4.5 Fetal Injury.

For a long time, we have known that use of ACE inhibitors during the *second* and *third* trimesters of pregnancy can injure the developing fetus. Specific effects include hypotension, hyperkalemia, skull hypoplasia, pulmonary hypoplasia, anuria, renal failure (reversible and irreversible), and death. Women who become pregnant while using ACE inhibitors should discontinue treatment as soon as possible. Infants who have been exposed to ACE inhibitors during the second or third trimester should be closely monitored for hypotension, oliguria, and hyperkalemia.

Are ACE inhibitors safe *early* in pregnancy? Maybe. Maybe not. Until recently, there were no data indicating risk, and hence first-trimester exposure was considered safe. However, in 2006, an article in the *New England Journal of Medicine* reported that, among 209 children exposed to ACE inhibitors during the first trimester, 18 (8.7%) had major congenital malformations,

compared with 3.2% of controls. These data contrast with animal studies, which suggest that such malformations are not likely. Furthermore, no mechanism by which ACE inhibitors might disrupt early embryogenesis is known. Nonetheless, given the new human data, it would seem that early exposure to ACE inhibitors can no longer be considered safe, and hence should be avoided.

44.2.4.6 Angioedema.

Angioedema is a potentially fatal reaction that develops in up to 1% of patients. Symptoms, which result from increased capillary permeability, include giant wheals and edema of the tongue, glottis, and pharynx. Severe reactions should be treated with subcutaneous epinephrine. If angioedema develops, ACE inhibitors should be discontinued and never used again. Angioedema is caused by accumulation of bradykinin secondary to inhibition of kinase II.

44.2.4.7 Dysgeusia and Rash.

Dysgeusia (impaired or distorted sense of taste) and rash are relatively common with captopril, but can occur with other ACE inhibitors as well. For some patients, dysgeusia may result in anorexia and weight loss. If these complications arise, the ACE inhibitor should be withdrawn. Both reactions resolve following cessation of treatment. At one time, researchers believed rash and dysgeusia were related to the sulfhydryl group found in the structure of captopril and some other ACE inhibitors. However, this appears to be untrue. Why? Because ACE inhibitors that lack a sulfhydryl group also cause these reactions.

44.2.4.8 Neutropenia.

Neutropenia, with its associated risk of infection, is a rare but serious complication. Neutropenia is most likely in patients with renal impairment and in those with collagen vascular diseases (eg, systemic lupus erythematosus, scleroderma). These patients should be followed closely. Fortunately, neutropenia is reversible when detected early. To promote early detection, a white blood cell count with differential should be obtained every 2 weeks during the first 3 months of therapy and periodically thereafter. If neutropenia develops, ACE inhibitors should be withdrawn immediately. Neutrophil counts should normalize in approximately 2 weeks. In the absence of early detection, neutropenia may progress to fatal agranulocytosis. Patients should be informed about early signs of infection (eg, fever, sore throat) and instructed to report them immediately. As with dysgeusia and rash, neutropenia is more common with captopril than with other ACE inhibitors.

44.2.5 Drug Interactions

44.2.5.1 Diuretics.

Diuretics may intensify first-dose hypotension. To prevent this interaction, diuretics should be withdrawn 1 week prior to initiating ACE inhibitor treatment. Diuretic therapy can be resumed later if needed.

44.2.5.2 Antihypertensive Agents.

The hypotensive effects of ACE inhibitors are often additive with those of other antihypertensive drugs (eg, diuretics, sympatholytics, vasodilators, calcium channel blockers). When an ACE inhibitor is added to an antihypertensive regimen, dosages of other drugs may require reduction.

44.2.5.3 Drugs That Raise Potassium Levels.

ACE inhibitors increase the risk of hyperkalemia caused by *potassium supplements* and *potassium-sparing diuretics*. The risk of hyperkalemia is increased because, by suppressing aldosterone secretion, ACE inhibitors can reduce excretion of potassium. To minimize the risk of hyperkalemia, potassium supplements and potassium-sparing diuretics should be employed only when clearly indicated.

44.2.5.4 Lithium.

ACE inhibitors can make lithium accumulate to toxic levels. Lithium levels should be monitored frequently.

44.2.5.5 Nonsteroidal Anti-Inflammatory Drugs (NSAIDs).

Aspirin, ibuprofen, and other NSAIDs may reduce the antihypertensive effects of ACE inhibitors.

44.2.6 Preparations, Dosage, and Administration

Except for enalaprilat, all ACE inhibitors are administered orally. Of the oral products, all are available in single-drug formulations, and most are also available in fixed-dose combinations with hydrochlorothiazide, a thiazide diuretic. Except for captopril and moexipril, all oral formulations may be administered without regard to meals; captopril and moexipril should be administered 1

Pharmacology for Nursing Care, 7th Edition

hour before meals. Dosages for all ACE inhibitors (except fosinopril) should be reduced in patients with renal impairment. Dosages for specific indications are summarized in [Table 43-1](#). Formulations are described below.

- Benazepril is available alone (5-, 10-, 20-, and 40-mg tablets) as *Lotensin*, and combined with hydrochlorothiazide as *Lotensin HCT*.
- Captopril is available alone (12.5-, 25-, 50-, and 100-mg tablets) as *Capoten*, and combined with hydrochlorothiazide as *Capozide*.
- Enalapril is available alone (2.5-, 5-, 10-, and 20-mg tablets) as *Vasotec*, and combined with hydrochlorothiazide as *Vaseretic*.
- Enalaprilat [Vasotec], the active form of enalapril, is available in solution (1.25 mg/mL) for IV therapy of severe hypertension. Enalaprilat is the only ACE inhibitor that is not given PO.
- Fosinopril is available alone (10-, 20-, and 40-mg tablets) as *Monopril*, and combined with hydrochlorothiazide as *Monopril-HCT*.
- Lisinopril is available alone (2.5-, 5-, 10-, 20-, 30-, and 40-mg tablets) as *Prinivil* and *Zestril*, and combined with hydrochlorothiazide as *Prinzide*.
- Moexipril is available alone (7.5- and 15-mg tablets) as *Univasc*, and combined with hydrochlorothiazide as *Uniretic*.
- Perindopril is available in tablets (2, 4, and 8 mg) as *Aceon*. The drug is not available in combination with hydrochlorothiazide.
- Quinapril is available alone (5-, 10-, 20-, and 40-mg tablets) as *Accupril*, and combined with hydrochlorothiazide as *Accuretic*.
- Ramipril is available in capsules (1.25, 2.5, 5, and 10 mg) as *Altace*. The drug is not available in combination with hydrochlorothiazide.
- Trandolapril is available in tablets (1, 2, and 4 mg) as *Mavik*. The drug is not available in combination with hydrochlorothiazide.

^{44.3} ANGIOTENSIN II RECEPTOR BLOCKERS

The angiotensin II receptor blockers (ARBs) are a relatively new family of drugs whose indications are evolving. Initially, ARBs were approved only for hypertension. Today, they also are approved for heart failure, diabetic nephropathy, myocardial infarction, and stroke prevention.

Like the ACE inhibitors, ARBs decrease the influence of angiotensin II. However, the mechanisms involved differ: Whereas ACE inhibitors block *production* of angiotensin II, ARBs block the *actions* of angiotensin II. Because both groups interfere with angiotensin II, they both have similar effects. They differ primarily in that ARBs do not cause cough or hyperkalemia.

Given that ACE inhibitors and ARBs have very similar effects, are these drugs considered clinically interchangeable? No. We have clear and extensive evidence that ACE inhibitors decrease cardiovascular morbidity and mortality. The evidence for ARBs is less convincing. Accordingly, until more is known, ACE inhibitors are preferred. For patients who cannot tolerate ACE inhibitors, ARBs are an appropriate second choice.

Seven ARBs are available. They are all very similar, and hence we will discuss them as a group, rather than choosing one as a prototype.

^{44.3.1} Mechanism of Action and Overview of Pharmacologic Effects

ARBs block access of angiotensin II to its receptors in blood vessels, the adrenals, and all other tissues. As a result, ARBs have effects much like those of the ACE inhibitors. By blocking angiotensin II receptors on blood vessels, ARBs cause dilation of arterioles and veins. By blocking angiotensin II receptors in the heart, ARBs can prevent angiotensin II from inducing pathologic changes in cardiac structure. By blocking angiotensin II receptors in the adrenals, ARBs decrease release of aldosterone, and can thereby increase renal excretion of sodium and water. Sodium and water excretion is further increased through dilation of renal blood vessels.

In contrast to the ACE inhibitors, ARBs do *not* inhibit kinase II, and hence do not increase levels of bradykinin in the lung. As a result, ARBs do not promote cough, the most common reason for stopping ACE inhibitors.

44.3.2 Therapeutic Uses

44.3.2.1 Hypertension.

All ARBs are approved for hypertension. Reductions in blood pressure equal those seen with ACE inhibitors. Whether ARBs share the ability of ACE inhibitors to reduce mortality has not been established.

44.3.2.2 Heart Failure.

Currently, only two ARBs—*valsartan* [Diovan] and *candesartan* [Atacand]—are approved for heart failure. In clinical trials, these drugs reduced symptoms, decreased hospitalizations, improved functional capacity, and increased left ventricular (LV) ejection fraction. More importantly, they prolonged survival. Because experience with these drugs is limited, they should be reserved for patients who cannot tolerate ACE inhibitors (because of cough). Although the other ARBs are not yet approved for heart failure, most authorities believe they are effective.

44.3.2.3 Diabetic Nephropathy.

Two ARBs—*irbesartan* [Avapro] and *losartan* [Cozaar]—are approved for managing nephropathy in hypertensive patients with type 2 diabetes. In clinical trials, these drugs delayed development of overt nephropathy, and slowed progression of established renal disease. Benefits are due in part to reductions in blood pressure, and in part to mechanisms that have not been determined. How do ARBs compare with ACE inhibitors? Although both groups of drugs can delay development of renal complications, only the ACE inhibitors have been shown to reduce mortality.

44.3.2.4 Myocardial Infarction.

In 2005, *valsartan* [Diovan] was approved for reducing cardiovascular mortality in post-MI patients with heart failure or LV dysfunction. Approval was based on the results of a major trial—the *Valsartan in Acute Myocardial Infarction Trial* (VALIANT)—that showed that valsartan was as effective as captopril at reducing short-term and long-term mortality in these patients.

44.3.2.5 Stroke Prevention.

One ARB—*losartan* [Cozaar]—is approved for reducing the risk of stroke in patients with hypertension and LV hypertrophy. In clinical studies, stroke prevention with losartan was better

than with atenolol (a beta blocker), even though both drugs produced an equivalent decrease in blood pressure. This observation indicates that the benefits of losartan cannot be explained on the basis of reduced blood pressure alone.

44.3.2.6 Migraine Headache.

As discussed in [Chapter 30](#), prophylactic therapy with candesartan [Atacand] can reduce the incidence and duration of migraine attacks.

44.3.3 Adverse Effects

All of the ARBs are well tolerated. In contrast to ACE inhibitors, ARBs do not cause clinically significant hyperkalemia. Furthermore, because ARBs do not promote accumulation of bradykinin in the lung, they do not induce cough.

44.3.3.1 Angioedema.

Like the ACE inhibitors, ARBs can cause angioedema, although the incidence may be lower with ARBs. If angioedema occurs, ARBs should be withdrawn immediately and never used again. Severe reactions are treated with subcutaneous epinephrine.

How do ARBs cause angioedema? Possibly by increasing bradykinin. Unlike ACE inhibitors, ARBs do not inhibit bradykinin breakdown. However, through an indirect mechanism, ARBs may be able to increase local bradykinin synthesis.

Is it reasonable to give an ARB to a patient who developed angioedema with an ACE inhibitor? Sometimes. About 8% of patients who experience angioedema with an ACE inhibitor will also get angioedema if given an ARB. Nonetheless, switching to an ARB may be worth the risk for specific patients, namely, those with a disorder for which ARBs are known to improve outcomes (ie, heart failure, diabetes, and myocardial infarction).

44.3.3.2 Fetal Harm.

Like the ACE inhibitors, ARBs can injure the developing fetus if taken during the second or third trimester of pregnancy, and hence are contraindicated during this period. Also, there is concern that ARBs and ACE inhibitors may harm the fetus earlier in pregnancy, and hence should be discontinued as soon as pregnancy is discovered.

44.3.3.3 Renal Failure.

Like the ACE inhibitors, ARBs can cause renal failure in patients with bilateral renal artery stenosis or stenosis in the artery to a single remaining kidney. Accordingly, ARBs are contraindicated for patients with these conditions.

44.3.4 Drug Interactions

The hypotensive effects of ARBs are additive with those of other antihypertensive drugs. When an ARB is added to an antihypertensive regimen, dosages of the other drugs may require reduction.

44.3.5 Preparations, Dosage, and Administration

All ARBs are administered PO, and all may be taken with or without food. In addition, all are available alone and in fixed-dose combinations with hydrochlorothiazide, a thiazide diuretic. Dosages for specific indications are summarized in [Table 43-2](#). Formulations are described below.

- Candesartan is available alone (4-, 8-, 16-, and 32-mg tablets) as *Atacand*, and combined with hydrochlorothiazide as *Atacand HCT*.

473

TABLE 43-2 Angiotensin II Receptor Blockers: Approved Indications and Adult Dosages

Generic Name	Trade Name	Approved Indications	Initial Dosage	Dosage Range
Candesartan	Atacand	Hypertension	16 mg once/day	8–32 mg/day in 1 or 2 doses
		Heart failure	4 mg once/day	4–32 mg once/day
Eprosartan	Teveten	Hypertension	600 mg once/day	400–800 mg/day in 1 or 2 doses
Irbesartan	Avapro	Hypertension	150 mg once/day	150–300 mg once/day
		Diabetic nephropathy*	300 mg once/day	300 mg once/day
Losartan	Cozaar	Hypertension	25–50 mg once/day	25–100 mg/day in 1 or 2 doses
		Stroke prevention†	50 mg once/day	50–100 mg once/day
		Diabetic nephropathy*	50 mg once/day	50–100 mg once/day
Olmesartan	Benicar	Hypertension	20 mg once/day	20–40 mg once/day
Telmisartan	Micardis	Hypertension	40 mg once/day	20–80 mg once/day
Valsartan	Diovan	Hypertension	80–160 mg once/day	80–320 mg once/day
		Heart failure	40 mg twice/day	80–160 mg twice/day
		Myocardial infarction	20 mg twice/day	80–160 mg twice/day

* In patients with type 2 diabetes.

† In patients with hypertension and left ventricular hypertrophy.

- Eprosartan is available alone (400- and 600-mg tablets) as *Teveten*, and combined with hydrochlorothiazide as *Teveten HCT*.
- Irbesartan is available alone (75-, 150-, and 300-mg tablets) as *Avapro*, and combined with hydrochlorothiazide as *Avalide*.
- Losartan is available alone (25-, 50-, and 100-mg tablets) as *Cozaar*, and combined with hydrochlorothiazide as *Hyzaar*.
- Olmesartan is available alone (5-, 20-, and 40-mg tablets) as *Benicar*, and combined with hydrochlorothiazide as *Benicar HCT*.

- Telmisartan is available alone (20-, 40-, and 80-mg tablets) as *Micardis*, and combined with hydrochlorothiazide as *Micardis HCT*.
- Valsartan is available alone (40-, 80-, 160-, and 320-mg tablets) as *Diovan*, and combined with hydrochlorothiazide as *Diovan HCT*.

44.4 ALISKIREN, A DIRECT RENIN INHIBITOR

Direct renin inhibitors (DRIs) are drugs that act on renin to inhibit the conversion of angiotensinogen into angiotensin I. By decreasing production of angiotensin I, DRIs can suppress the entire RAAS. Currently, only one DRI is available.

Aliskiren [Tekturna], approved for hypertension in 2007, was the first DRI on the market. Blood pressure reduction equals that seen with ACE inhibitors. Aliskiren causes less cough and angioedema than the ACE inhibitors, but poses similar risks to the developing fetus.

44.4.1 Mechanism of Action

Aliskiren binds tightly with renin, and thereby inhibits the cleavage of angiotensinogen into angiotensin I. Since this reaction is the first and rate-limiting step in the production of angiotensin II and aldosterone, aliskiren can reduce the influence of the entire RAAS. In clinical trials, the drug decreased plasma renin activity by 50% to 80%. Although aliskiren works at an earlier step than either the ACE inhibitors or ARBs, there is no proof that doing so results in superior clinical outcomes.

44.4.2 Therapeutic Use

Aliskiren is approved only for treatment of *hypertension*. It may be used alone or in combination with other antihypertensives. In clinical trials, aliskiren reduced blood pressure to the same extent as did ACE inhibitors, ARBs, or calcium channel blockers. Maximal effects developed within 2 weeks. Although aliskiren can reduce blood pressure in hypertensive patients, we don't know if the drug also reduces negative outcomes (ie, blindness, stroke, kidney disease, death). In contrast, the ability of ACE inhibitors and ARBs to improve outcomes is well established. Until the long-term benefits and safety of aliskiren are known, older antihypertensives should be considered first. In addition to its use in hypertension, aliskiren is under investigation for treating heart failure and renal failure associated with diabetes.

44.4.3 Pharmacokinetics

Aliskiren is administered orally, and bioavailability is low (only 2.5%). Dosing with a *high-fat meal* makes availability much lower (about 0.8%). Aliskiren undergoes some metabolism by CYP3A4 (the 3A4 isozyme of cytochrome P450), but the extent of metabolism is not known. About 25% of the drug is eliminated unchanged in the urine. The half-life is about 24 hours.

44.4.4 Adverse Effects

Aliskiren is generally well tolerated. At usual doses, the risk of angioedema, cough, or hyperkalemia is low. At high therapeutic doses, some patients experience diarrhea. Like other drugs that affect the RAAS, aliskiren should be avoided during pregnancy.

44.4.4.1 Angioedema and Cough.

With ACE inhibitors, angioedema and cough result from inhibition of kinase II. Since aliskiren does not inhibit kinase II, the risk of these effects is low. In clinical trials, the incidence of cough was 1.1% with aliskiren, versus 5% to 10% with an ACE inhibitor. Similarly, the incidence of angioedema was 0.06% with aliskiren, versus 1% with an ACE inhibitor. If angioedema does occur, aliskiren should be discontinued immediately.

44.4.4.2 Gastrointestinal Effects.

Aliskiren causes dose-dependent *diarrhea*, seen in 2.3% of patients taking 300 mg/day. Women and the elderly are most susceptible. Excessive doses (600 mg/day) are associated with abdominal pain and dyspepsia.

44.4.4.3 Hyperkalemia.

Like the ACE inhibitors, aliskiren rarely causes hyperkalemia when used alone. However, hyperkalemia might be expected if aliskiren were combined use with an ACE inhibitor, potassium-sparing diuretic, or potassium supplements.

474

475

44.4.4.4 Fetal Injury and Death.

Although aliskiren has not been studied in pregnant women, the drug is likely to pose a risk of major congenital malformations and fetal death. Why? Because the risk of these events is well established with other drugs that suppress the RAAS. Therefore, like the ACE inhibitors and

ARBs, aliskiren is contraindicated during the second and third trimesters, and should be discontinued as soon as possible when pregnancy occurs.

44.4.5 Drug Interactions

Aliskiren undergoes some metabolism by CYP3A4, but it neither induces nor inhibits the P450 system. In clinical trials, aliskiren had no significant interactions with atenolol, digoxin, amlodipine, valsartan, ramipril, or hydrochlorothiazide. However, levels of aliskiren were significantly raised by atorvastatin and ketoconazole (a P450 inhibitor), and significantly lowered by irbesartan. Levels of furosemide were lowered by aliskiren.

44.4.6 Preparations, Dosage, and Administration

Aliskiren is available alone under the trade name *Tekturna*, and in combination with hydrochlorothiazide under the trade name *Tekturna HCT*. Both formulations are indicated for hypertension.

Aliskiren alone [Tekturna] is available in tablets (150 and 30 mg) for oral dosing. The initial dosage is 150 mg once a day. If control of blood pressure is inadequate, dosage may be increased to 300 mg once a day. Daily doses above 300 mg will not increase benefits, but will increase the risk of diarrhea. Since high-fat meals decrease absorption substantially, each daily dose should be taken at the same time with respect to meals (eg, 1 hour before dinner), so as to achieve a consistent response.

Aliskiren/hydrochlorothiazide [Tekturna HCT] is available in four strengths—150 mg/12.5 mg, 150 mg/25 mg, 300 mg/12.5 mg, and 300 mg/25 mg—for once-daily dosing. As with Tekturna, each daily dose should be taken at the same time with respect to meals.

44.5 ALDOSTERONE ANTAGONISTS

Aldosterone antagonists are drugs that block receptors for aldosterone. Two such agents are available: eplerenone and spironolactone. Both drugs have similar structures and actions, and both are used for the same disorders: hypertension and heart failure. They differ, however, in that spironolactone is less selective than eplerenone. As a result, spironolactone causes more side effects.

44.5.1 Eplerenone

Eplerenone [Inspra], approved in September 2002, is the first representative of a new class of agents: *selective aldosterone receptor blockers*. The drug is used for hypertension and heart failure, and has one significant side effect: hyperkalemia.

44.5.1.1 Mechanism of Action

Eplerenone produces selective blockade of aldosterone receptors, having little or no effect on receptors for other steroid hormones (eg, glucocorticoids, progesterone, androgens). In the kidney, activation of aldosterone receptors promotes excretion of potassium and retention of sodium and water. Receptor blockade has the opposite effect: retention of potassium and increased excretion of sodium and water. Loss of sodium and water reduces blood volume and blood pressure. Blockade of aldosterone receptors at nonrenal sites may prevent or reverse pathologic effects of aldosterone on cardiovascular structure and function.

44.5.1.2 Therapeutic Use

44.5.1.2.1 Hypertension.

For treatment of hypertension, eplerenone may be used alone or in combination with other antihypertensive agents. Maximal reductions in blood pressure take about 4 weeks to develop. In clinical trials, reductions in blood pressure were equivalent to those produced by spironolactone, and superior to those produced by losartan (an ARB). In patients already using an ACE inhibitor or an ARB, adding eplerenone produced a further reduction in blood pressure.

Although it is clear that eplerenone can lower blood pressure, we have no information on what really matters: the drug's ability to reduce morbidity and mortality. Until more is known, eplerenone should be reserved for patients who have not responded to traditional antihypertensive drugs.

44.5.1.2.2 Heart Failure.

In patients with heart failure, eplerenone can improve symptoms, reduce hospitalizations, and prolong life. Benefits appear to derive from blocking the adverse effects of aldosterone on cardiovascular structure and function. Use of eplerenone in heart failure is discussed in [Chapter 47](#).

44.5.1.3 Pharmacokinetics

Eplerenone is administered orally. Absorption is not affected by food. Plasma levels peak about 1.5 hours after dosing. Absolute bioavailability is unknown. Eplerenone undergoes metabolism by CYP3A4 (the 3A4 isozyme of cytochrome P450), followed by excretion in the urine (67%) and feces (32%). The elimination half-life is 4 to 6 hours.

44.5.1.4 Adverse Effects

Eplerenone is generally well tolerated. The incidence of adverse effects is nearly identical to that of placebo. A few adverse effects—diarrhea, abdominal pain, cough, fatigue, gynecomastia, flu-like syndrome—occur slightly (1% to 2%) more often with eplerenone than with placebo.

44.5.1.4.1 Hyperkalemia.

The greatest risk is hyperkalemia, which can occur secondary to potassium retention. Because of this risk, combined use with potassium supplements, salt substitutes, or potassium-sparing diuretics (eg, spironolactone, triamterene) is contraindicated. Combined use with ACE inhibitors or ARBs is permissible, but should be done with caution. Eplerenone is contraindicated for patients with high serum potassium (above 5.5 mEq/L), and for patients with impaired renal function or type 2 diabetes with microalbuminuria, both of which can promote hyperkalemia. Monitoring potassium levels is recommended for patients at risk (eg, those taking ACE inhibitors or ARBs).

44.5.1.5 Drug Interactions

Inhibitors of CYP3A4 can increase levels of eplerenone, thereby posing a risk of toxicity. Weak inhibitors (eg, erythromycin, saquinavir, verapamil, fluconazole) can double eplerenone levels. Strong inhibitors (eg, ketoconazole, itraconazole) can increase levels fivefold. If eplerenone is combined with a weak inhibitor, eplerenone dosage should be reduced. Eplerenone should not be combined with strong inhibitors.

Drugs that raise potassium levels can increase the risk of hyperkalemia. Eplerenone should not be combined with potassium supplements, salt substitutes, or potassium-sparing diuretics. Combining the drug with ACE inhibitors or ARBs should be done with caution.

Drugs similar to eplerenone (eg, ACE inhibitors and diuretics) are known to increase levels of *lithium*. Although the combination of eplerenone and lithium has not been studied, caution is nonetheless advised. Lithium levels should be measured frequently.

475

476

44.5.1.6 Preparations, Dosage, and Administration

Eplerenone [Inspra] is available in 25- and 50-mg tablets. The usual starting dosage is 50 mg once a day, taken with or without food. After 4 weeks, dosage can be increased to 50 mg twice daily (if the hypotensive response has been inadequate). Raising the dosage above 100 mg/day is not recommended. Why? Because doing so is unlikely to increase the therapeutic response,

but *will* increase the risk of hyperkalemia. In patients taking weak inhibitors of CYP3A4, the initial dosage should be reduced by 50% (to 25 mg once a day).

44.5.2 Spironolactone

Spironolactone [Aldactone], a much older drug than eplerenone, blocks receptors for aldosterone, but also binds with receptors for other steroid hormones (eg, glucocorticoids, progesterone, androgens). Blockade of aldosterone receptors underlies beneficial effects in hypertension and heart failure, as well as the drug's major adverse effect: hyperkalemia. Binding with receptors for other steroid hormones underlies additional adverse effects: gynecomastia, menstrual irregularities, impotence, hirsutism, and deepening of the voice. The basic pharmacology of spironolactone and its use in heart failure are discussed in [Chapters 40](#) and [47](#), respectively.

44.5.2.1

KEY POINTS

- The RAAS helps regulate blood pressure, blood volume, and fluid and electrolyte balance. The system can mediate cardiovascular pathology.
- The RAAS acts through production of angiotensin II and aldosterone.
- Angiotensin II has much greater biologic activity than angiotensin I or angiotensin III.
- Angiotensin II is formed by the actions of two enzymes: renin and ACE.
- Angiotensin II causes vasoconstriction (primarily in arterioles) and release of aldosterone. In addition, angiotensin II can promote pathologic changes in the heart and blood vessels.
- Aldosterone acts on the kidneys to promote retention of sodium and water. In addition, aldosterone can also mediate pathologic changes in cardiovascular function.
- The RAAS raises blood pressure by causing vasoconstriction and by increasing blood volume (secondary to aldosterone-mediated retention of sodium and water).
- In addition to the traditional RAAS, in which angiotensin II is produced in the blood and then carried to target tissues, angiotensin II can be produced locally by individual tissues.
- Beneficial effects of ACE inhibitors result largely from inhibition of ACE and partly from inhibition of kinase II (the name for ACE when the substrate is bradykinin).

- By inhibiting ACE, ACE inhibitors decrease production of angiotensin II. The result is vasodilation, decreased blood volume, and prevention or reversal of pathologic changes in the heart and blood vessels mediated by angiotensin II and aldosterone.
- ACE inhibitors are used to treat patients with hypertension, heart failure, myocardial infarction (MI), and nephropathy, both diabetic and nondiabetic. In addition, they are used to prevent MI, stroke, and death (from cardiovascular causes) in patients at high risk for a cardiovascular event.
- ACE inhibitors can produce serious first-dose hypotension by causing a sharp drop in circulating angiotensin II.
- Cough, secondary to accumulation of bradykinin, is the most common reason for discontinuing ACE inhibitors.
- By suppressing aldosterone release, ACE inhibitors can cause hyperkalemia. Exercise caution in patients taking potassium supplements, salt substitutes, or potassium-sparing diuretics.
- ACE inhibitors can cause major fetal malformations, and should be avoided during pregnancy. Until recently, we thought that risk was limited to exposure during the second and third trimesters. However, new data indicate that exposure during the first trimester may also be dangerous as well.
- ACE inhibitors can cause a precipitous drop in blood pressure in patients with bilateral renal artery stenosis (or stenosis in the artery to a single remaining kidney).
- Angiotensin II receptor blockers (ARBs) block the actions of angiotensin II in blood vessels, the adrenals, and all other tissues.
- ARBs are similar to ACE inhibitors in that they cause vasodilation, suppress aldosterone release, promote excretion of sodium and water, reduce blood pressure, and cause birth defects and angioedema.
- ARBs differ from ACE inhibitors in that they do not cause hyperkalemia or cough.
- Aliskiren, a DRI, binds tightly with renin and thereby inhibits cleavage of angiotensinogen into angiotensin I. As a result, the drug suppresses the entire RAAS.

- Like the ACE inhibitors and ARBs, aliskiren causes vasodilation, suppresses aldosterone release, promotes excretion of sodium and water, reduces blood pressure, and causes birth defects and angioedema.
- Despite their similarities, aliskiren, ARBs, and ACE inhibitors are not clinically interchangeable.
- Aldosterone antagonists (spironolactone, eplerenone) block receptors for aldosterone.
- By blocking aldosterone receptors, aldosterone antagonists can (1) promote renal excretion of sodium and water (and can thereby reduce blood volume and blood pressure) and (2) prevent or reverse pathologic effects of aldosterone on cardiovascular structure and function.

476

44.5.2.2

Summary of Major Nursing Implications*

477

44.5.2.2.1

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Benazepril

Captopril

Enalapril

Enalaprilat

Fosinopril

Lisinopril

Moexipril

Perindopril

Quinapril

Ramipril

Trandolapril

Unless indicated otherwise, the implications summarized below pertain to all of the ACE inhibitors.

44.5.2.2...

Preadministration Assessment

44.5.2.2...

Therapeutic Goal

Reduction of blood pressure in patients with hypertension (*all ACE inhibitors*).

Hemodynamic improvement in patients with heart failure (*captopril, enalapril, fosinopril, lisinopril, moexipril, quinapril*).

Slowed progression of diabetic nephropathy (*captopril*).

Reduction of mortality following acute MI (*lisinopril*).

Treatment of heart failure after MI (*ramipril, trandolapril*).

Reduction of risk of MI, stroke, or death from cardiovascular causes in patients at high risk (*ramipril*).

Reduction of cardiovascular mortality or nonfatal MI in patients with stable coronary artery disease (*perindopril*).

44.5.2.2...

Baseline Data

Determine blood pressure and obtain a white blood cell count and differential.

44.5.2.2...

Identifying High-Risk Patients

ACE inhibitors are *contraindicated* during the second and third trimesters of pregnancy and for patients with (1) bilateral renal artery stenosis (or stenosis in the artery to a single remaining kidney) or (2) a history of hypersensitivity reactions (especially angioedema) to ACE inhibitors.

Exercise *caution* in patients with salt or volume depletion, renal impairment, or collagen vascular disease, and in those taking potassium supplements, salt substitutes, potassium-sparing diuretics, aliskiren, or lithium.

Implementation: Administration

Routes

Oral. All ACE inhibitors (except enalaprilat).

Intravenous. Enalaprilat.

Dosage and Administration

Begin therapy with low doses and then gradually increase the dosage.

Instruct patients to administer captopril and moexipril at least 1 hour before meals. All other oral ACE inhibitors can be administered with food.

Ongoing Evaluation and Interventions

Monitoring Summary

Monitor blood pressure closely for 2 hours after the first dose and periodically thereafter. Obtain a white blood cell count and differential every 2 weeks for the first 3 months of therapy and periodically thereafter.

Evaluating Therapeutic Effects

Hypertension.

Monitor for reduced blood pressure. The usual target pressure is systolic/diastolic of 140/90 mm Hg.

Heart Failure.

Monitor for lessening of signs and symptoms (eg, dyspnea, cyanosis, jugular vein distention, edema).

44.5.2.2...

Diabetic Nephropathy.

Monitor for proteinuria.

44.5.2.2...

Minimizing Adverse Effects

44.5.2.2...

First-Dose Hypotension.

Severe hypotension can occur with the first dose. Minimize hypotension by (1) withdrawing diuretics 1 week before initiating ACE inhibitors and (2) using low initial doses. Monitor blood pressure for 2 hours following the first dose. **Instruct patients to lie down if hypotension develops.** If necessary, infuse normal saline to restore pressure.

44.5.2.2...

Cough.

Warn patients about the possibility of persistent, dry, irritating, nonproductive cough. Instruct them to consult the prescriber if cough is bothersome. It may be necessary to discontinue the ACE inhibitor.

44.5.2.2...

Hyperkalemia.

ACE inhibitors may increase potassium levels. **Instruct patients to avoid potassium supplements and potassium-containing salt substitutes unless they are prescribed by the provider.** Potassium-sparing diuretics must also be avoided.

44.5.2.2...

Fetal Injury.

Warn women of child-bearing age that taking ACE inhibitors during the *second* and *third* trimesters of pregnancy can cause major fetal injury (hypotension, hyperkalemia, skull hypoplasia, anuria, reversible and irreversible renal failure, death), and that taking these drugs earlier in pregnancy may pose a risk as well. If the patient becomes pregnant, withdraw ACE inhibitors as soon as possible. Closely monitor infants who have been exposed to ACE inhibitors during the second or third trimester for hypotension, oliguria, and hyperkalemia. **Reassure women who took ACE inhibitors during the *first* trimester that risk to the fetus is probably low.**

44.5.2.2...

Angioedema.

This rare and potentially fatal reaction is characterized by giant wheals and edema of the tongue, glottis, and pharynx. **Instruct patients to seek immediate medical attention if these symptoms develop.** If angioedema is diagnosed, ACE inhibitors should be discontinued and never used again. Treat severe reactions with subcutaneous epinephrine.

44.5.2.2...

Renal Failure.

Renal failure is a risk for patients with bilateral renal artery stenosis or stenosis in the artery to a single remaining kidney. ACE inhibitors are contraindicated for these people.

477

44.5.2.2...

Dysgeusia and Rash (Mainly with Captopril).

Minimize these reactions by avoiding high doses. **Instruct patients to notify the prescriber if rash or dysgeusia persists.** If dysgeusia results in anorexia and weight loss, withdraw the drug. Rash and dysgeusia resolve with cessation of treatment.

478

44.5.2.2...

Neutropenia (Mainly with Captopril).

Neutropenia poses a high risk of infection. **Inform patients about early signs of infection (fever, sore throat, mouth sores) and instruct them to notify the prescriber if these occur.** Obtain white blood cell counts and differentials every 2 weeks during the first 3 months of therapy and periodically thereafter. If neutropenia develops, withdraw the drug immediately; neutrophil counts should normalize in approximately 2 weeks. Neutropenia is most likely in patients with renal impairment and collagen vascular diseases (eg, systemic lupus erythematosus, scleroderma); monitor these patients closely.

44.5.2.2...

Minimizing Adverse Interactions

44.5.2.2...

Diuretics.

Diuretics may intensify first-dose hypotension. Withdraw diuretics 1 week prior to beginning an ACE inhibitor. Diuretics may be resumed later if needed.

44.5.2.2...

Antihypertensive Agents.

The antihypertensive effects of ACE inhibitors are additive with those of other antihypertensive drugs (eg, diuretics, sympatholytics, vasodilators, calcium channel blockers). When an ACE inhibitor is added to an antihypertensive regimen, dosages of the other drugs may require reduction.

44.5.2.2...

Drugs That Elevate Potassium Levels.

ACE inhibitors increase the risk of hyperkalemia associated with *potassium supplements*, *potassium-sparing diuretics*, and possibly *aliskiren*. Risk can be minimized by avoiding potassium supplements and potassium-sparing diuretics except when they are clearly indicated.

44.5.2.2...

Lithium.

ACE inhibitors can increase serum levels of lithium, causing toxicity. Monitor lithium levels frequently.

44.5.2.2...

Nonsteroidal Anti-inflammatory Drugs.

NSAIDs (eg, aspirin, ibuprofen) can interfere with the antihypertensive effects of ACE inhibitors. **Advise patients to minimize NSAID use.**

44.5.2.2.2

ANGIOTENSIN II RECEPTOR BLOCKERS

Candesartan

Eprosartan

Irbesartan

Losartan

Olmesartan

Telmisartan

Valsartan

Unless indicated otherwise, the implications summarized below pertain to all of the ARBs.

Preadministration Assessment

Therapeutic Goal

Reduction of blood pressure in patients with hypertension (*all ARBs*).

Treatment of heart failure (*candesartan, valsartan*).

Slowed progression of diabetic nephropathy (*irbesartan, losartan*).

Stroke prevention in patients with hypertension and LV hypertrophy (*losartan*).

Baseline Data

Determine blood pressure.

Identifying High-Risk Patients

ARBs are *contraindicated* during the second and third trimesters of pregnancy and for patients with either (1) bilateral renal artery stenosis (or stenosis in the artery to a single remaining kidney) or (2) a history of hypersensitivity reactions (especially angioedema) to ARBs.

Implementation: Administration

Route

Oral.

Dosage and Administration

Inform patients that ARBs may be taken with or without food.

Ongoing Evaluation and Interventions

Evaluating Therapeutic Effects

Hypertension.

Monitor for reduced blood pressure. The usual target pressure is systolic/diastolic of 140/90 mm Hg.

Heart Failure.

Monitor for lessening of signs and symptoms (eg, dyspnea, cyanosis, jugular vein distention, edema).

Diabetic Nephropathy.

Monitor for proteinuria.

Minimizing Adverse Effects

Angioedema.

This rare and potentially fatal reaction is characterized by giant wheals and edema of the tongue, glottis, and pharynx. **Instruct patients to seek immediate medical attention if these symptoms develop.** If angioedema is diagnosed, ARBs should be discontinued and never used again. Treat severe reactions with subcutaneous epinephrine.

Fetal Injury.

Warn women of child-bearing age that ARBs can cause fetal injury during the *second* and *third* trimesters of pregnancy, and may pose a risk earlier in pregnancy as well. If the patient becomes pregnant, withdraw ARBs as soon as possible. Closely monitor infants who have been exposed to ARBs during the second or third trimester for hypotension, oliguria, and hyperkalemia. **Reassure women who took ARBs during the *first* trimester that risk to the fetus is low.**

44.5.2.2...

Dosage and Administration

Advise patients to take each daily dose at the same time with respect to meals (eg, 1 hour before dinner). Dosage should be low (150 mg/day) initially, and increased to a maximum of 300 mg/day, if needed.

44.5.2.2...

Ongoing Evaluation and Interventions

44.5.2.2...

Minimizing Adverse Effects

44.5.2.2...

Hyperkalemia.

Aliskiren may increase potassium levels. **Instruct patients to avoid potassium supplements and potassium-containing salt substitutes unless they are prescribed by the provider.** Potassium-sparing diuretics must also be avoided.

44.5.2.2...

Fetal Injury.

Warn women of child-bearing age that aliskiren taken during the *second* and *third* trimesters of pregnancy can cause fetal injury (hypotension, hyperkalemia, skull hypoplasia, anuria, reversible and irreversible renal failure, death). If the patient becomes pregnant, withdraw ACE inhibitors as soon as possible. Closely monitor infants who have been exposed to aliskiren during the second or third trimester for hypotension, oliguria, and hyperkalemia. **Reassure women who took aliskiren during the *first* trimester that this does not represent a risk to the fetus.**

44.5.2.2...

Angioedema.

This rare and potentially fatal reaction is characterized by giant wheals and edema of the tongue, glottis, and pharynx. **Instruct patients to seek immediate medical attention if these symptoms develop.** If angioedema is diagnosed, aliskiren should be discontinued and never used again. Treat severe reactions with subcutaneous epinephrine.

44.5.2.2...

Minimizing Adverse Interactions

44.5.2.2...

Drugs That Elevate Potassium Levels.

Aliskiren increases the risk of hyperkalemia associated with *ACE inhibitors*, *potassium supplements*, and *potassium-sparing diuretics*. Risk can be minimized by avoiding ACE inhibitors, potassium supplements, and potassium-sparing diuretics except when they are clearly indicated.

44.5.2.2...

Antihypertensive Agents.

The antihypertensive effects of aliskiren are additive with those of other antihypertensive drugs (eg, diuretics, sympatholytics, vasodilators, calcium channel blockers). When aliskiren is added to an antihypertensive regimen, dosages of the other drugs may require reduction.

* Patient education information is highlighted as blue text.

⁴⁵CHAPTER 44 Calcium Channel Blockers

Calcium channel blockers (CCBs) are drugs that prevent calcium ions from entering cells. These agents have their greatest effects on the heart and blood vessels. CCBs are used widely to treat hypertension, angina pectoris, and cardiac dysrhythmias. Since 1995, there has been controversy about the safety of CCBs, especially in patients with hypertension and diabetes. Alternative names for CCBs are *calcium antagonists* and *slow channel blockers*.

^{45.1} CALCIUM CHANNELS: PHYSIOLOGIC FUNCTIONS AND CONSEQUENCES OF BLOCKADE

Calcium channels are gated pores in the cytoplasmic membrane that regulate entry of calcium ions into cells. Calcium entry plays a critical role in the function of vascular smooth muscle (VSM) and the heart.

^{45.1.1} Vascular Smooth Muscle

In VSM, calcium channels regulate contraction. When an action potential travels down the surface of a smooth muscle cell, calcium channels open and calcium ions flow inward, thereby initiating the contractile process. If calcium channels are blocked, contraction will be prevented and vasodilation will result.

At therapeutic doses, CCBs act selectively on *peripheral arterioles* and *arteries and arterioles of the heart*. CCBs have no significant effect on veins.

^{45.1.2} Heart

In the heart, calcium channels help regulate function of the myocardium, the sinoatrial (SA) node, and the atrioventricular (AV) node. Calcium channels at all three sites are coupled to beta₁-adrenergic receptors.

^{45.1.2.1} Myocardium.

In cardiac muscle, calcium entry has a positive inotropic effect. That is, calcium increases force of contraction. If calcium channels in atrial and ventricular muscle are blocked, contractile force will diminish.

^{45.1.2.2} SA Node.

Pacemaker activity of the SA node is regulated by calcium influx. When calcium channels are open, spontaneous discharge of the SA node increases. Conversely, when calcium channels

close, pacemaker activity declines. Hence, the effect of calcium channel blockade is to reduce heart rate.

45.1.2.3 AV Node.

Impulses that originate in the SA node must pass through the AV node on their way to the ventricles. Because of this arrangement, regulation of AV conduction plays a critical role in coordinating contraction of the ventricles with contraction of the atria.

The excitability of AV nodal cells is regulated by calcium entry. When calcium channels are open, calcium entry increases and cells of the AV node discharge more readily. Conversely, when calcium channels are closed, discharge of AV nodal cells is suppressed. Hence, the effect of calcium channel blockade is to decrease velocity of conduction through the AV node.

45.1.2.4 Coupling of Cardiac Calcium Channels to Beta₁Adrenergic Receptors.

In the heart, calcium channels are coupled to beta₁-adrenergic receptors ([Fig. 44-1](#)). As a result, when cardiac beta₁ receptors are activated, calcium influx is enhanced. Conversely, when beta₁ receptors are blocked, calcium influx is suppressed. Because of this relationship, CCBs and beta blockers have identical effects on the heart. That is, they both reduce force of contraction, slow heart rate, and suppress conduction through the AV node.

45.2 CALCIUM CHANNEL BLOCKERS: CLASSIFICATION AND SITES OF ACTION

45.2.1 Classification

The CCBs used in the United States belong to three chemical families ([Table 44-1](#)). The largest family is the *dihydropyridines*, for which *nifedipine* is the prototype. This family name is encountered frequently and hence is worth remembering. The other two families consist of orphans: *verapamil* is the only *phenylalkylamine*, and *diltiazem* is the only *benzothiazepine*. The drug names are important; the family names are not.

45.2.2 Sites of Action

At therapeutic doses, the dihydropyridines act primarily on arterioles; in contrast, verapamil and diltiazem act on arterioles *and* the heart (see [Table 44-1](#)). However, although dihydropyridines don't affect the heart at *therapeutic* doses, *toxic* doses can produce dangerous cardiac suppression (just like verapamil and diltiazem can). The differences in selectivity among CCBs are based on structural differences among the drugs themselves and structural differences among calcium channels.

Figure 44-1 Coupling of cardiac calcium channels with beta₁-adrenergic receptors. In the heart, beta₁ receptors are coupled to calcium channels. As a result, when cardiac beta₁ receptors are activated, calcium influx is enhanced. The process works as follows. Binding of an agonist (eg, norepinephrine) causes a conformational change in the beta receptor, which in turn causes a change in G protein, converting it from an inactive state (in which GDP is bound to the alpha subunit) to an active state (in which GTP is bound to the alpha subunit). (G protein is so named because it binds guanine nucleotides: GDP and GTP.) Following activation, the alpha subunit dissociates from the rest of G protein and activates adenylyl cyclase, an enzyme that converts ATP to cyclic AMP (cAMP). cAMP then activates protein kinase, an enzyme that phosphorylates proteins—in this case, the calcium channel. Phosphorylation changes the channel such that calcium entry is enhanced when the channel opens. (Opening of the channel is triggered by a change in membrane voltage [ie, by passage of an action potential].) The effect of calcium entry on cardiac function is determined by the type of cell involved. If the cell is in the SA node, heart rate increases; if the cell is in the AV node, impulse conduction through the node accelerates; and if the cell is part of the myocardium, force of contraction is increased. Because binding of a single agonist molecule to a single beta receptor stimulates the synthesis of many cAMP molecules, with the subsequent activation of many protein kinase molecules, causing the phosphorylation of many calcium

channels, this system can greatly amplify the signal initiated by the agonist.

45.3 VERAPAMIL AND DILTIAZEM: AGENTS THAT ACT ON VASCULAR SMOOTH MUSCLE AND THE HEART

45.3.1 Verapamil

Verapamil [Calan, Covera-HS, Isoptin SR, Verelan] blocks calcium channels in blood vessels and in the heart. Major indications are angina pectoris, essential hypertension, and cardiac dysrhythmias. Verapamil was the first CCB available and will serve as our prototype for the group.

45.3.1.1 Hemodynamic Effects

The overall hemodynamic response to verapamil is the net result of (1) direct effects on the heart and blood vessels and (2) reflex responses.

45.3.1.1.1 Direct Effects.

By blocking calcium channels in the heart and blood vessels, verapamil has five direct effects:

- Blockade at peripheral arterioles causes dilation, and thereby reduces arterial pressure.

- Blockade at arteries and arterioles of the heart increases coronary perfusion.
- Blockade at the SA node reduces heart rate.
- Blockade at the AV node decreases AV nodal conduction.
- Blockade in the myocardium decreases force of contraction.

Of the direct effects on the heart, reduced AV conduction is the most important.

45.3.1.1.2

Indirect (Reflex) Effects.

Verapamil-induced lowering of blood pressure activates the baroreceptor reflex, causing increased firing of sympathetic nerves to the heart. Norepinephrine released from these nerves acts to increase heart rate, AV conduction, and force of contraction. However, since these same three parameters are suppressed by the direct actions of verapamil, the direct and indirect effects tend to neutralize each other.

481

482

TABLE 44-1 Calcium Channel Blockers: Classification, Sites of Action, and Indications

		Indications			
Classification	Sites of Action	Hypertension	Angina	Dysrhythmias	Others
Dihydropyridines					
Nifedipine [Adalat, Nifediac, Nifedical, Procardia]	Arterioles	✓	✓		§
Amlodipine [Norvasc]	Arterioles	✓	✓		
Clevidipine [Cleviprex]	Arterioles				§
Felodipine [Plendil]	Arterioles	✓			
Isradipine [DynaCirc]	Arterioles	✓			
Nicardipine [Cardene]	Arterioles	✓	✓		
Nimodipine [Nimotop]	Arterioles				‡
Nisoldipine [Sular]	Arterioles	✓			§
Phenylalkylamines					
Verapamil [Calan, Covera-HS, Isoptin SR, Verelan]	Arterioles/heart	✓	✓	✓	§
Benzothiazepines					
Diltiazem [Cardizem, Dilacor-XR, others]	Arterioles/heart	✓	✓	✓	
* Suppression of preterm labor (investigational use).					
† Only for IV treatment of <i>severe</i> hypertension.					
‡ Prophylaxis of neurologic injury after rupture of an intracranial aneurysm.					
§ MigrainDe headache (investigational use).					

45.3.1.1.3

Net Effect.

Because the direct effects of verapamil on the heart are counterbalanced by indirect effects, the drug has little or no net effect on cardiac performance: For most patients, heart rate, AV conduction, and contractility are not noticeably altered. Consequently, the overall cardiovascular effect of verapamil is simply vasodilation accompanied by reduced arterial pressure and increased coronary perfusion.

45.3.1.2 Pharmacokinetics

Verapamil may be administered orally and IV. The drug is well absorbed following oral administration, but undergoes extensive metabolism on its first pass through the liver. Consequently, only about 20% of an oral dose reaches the systemic circulation. Effects begin in 30 minutes and peak within 5 hours. Elimination is primarily by hepatic metabolism. Because the drug is eliminated by the liver, doses must be reduced substantially in patients with hepatic impairment.

45.3.1.3 Therapeutic Uses

45.3.1.3.1 Angina Pectoris.

Verapamil is used widely to treat angina pectoris. The drug is approved for vasospastic angina and angina of effort. Benefits in both disorders derive from vasodilation. The role of verapamil in antianginal therapy is discussed further in [Chapter 50](#).

45.3.1.3.2 Essential Hypertension.

Verapamil is a first-line agent for chronic hypertension. The drug lowers blood pressure by promoting dilation of arterioles. The role of verapamil and other CCBs in hypertension is discussed in [Chapter 46](#).

45.3.1.3.3 Cardiac Dysrhythmias.

Verapamil, administered IV, is used to slow ventricular rate in patients with atrial flutter, atrial fibrillation, and paroxysmal supraventricular tachycardia. Benefits derive from suppressing impulse conduction through the AV node, thereby preventing the atria from driving the ventricles at an excessive rate. Antidysrhythmic applications are discussed in [Chapter 48](#).

45.3.1.3.4 Migraine.

Verapamil can help prevent migraine headache. This investigational use is discussed in [Chapter 30](#).

45.3.1.4 Adverse Effects

45.3.1.4.1 Common Effects.

Verapamil is generally well tolerated. *Constipation* occurs frequently and is the most common complaint. This problem, which can be especially severe in the elderly, can be minimized by increasing dietary fluids and fiber. Constipation results from blockade of calcium channels in smooth muscle of the intestine. Other common effects—*dizziness, facial flushing, headache, and edema of the ankles and feet*—occur secondary to vasodilation.

45.3.1.4.2 Cardiac Effects.

Blockade of calcium channels in the heart can compromise cardiac function. In the SA node, calcium channel blockade can cause bradycardia; in the AV node, blockade can cause partial or complete AV block; and in the myocardium, blockade can decrease contractility. When the heart is healthy, these effects are rarely of clinical significance. However, in patients with certain cardiac diseases, verapamil can seriously exacerbate dysfunction. Accordingly, the drug must be used with special caution in patients with cardiac failure, and must not be used at all in patients with sick sinus syndrome or second-degree or third-degree AV block.

45.3.1.4.3 Other Effects.

In older patients, CCBs have been associated with *chronic eczematous eruptions*. Although a causal relationship has not been proved, it might be wise to withdraw CCBs from older patients who develop an unexplained eczematous rash.

Gingival hyperplasia (overgrowth of gum tissue) has been reported.

482

45.3.1.5 Drug Interactions

483

45.3.1.5.1 Digoxin.

Like verapamil, digoxin suppresses impulse conduction through the AV node. Accordingly, when these drugs are used concurrently, the risk of AV block is increased. Patients receiving the combination should be monitored closely.

Verapamil increases plasma levels of digoxin by about 60%, thereby increasing the risk of digoxin toxicity. If signs of toxicity appear, digoxin dosage should be reduced.

45.3.1.5.2 Beta-Adrenergic Blocking Agents.

Beta blockers and verapamil have the same effects on the heart: they decrease heart rate, AV conduction, and contractility. Hence, when a beta blocker and verapamil are used together, there is a risk of excessive cardiosuppression. To minimize risk, beta blockers and IV verapamil should be administered several hours apart.

45.3.1.6 Toxicity

45.3.1.6.1 Clinical Manifestations.

Overdose can produce severe hypotension and cardiotoxicity (bradycardia, AV block, ventricular tachydysrhythmias).

45.3.1.6.2 Treatment.

45.3.1.6.2.1 General Measures.

Verapamil can be removed from the GI tract with gastric lavage followed by a cathartic. Intravenous calcium gluconate can counteract both vasodilation and negative inotropic effects, but will not reverse AV block.

45.3.1.6.2.2 Hypotension.

Hypotension can be treated with IV norepinephrine, which promotes vasoconstriction (by activating α_1 receptors on blood vessels) and increases cardiac output (by activating β_1 receptors in the heart). Placing the patient in modified Trendelenburg's position (legs elevated) and administering IV fluids may also help.

45.3.1.6.2.3 Bradycardia and AV Block.

Bradycardia and AV block can be treated with isoproterenol (a beta-adrenergic agonist) and with atropine (an anticholinergic drug that blocks parasympathetic influences on the heart). If pharmacologic measures are inadequate, electronic pacing may be required.

45.3.1.6.2.4 Ventricular Tachydysrhythmias.

The preferred treatment is direct-current (DC) cardioversion. Antidysrhythmic drugs (procainamide, lidocaine) may also be tried.

45.3.1.7 Preparations, Dosage, and Administration

45.3.1.7.1 Oral.

Verapamil is available in standard tablets (40, 80, and 120 mg) as Calan; sustained-release tablets (120, 180, and 240 mg) as Calan SR, Covera-HS, and Isoptin SR; and sustained-release capsules (120, 180, 240, and 360 mg) as Verelan. In addition, verapamil is available as Verelan PM (100-, 200-, and 300-mg capsules), a timed-release formulation that, when administered at bedtime, produces maximum verapamil levels in the morning. The sustained-, timed-, and extended-release formulations are approved only for hypertension. Instruct patients to swallow these products intact, without crushing or chewing. A fixed-dose combination with trandolapril (an angiotensin-converting enzyme [ACE] inhibitor) is available under the trade name *Tarka*.

The usual initial dosage for *angina pectoris* is 80 to 120 mg 3 times a day. The usual initial dosage for *essential hypertension* is 80 mg 3 times a day (using standard tablets), 240 mg of a sustained-release formulation (administered once a day in the morning with food), or 200 mg of Verelan PM (administered once a day at bedtime). Dosages should be reduced for elderly patients and for patients with advanced renal or liver disease. Dosages for dysrhythmias are presented in [Chapter 48](#).

45.3.1.7.2 Intravenous.

Intravenous verapamil is used for dysrhythmias. Because IV verapamil can cause severe adverse cardiovascular effects, blood pressure and the electrocardiogram (ECG) should be monitored and equipment for resuscitation should be immediately available. Intravenous dosages for dysrhythmias are presented in [Chapter 48](#).

45.3.2 Diltiazem

45.3.2.1 Actions and Uses.

Like verapamil, diltiazem [Cardizem, Dilacor-XR, others] blocks calcium channels in the heart and blood vessels. As a result, the actions and applications of the two drugs are very similar. Diltiazem has the same effects on cardiovascular function as verapamil. Both drugs lower blood pressure through arteriolar dilation and, because their direct suppressant actions are balanced by reflex cardiac stimulation, both have little *net* effect on the heart. Like verapamil, diltiazem is used for angina pectoris, essential hypertension, and cardiac dysrhythmias (atrial flutter, atrial fibrillation, and paroxysmal supraventricular tachycardia).

45.3.2.2 Pharmacokinetics.

Oral diltiazem is well absorbed and then extensively metabolized on its first pass through the liver. As a result, bioavailability is only about 50%. Effects begin rapidly (within a few minutes) and peak within half an hour. The drug undergoes nearly complete metabolism prior to elimination in the urine and feces.

45.3.2.3 Adverse Effects.

Adverse effects are like those of verapamil, except that diltiazem causes less constipation. The most common effects are dizziness, flushing, headache, and edema of the ankles and feet. Like verapamil, diltiazem can exacerbate cardiac dysfunction in patients with bradycardia, sick sinus syndrome, heart failure, or second-degree or third-degree AV block. Like other CCBs, diltiazem may cause chronic eczematous rash in the elderly.

45.3.2.4 Drug Interactions.

Like verapamil, diltiazem can exacerbate digoxin-induced suppression of AV conduction, and can intensify the cardiosuppressant effects of beta blockers. Patients receiving diltiazem concurrently with digoxin or a beta blocker should be monitored closely for cardiac status.

45.3.2.5 Preparations, Dosage, and Administration.

Oral diltiazem is available in standard tablets (30, 60, 90, and 120 mg) as Cardizem, extended-release tablets (120, 180, 240, 300, 360, and 420 mg) as Cardizem LA, and sustained-release capsules (60, 90, 120, 180, 240, 300, 360, and 420 mg) as Cardizem CD, Cartia XT, Dilacor XR, Dilt-CD, Dilt-XR, Diltia XT, Taztia XT and Tiazac. The drug is also available in solution (5 mg/mL) for IV administration under the trade name Cardizem. The usual initial dosage for hypertension is 180 mg once a day with Cardizem CD, 60 to 120 mg twice a day with Cardizem CD or Dilacor XR, and 180 to 240 mg once a day with Cardizem LA. Angina pectoris can be treated with standard tablets (30 mg 4 times a day initially and 60 mg 4 times a day for maintenance). Intravenous diltiazem is reserved for dysrhythmias.

45.4 DIHYDROPYRIDINES: AGENTS THAT ACT MAINLY ON VASCULAR SMOOTH MUSCLE

All of the drugs discussed in this section belong to the *dihydropyridine* family. At therapeutic doses, these drugs produce significant blockade of calcium channels in blood vessels and minimal blockade of calcium channels in the heart. The dihydropyridines are similar to verapamil in some respects but quite different in others.

45.4.1 Nifedipine

Nifedipine [Adalat, Nifedical, Nifediac, Procardia] was the first dihydropyridine available and will serve as our prototype for the group. Like verapamil, nifedipine blocks calcium channels in VSM and thereby promotes vasodilation. However, in contrast to verapamil, nifedipine produces very little blockade of calcium channels in the heart. As a result, nifedipine cannot be used to treat dysrhythmias, does not cause cardiac suppression, and is less likely than verapamil to exacerbate pre-existing cardiac disorders. Nifedipine also differs from verapamil in that nifedipine is more likely to cause reflex tachycardia. Contrasts between nifedipine and verapamil are summarized in [Table 44-2](#).

45.4.1.1 Hemodynamic Effects

45.4.1.1.1 Direct Effects.

The direct effects of nifedipine on the cardiovascular system are limited to blockade of calcium channels in VSM. Blockade of calcium channels in peripheral arterioles causes vasodilation, and thereby lowers arterial pressure. Channel blockade in arteries and arterioles of the heart increases coronary perfusion. Because nifedipine does not block cardiac calcium channels at usual therapeutic doses, the drug has no *direct* suppressant effects on automaticity, AV conduction, or contractile force.

45.4.1.1.2 Indirect (Reflex) Effects.

By lowering blood pressure, nifedipine activates the baroreceptor reflex, thereby causing sympathetic stimulation of the heart. Because nifedipine lacks direct cardiosuppressant actions, cardiac stimulation is unopposed, and hence heart rate and contractile force increase.

483

TABLE 44-2 Comparisons and Contrasts Between Nifedipine and Verapamil

Property	Drug	
	Nifedipine	Verapamil
Direct Effects on the Heart and Arterioles		
Arteriolar dilation	Yes	Yes
Effects on the heart		
Reduced automaticity	No	Yes
Reduced AV conduction	No	Yes
Reduced contractile force	No	Yes
Major Indications		
Hypertension	Yes	Yes
Angina pectoris (classic and variant)	Yes	Yes
Dysrhythmias	No	Yes
Adverse Effects		
Exacerbation of		
AV block	No	Yes
Sick sinus syndrome	No	Yes
Heart failure	No	Yes
Effects secondary to vasodilation		
Edema (ankles and feet)	Yes	Yes
Flushing	Yes	Yes
Headaches	Yes	Yes
Dizziness	Yes	Yes
Reflex tachycardia	Yes	No
Constipation	No	Yes
Drug Interactions		
Intensifies digoxin-induced AV block	No	Yes
Intensifies cardiosuppressant effects of beta blockers	No	Yes
Often combined with a beta blocker to suppress reflex tachycardia	Yes	No
AV = atrioventricular.		

It is important to note that reflex effects occur primarily with the *fast-acting* formulation of nifedipine, not with the sustained-release formulation. Why? Because the baroreceptor reflex is turned on only by a *rapid* fall in blood pressure; a gradual decline will not activate the reflex. With the fastacting formulation, blood levels of nifedipine rise quickly, and hence blood pressure drops quickly and the reflex is turned on. Conversely, with the sustained-release formulation, blood levels of nifedipine rise slowly, and hence blood pressure falls slowly and the reflex is blunted.

45.4.1.1.3 Net Effect.

The overall hemodynamic response to nifedipine is simply the sum of its direct effect (vasodilation) and indirect effect (reflex cardiac stimulation). Accordingly, nifedipine (1) lowers blood pressure, (2) increases heart rate, and (3) increases contractile force. Please note, however, that the reflex increases in heart rate and contractile force are transient and occur primarily with the rapid-acting formulation.

45.4.1.2 Pharmacokinetics

Nifedipine is well absorbed following oral administration, but undergoes extensive first-pass metabolism. As a result, only about 50% of an oral dose reaches the systemic circulation. With the fast-acting formulation, effects begin rapidly and peak in 30 minutes; with the sustained-release formulation, effects begin in 20 minutes and peak in 6 hours. Nifedipine is fully metabolized prior to excretion in the urine.

45.4.1.3 Therapeutic Uses

45.4.1.3.1 Angina Pectoris.

Nifedipine is indicated for vasospastic angina and angina of effort. The drug is usually combined with a beta blocker to prevent reflex stimulation of the heart, which could intensify anginal pain. Long-term use reduces the rates of overt heart failure, coronary angiography, and coronary bypass surgery—but not rates of stroke, myocardial infarction, or death. The role of nifedipine in angina is discussed further in [Chapter 50](#).

45.4.1.3.2 Hypertension.

Nifedipine is used widely to treat *essential hypertension*. Only the sustained-release formulation should be used. In the past, nifedipine was used for *hypertensive emergencies*, but has largely been replaced by drugs that are safer. The use of CCBs in essential hypertension is discussed further in [Chapter 46](#).

45.4.1.3.3 Investigational Uses.

Nifedipine has been used on an investigational basis to *suppress preterm labor* (see [Chapter 63](#)).

45.4.1.4 Adverse Effects

Some adverse effects are like those of verapamil; others are quite different. Like verapamil, nifedipine can cause *flushing, dizziness, headache, peripheral edema, and gingival hyperplasia*, and may pose a risk of *chronic eczematous rash* in older patients. In contrast to verapamil, nifedipine causes very little constipation. Also, since nifedipine causes minimal blockade of calcium channels in the heart, the drug is not likely to exacerbate AV block, heart failure, bradycardia, or sick sinus syndrome. Accordingly, nifedipine is preferred to verapamil for patients with these disorders.

484

485

A response that occurs with nifedipine that does not occur with verapamil is *reflex tachycardia*. This response is problematic in that it increases cardiac oxygen demand and can thereby increase pain in patients with angina. To prevent reflex tachycardia, nifedipine can be combined with a beta blocker (eg, propranolol).

Rapid-acting nifedipine has been associated with increased mortality in patients with myocardial infarction and unstable angina. Other rapid-acting CCBs have been associated with an increased risk of myocardial infarction in patients with hypertension. However, in both cases, a cause-and-effect relationship has not been established. Nonetheless, the National Heart, Lung, and Blood Institute has recommended that rapid-acting nifedipine, especially in higher doses, be used with great caution, if at all. It is important to note that these adverse effects have not been associated with *sustained-release* nifedipine or with any other long-acting CCB.

45.4.1.5 Drug Interactions

45.4.1.5.1 Beta-Adrenergic Blockers.

Beta blockers are combined with nifedipine to prevent reflex tachycardia. It is important to note that, whereas beta blockers can *decrease* the adverse cardiac effects of *nifedipine*, they can *intensify* the adverse cardiac effects of *verapamil* and *diltiazem*.

45.4.1.6 Toxicity

When taken in excessive dosage, nifedipine loses selectivity. Hence, toxic doses affect the heart in addition to blood vessels. Consequently, the manifestations and treatment of nifedipine overdose are the same as described above for verapamil.

45.4.1.7 Preparations, Dosage, and Administration

Nifedipine is available in capsules (10 and 20 mg) as Adalat and Procardia and sustained-release tablets (30, 60, and 90 mg) as Adalat CC, Nifedical XL, Nifediac CC, and Procardia XL.

Instruct patients to swallow sustained-release tablets whole, without crushing or chewing.

For treatment of *angina pectoris*, the usual initial dosage is 10 mg 3 times a day. The usual maintenance dosage is 10 to 20 mg 3 times a day. The maximum recommended dosage is 180 mg/day.

For *essential hypertension*, only the sustained-release tablets are approved. The usual initial dosage is 30 mg once a day.

45.4.2 Other Dihydropyridines

In addition to nifedipine, seven other dihydropyridines are available. All are similar to nifedipine. Like nifedipine, these drugs produce greater blockade of calcium channels in VSM than in the heart.

45.4.2.1 Nicardipine.

At therapeutic doses, nicardipine [Cardene, Cardene SR, Cardene I.V.] produces selective blockade of calcium channels in blood vessels and has minimal direct effects on the heart. The drug has two indications: essential hypertension and effort-induced angina pectoris. The most common adverse effects are flushing, headache, asthenia (weakness), dizziness, palpitations, and edema of the ankles and feet. As with other CCBs, eczematous rash may develop in older patients. Gingival hyperplasia (overgrowth of gum tissue) has been reported. Like nifedipine, nicardipine can be combined with a beta blocker to promote therapeutic effects and suppress reflex tachycardia. Nicardipine is available in standard capsules (20 and 30 mg) as Cardene, sustained-release capsules (30, 45, and 60 mg) as Cardene SR, and an IV formulation (2.5 mg/mL) as Cardene I.V. The usual initial dosage for *angina pectoris* is 20 mg 3 times a day using the standard capsules. The usual initial dosage for *essential hypertension* is 20 mg 3 times a day (using standard capsules) or 30 mg twice a day (using sustained-release capsules).

45.4.2.2 Amlodipine.

At therapeutic doses, amlodipine [Norvasc] produces selective blockade of calcium channels in blood vessels, having minimal direct effects on the heart. Approved indications are essential hypertension and angina pectoris (effort induced and vasospastic). Amlodipine is administered orally and absorbed slowly; peak levels develop in 6 to 12 hours. The drug has a long half-life (30 to 50 hours) and therefore is effective with once-a-day dosing. Principal adverse effects are peripheral and facial edema. Flushing, dizziness, and headache may also occur, as may eczematous rash in older patients. In contrast to other dihydropyridines, amlodipine causes little reflex tachycardia. Amlodipine is available in 2.5-, 5-, and 10-mg tablets. The usual initial dosage for hypertension or angina pectoris is 5 mg once a day. A fixed-dose combination with benazepril (an ACE inhibitor) is available under the trade name *Lotrel*.

45.4.2.3 Isradipine.

Like nifedipine, isradipine [DynaCirc, DynaCirc CR] produces relatively selective blockade of calcium channels in blood vessels. In the United States, the drug is approved only for hypertension. Isradipine is rapidly absorbed following oral administration, but undergoes extensive first-pass metabolism. Parent drug and metabolites are excreted in the urine. The most common side effects are facial flushing (11%), headache (14%), dizziness (7%), and ankle edema (7%). Eczematous rash may develop in older patients. In contrast to nifedipine, isradipine causes minimal reflex tachycardia. The drug is available in capsules (2.5 and 5 mg) and controlled-release tablets (5 and 10 mg). The usual antihypertensive dosage is 2.5 to 5 mg twice a day.

45.4.2.4 Felodipine.

Felodipine [Plendil] produces selective blockade of calcium channels in blood vessels. In the United States, the drug is approved only for hypertension. Felodipine is well absorbed following oral administration but undergoes extensive first-pass metabolism. As a result, bioavailability is low—only 20%. Plasma levels peak in 2.5 to 5 hours and then decay with a half-life of 24 hours. Because of its prolonged half-life, felodipine is effective with once-a-day dosing. Characteristic adverse effects are reflex tachycardia, peripheral edema, headache, facial flushing, and dizziness. Eczematous rash may develop in older patients. Gingival hyperplasia has been reported. Felodipine is available in extended-release tablets (2.5, 5, and 10 mg). The usual dosage for hypertension is 5 to 10 mg once a day. A fixed-dose combination with enalapril (an ACE inhibitor) is available under the trade name *Lexxel*.

45.4.2.5 Nimodipine.

Nimodipine [Nimotop] produces selective blockade of calcium channels in *cerebral blood vessels*. The only approved application is prophylaxis of neurologic injury following rupture of an intracranial aneurysm. Benefits derive from preventing the cerebral arterial spasm that follows subarachnoid hemorrhage (SAH) and can result in ischemic neurologic injury. Dosing (60 mg every 4 hours) should begin within 96 hours of SAH and continue for 21 days. Nimodipine is available in 30-mg liquid-filled capsules for oral administration only. *Nimodipine must never be given parenterally* (eg, IM, IV) owing to a risk of potentially fatal cardiovascular events.

45.4.2.6 Nisoldipine.

Like nifedipine, nisoldipine [Sular] produces selective blockade of calcium channels in blood vessels; the drug has minimal direct effects on the heart. The only approved indication is hypertension. Nisoldipine is well absorbed following oral administration, but the first-pass effect limits bioavailability to 5%. Plasma levels peak 6 hours after administration. The most common side effects are dizziness, headache, and peripheral edema. Reflex tachycardia may also occur. As with other CCBs, eczematous rash may develop in older patients. Nisoldipine is available in extended-release tablets (10, 20, 30, and 40 mg). The dosage for hypertension is 20 to 60 mg once a day.

45.4.2.7 Clevidipine.

Clevidipine [Cleviprex], approved in 2008, is indicated only for *intravenous* therapy of *severe* hypertension, defined as systolic blood pressure above 180 mm Hg or diastolic pressure above 115 mm Hg. The drug has an ultrashort half-life (about 1 minute), owing to rapid inactivation by plasma esterases. Effects are not altered by impairment of liver or kidney function. Because of IV dosing and rapid inactivation, blood pressure falls quickly and then rises quickly when the infusion is slowed or stopped. As a result, responses can be easily titrated. Clevidipine is formulated in a lipid emulsion made from soybean oil and egg yolk phospholipids, and hence is contraindicated for patients allergic to soy beans or eggs. Clevidipine is supplied in single-dose vials (50 or 100 mL) at a concentration of 0.5 mg/mL. For patients with severe hypertension, the infusion rate is 1 to 2 mg/hr initially, and can be doubled every 3 minutes up to a maximum of 32 mg/hr. In clinical trials, the average time to reach the target blood pressure was 10.9 minutes. The most common side effects are headache, nausea, and vomiting. Like other dihydropyridines, clevidipine can cause hypotension and reflex tachycardia.

45.4.2.7.1

KEY POINTS

- Calcium channels are gated pores in the cytoplasmic membrane that regulate calcium entry into cells.
- In blood vessels, calcium entry causes vasoconstriction, and hence calcium channel blockade causes vasodilation.
- In the heart, calcium entry increases heart rate, AV conduction, and myocardial contractility, and hence calcium channel blockade has the opposite effects.
- In the heart, calcium channels are coupled to β_1 receptors, activation of which enhances calcium entry. As a result, calcium channel blockade and beta blockade have identical effects on cardiac function.
- At therapeutic doses, nifedipine and the other dihydropyridines act primarily on VSM; in contrast, verapamil and diltiazem act on VSM *and* on the heart.
- All CCBs promote vasodilation, and hence are useful in hypertension and angina pectoris.
- Because they suppress AV conduction, verapamil and diltiazem are useful for treating cardiac dysrhythmias (in addition to hypertension and angina pectoris).
- Because of their cardiosuppressant effects, verapamil and diltiazem can cause bradycardia, partial or complete AV block, and exacerbation of heart failure.
- Beta blockers intensify cardiosuppression caused by verapamil and diltiazem.
- Nifedipine and other dihydropyridines can cause reflex tachycardia. Tachycardia is most intense with rapid-acting formulations, and much less intense with sustained-release formulations.
- Beta blockers can be used to suppress reflex tachycardia caused by nifedipine and other dihydropyridines.
- Because they cause vasodilation, all CCBs can cause dizziness, headache, and peripheral edema.
- In toxic doses, nifedipine and other dihydropyridines can cause cardiosuppression, just like verapamil and diltiazem.

- Rapid-acting nifedipine has been associated with increased mortality in patients with myocardial infarction and unstable angina, although a cause-and-effect relationship has not been established. The National Heart, Lung, and Blood Institute has recommended that rapid-acting nifedipine, especially in higher doses, be used with great caution, if at all.

45.4.2.7.2

Summary of Major Nursing Implications*

45.4.2.7.2.1

VERAPAMIL AND DILTIAZEM

45.4.2.7.2....

Preadministration Assessment

45.4.2.7.2....

Therapeutic Goal

Verapamil and diltiazem are indicated for *hypertension*, *angina pectoris*, and *cardiac dysrhythmias* (atrial fibrillation, atrial flutter, and paroxysmal supraventricular tachycardia).

45.4.2.7.2....

Baseline Data

For *all patients*, determine blood pressure and pulse rate, and obtain laboratory evaluations of liver and kidney function. For patients with *angina pectoris*, obtain baseline data on the frequency and severity of anginal attacks. For baseline data relevant to *hypertension*, see [Chapter 46](#).

45.4.2.7.2....

Identifying High-Risk Patients

Verapamil and diltiazem are *contraindicated* for patients with severe hypotension, sick sinus syndrome (in the absence of electronic pacing), and second-degree or third-degree AV block. Use with *caution* in patients with heart failure or liver impairment and in patients taking digoxin or beta blockers.

45.4.2.7.2....

Implementation: Administration

45.4.2.7.2....

Routes

Oral, IV.

45.4.2.7.2....	Administration	
45.4.2.7.2....	Oral.	
	<i>Verapamil</i> and <i>diltiazem</i> may be used for angina pectoris and essential hypertension. <i>Verapamil</i> may be used with digoxin to control ventricular rate in patients with atrial fibrillation and atrial flutter.	
	<i>Sustained-release formulations</i> are reserved for essential hypertension. Instruct patients to swallow sustained-release formulations whole, without crushing or chewing.	
	Prior to administration, measure blood pressure and pulse rate. If hypotension or bradycardia is detected, withhold medication and notify the prescriber.	
45.4.2.7.2....	Intravenous.	
	Intravenous therapy (with verapamil or diltiazem) is reserved for cardiac dysrhythmias. Perform injections slowly (over 2 to 3 minutes). Monitor the ECG for AV block, sudden reduction in heart rate, and prolongation of the PR or QT interval. Have facilities for cardioversion and cardiac pacing immediately available.	
45.4.2.7.2....	Ongoing Evaluation and Interventions	
45.4.2.7.2....	Evaluating Therapeutic Effects	
45.4.2.7.2....	Angina Pectoris.	
	Keep an ongoing record of anginal attacks, noting the time and intensity of each attack and the likely precipitating event. Teach outpatients to chart the time, intensity, and circumstances of their attacks, and to notify the prescriber if attacks increase.	486
45.4.2.7.2....	Essential Hypertension.	487
	Monitor blood pressure periodically. For most patients, the goal is to reduce systolic/diastolic pressure to a value below 140/90 mm Hg. Teach patients to self-monitor their blood pressure and to maintain a blood pressure record.	

45.4.2.7.2....

Minimizing Adverse Effects

45.4.2.7.2....

Cardiosuppression.

Verapamil and diltiazem can cause bradycardia, AV block, and heart failure.

Inform patients about manifestations of cardiac effects (eg, slow heartbeat, shortness of breath, weight gain) and instruct them to notify the prescriber if these occur. If cardiac impairment is severe, drug use should stop.

45.4.2.7.2....

Peripheral Edema.

Inform patients about signs of edema (swelling in ankles or feet) and instruct them to notify the prescriber if these occur. If necessary, edema can be reduced with a diuretic.

45.4.2.7.2....

Constipation.

Constipation occurs primarily with *verapamil*. **Advise patients that constipation can be minimized by increasing dietary fluid and fiber.**

45.4.2.7.2....

Minimizing Adverse Interactions

45.4.2.7.2....

Digoxin.

The combination of digoxin with verapamil or diltiazem increases the risk of partial or complete AV block. Monitor for indications of impaired AV conduction (missed beats, slowed ventricular rate).

Verapamil (and possibly diltiazem) can increase plasma levels of digoxin. Digoxin dosage should be reduced.

45.4.2.7.2....

Beta Blockers.

Concurrent use of a beta blocker with verapamil or diltiazem can cause bradycardia, AV block, or heart failure. Monitor closely for cardiac suppression. Administer *intravenous verapamil* and beta blockers several hours apart.

45.4.2.7.2....

Managing Acute Toxicity

Remove unabsorbed drug with gastric lavage followed by a cathartic. Give intravenous calcium to help counteract excessive vasodilation and reduced myocardial contractility.

To raise blood pressure, give IV norepinephrine. Intravenous fluids and placing the patient in modified Trendelenburg's position can also help.

Bradycardia and AV block can be reversed with isoproterenol and atropine. If these are inadequate, electronic pacing may be required.

Ventricular tachydysrhythmias can be treated with DC cardioversion.

Antidysrhythmic drugs (lidocaine or procainamide) may also be used.

45.4.2.7.2.2

DIHYDROPYRIDINES

Amlodipine

Clevidipine

Felodipine

Isradipine

Nicardipine

Nifedipine

Nimodipine

Nisoldipine

45.4.2.7.2....

Preadministration Assessment

45.4.2.7.2....

Therapeutic Goal

Amlodipine, nifedipine, and nicardipine are approved for essential hypertension and angina pectoris.

Isradipine, felodipine, and nisoldipine are approved for hypertension only.

Nimodipine is used only for subarachnoid hemorrhage.

Clevidipine is used only for severe hypertension.

45.4.2.7.2....

Baseline Data

See nursing implications for *Verapamil and Diltiazem*.

45.4.2.7.2....

Identifying High-Risk Patients

Use dihydropyridines with *caution* in patients with hypotension, sick sinus syndrome (in the absence of electronic pacing), angina pectoris (because of reflex tachycardia), heart failure, and second-degree or third-degree AV block.

45.4.2.7.2....

Implementation: Administration

45.4.2.7.2....

Route

Oral. All dihydropyridines except clevidipine.

Intravenous. Nicardipine, clevidipine.

45.4.2.7.2....

Administration

Instruct patients to swallow sustained-release formulations whole, without crushing or chewing.

45.4.2.7.2....

Ongoing Evaluation and Interventions

45.4.2.7.2....

Evaluating Therapeutic Effects

See nursing implications for *Verapamil and Diltiazem*.

45.4.2.7.2....

Minimizing Adverse Effects

45.4.2.7.2....

Reflex Tachycardia.

Reflex tachycardia can be suppressed with a beta blocker.

45.4.2.7.2....

Peripheral Edema.

Inform patients about signs of edema (swelling in ankles or feet) and instruct them to notify the prescriber if these occur. If necessary, edema can be reduced with a diuretic.

45.4.2.7.2....

Managing Acute Toxicity

See nursing implications for *Verapamil* and *Diltiazem*.

* Patient education information is highlighted as **blue text**.

⁴⁶CHAPTER 45 Vasodilators

Vasodilation can be produced with a variety of drugs. The major classes of vasodilators, along with representative agents, are listed in [Table 45-1](#). Some of these drugs act primarily on arterioles, some act primarily on veins, and some act on both types of vessel. The vasodilators are widely used, with indications ranging from hypertension to angina pectoris to heart failure. Many of the vasodilators have been discussed in previous chapters. Four agents—hydralazine, minoxidil, diazoxide, and nitroprusside—are introduced here.

In approaching the vasodilators, we begin by considering concepts that apply to the vasodilators as a group. After that we discuss the pharmacology of individual agents.

^{46.1}BASIC CONCEPTS IN VASODILATOR PHARMACOLOGY

^{46.1.1}Selectivity of Vasodilatory Effects

Vasodilators differ from one another with respect to the types of blood vessels they affect. Some agents (eg, hydralazine) produce selective dilation of arterioles. Others (eg, nitroglycerin) produce selective dilation of veins. Still others (eg, prazosin) dilate arterioles *and* veins. The selectivity of some important vasodilators is summarized in [Table 45-2](#).

The selectivity of a vasodilator determines its hemodynamic effects. For example, drugs that dilate *resistance vessels* (arterioles) cause a decrease in cardiac *afterload* (the force the heart works against to pump blood). By decreasing afterload, arteriolar dilators reduce cardiac work while causing cardiac output and tissue perfusion to increase. In contrast, drugs that dilate *capacitance vessels* (veins) reduce the force with which blood is returned to the heart, which reduces ventricular filling. This reduction in filling decreases cardiac *preload* (the degree of stretch of the ventricular muscle prior to contraction), which in turn decreases the force of ventricular contraction. Hence, by decreasing preload, venous dilators cause a decrease in cardiac work, along with a decrease in cardiac output and tissue perfusion.

TABLE 45-1 Types of Vasodilators

Category	Examples
Drugs Acting on the Renin-Angiotensin-Aldosterone System	
Angiotensin-Converting Enzyme Inhibitors	Captopril Enalapril
Angiotensin II Receptor Blockers	Losartan Valsartan
Direct Renin Inhibitors	Aliskiren
Organic Nitrates	Nitroglycerin Isosorbide dinitrate
Calcium Channel Blockers	Diltiazem Verapamil Nifedipine
Sympatholytic Drugs	
Alpha-Adrenergic Blockers	Phentolamine Phenoxybenzamine Prazosin Terazosin
Ganglionic Blockers	Mecamylamine
Adrenergic Neuron Blockers	Reserpine Guanadrel
Centrally Acting Agents	Clonidine Methyldopa
Drugs for Pulmonary Arterial Hypertension	Bosentan Epoprostenol
Other Important Vasodilators	Hydralazine Minoxidil Nitroprusside Diazoxide Nesiritide

Because hemodynamic responses to dilation of arterioles and veins differ, the selectivity of a vasodilator is a major determinant of its effects, both therapeutic and undesired. Undesired effects

related to selective dilation of arterioles and veins are discussed below. Therapeutic implications of selective dilation are discussed in [Chapters 46, 47, 50, 52, and 106](#)—the chapters in which the primary uses of the vasodilators are presented.

488

TABLE 45-2 Vasodilator Selectivity

489

Vasodilator	Site of Vasodilation	
	Arterioles	Veins
Hydralazine	+	
Minoxidil	+	
Diltiazem	+	
Nifedipine	+	
Verapamil	+	
Diazoxide	+	
Prazosin	+	+
Terazosin	+	+

Nitroprusside	+	+
Captopril	+	+
Enalapril	+	+
Losartan	+	+
Aliskiren	+	+
Nitroglycerin		+
Isosorbide dinitrate		+

46.1.2 Overview of Therapeutic Uses

The vasodilators, as a group, have a broad spectrum of uses. Principal indications are *essential hypertension, hypertensive crisis, angina pectoris, heart failure, and myocardial infarction*. Additional indications include *pheochromocytoma, peripheral vascular disease, pulmonary arterial hypertension, and production of controlled hypotension during surgery*. The specific applications of any particular agent are determined by its pharmacologic profile. Important facets of that profile are route of administration, site of vasodilation (arterioles, veins, or both), and intensity and duration of effects.

46.1.3 Adverse Effects Related to Vasodilation

46.1.3.1 Postural Hypotension

Postural (orthostatic) hypotension is defined as a fall in blood pressure brought on by moving from a supine or seated position to an upright position. The underlying cause is relaxation of smooth muscle in *veins*. Because of venous relaxation, gravity causes blood to “pool” in veins, thereby decreasing venous return to the heart. Reduced venous return causes a decrease in cardiac output and a corresponding drop in blood pressure. Hypotension from venous dilation is minimal in recumbent subjects because, when we are lying down, the impact of gravity on venous return is small.

Patients receiving vasodilators should be informed about symptoms of hypotension (lightheadedness, dizziness) and advised to sit or lie down if these occur. Failure to follow this advice may result in fainting. Patients should also be informed that they can minimize hypotension by avoiding abrupt transitions from a supine or seated position to an upright position.

46.1.3.2 Reflex Tachycardia

Reflex tachycardia can be produced by dilation of arterioles *or* veins. The mechanism is this: (1a) *arteriolar* dilation causes a direct decrease in arterial pressure or (1b) *venous* dilation reduces cardiac output, which in turn reduces arterial pressure; (2) baroreceptors in the aortic arch and carotid sinus sense the drop in pressure and relay this information to the vasomotor center of the medulla; and (3) in an attempt to bring blood pressure back up, the medulla sends impulses along sympathetic nerves instructing the heart to beat faster.

Reflex tachycardia is undesirable for two reasons. First, tachycardia can put an unacceptable burden on the heart. Second, if the vasodilator was given to reduce blood pressure, tachycardia would raise pressure and thereby counteract the desired effect.

To help prevent vasodilator-induced reflex tachycardia, patients can be pretreated with a beta blocker (eg, propranolol), which will block sympathetic stimulation of the heart.

46.1.3.3 Expansion of Blood Volume

Prolonged use of *arteriolar* or *venous* dilators can cause an increase in blood volume (secondary to prolonged reduction of blood pressure). The increase in volume represents an attempt by the body to restore blood pressure to pretreatment levels.

Why does blood volume increase? First, reduced blood pressure triggers secretion of aldosterone by the adrenal glands. Aldosterone then acts on the kidney to promote retention of sodium and water, thereby increasing blood volume. Second, by reducing arterial pressure, vasodilators decrease both renal blood flow and glomerular filtration rate; because filtrate volume is decreased, the kidney is able to reabsorb an increased fraction of filtered sodium and water, which causes blood volume to expand.

Increased blood volume can negate the beneficial effects of the vasodilator. For example, if volume increases during the treatment of hypertension, blood pressure will rise and the benefits of therapy will be canceled. To prevent the kidney from neutralizing the beneficial effects of vasodilation, patients often receive concurrent therapy with a diuretic, which prevents fluid retention and volume expansion.

46.2 PHARMACOLOGY OF INDIVIDUAL VASODILATORS

In this section we focus on four drugs: hydralazine, minoxidil, diazoxide, and sodium nitroprusside. All of the other vasodilators are discussed at length in other chapters, and hence discussion of them here is brief.

46.2.1 Hydralazine

46.2.1.1 Cardiovascular Effects

Hydralazine [Apresoline] causes selective dilation of arterioles. The drug has little or no effect on veins. Arteriolar dilation results from a direct action on vascular smooth muscle (VSM). The exact mechanism is unknown. In response to arteriolar dilation, peripheral resistance and arterial blood pressure fall. In addition, heart rate and myocardial contractility increase, largely by reflex mechanisms. Because hydralazine acts selectively on arterioles, postural hypotension is minimal.

46.2.1.2 Pharmacokinetics

46.2.1.2.1 Absorption and Time Course of Action.

Hydralazine is readily absorbed following oral administration. Effects begin within 45 minutes and persist for 6 hours or more. With parenteral administration, effects begin fast (within 10 minutes) and last 2 to 4 hours.

489

46.2.1.2.2 Metabolism.

Hydralazine is inactivated by a metabolic process known as *acetylation*. The ability to acetylate drugs is genetically determined. Some people are rapid acetylators; some are slow acetylators. The distinction between rapid and slow acetylators can be clinically significant. Why? Because individuals who acetylate hydralazine slowly are likely to have higher blood levels of the drug, which can result in excessive vasodilation and other undesired effects. To avoid hydralazine accumulation, dosage should be reduced in slow acetylators.

46.2.1.3 Therapeutic Uses

46.2.1.3.1 Essential Hypertension.

Oral hydralazine can be used to lower blood pressure in patients with essential hypertension. The regimen almost always includes a beta blocker, and may also include a diuretic. Although commonly employed in the past, hydralazine has been largely replaced by newer antihypertensive agents (see [Chapter 46](#)).

46.2.1.3.2 Hypertensive Crisis.

Parenteral hydralazine is used to lower blood pressure rapidly in severe hypertensive episodes. The drug should be administered in small, incremental doses. If dosage is excessive, severe hypotension may replace the hypertension. Treatment of hypertensive emergencies is discussed in [Chapter 46](#).

46.2.1.3.3 Heart Failure.

As discussed in [Chapter 47](#), hydralazine (usually in combination with isosorbide dinitrate) can be used short term to reduce afterload in patients with heart failure. With prolonged therapy, tolerance to hydralazine develops.

46.2.1.4 Adverse Effects

46.2.1.4.1 Reflex Tachycardia.

By lowering arterial blood pressure, hydralazine can trigger reflex stimulation of the heart, thereby causing cardiac work and myocardial oxygen demand to increase. Because hydralazine-induced reflex tachycardia is frequently severe, the drug is usually combined with a beta blocker.

46.2.1.4.2 Increased Blood Volume.

Hydralazine-induced hypotension can cause sodium and water retention and a corresponding increase in blood volume. A diuretic can prevent volume expansion.

46.2.1.4.3 Systemic Lupus Erythematosus–like Syndrome.

Hydralazine can cause an acute rheumatoid syndrome that closely resembles systemic lupus erythematosus (SLE). Symptoms include muscle pain, joint pain, fever, nephritis, pericarditis, and the presence of antinuclear antibodies. The syndrome occurs most frequently in slow acetylators and is rare when dosage is kept below 200 mg/day. If an SLE–like reaction occurs, hydralazine should be discontinued. Symptoms are usually reversible but may take 6 or more months to resolve. In some cases, rheumatoid symptoms persist for years.

46.2.1.4.4 Other Adverse Effects.

Common responses include *headache*, *dizziness*, *weakness*, and *fatigue*. These reactions are related to hydralazine-induced hypotension.

46.2.1.5 Drug Interactions

Hydralazine is combined with a *beta blocker* to protect against reflex tachycardia, and with *diuretics* to prevent sodium and water retention and expansion of blood volume. Drugs that lower blood pressure will intensify hypotensive responses to hydralazine. Accordingly, if hydralazine is used with other *antihypertensive agents*, care is needed to avoid excessive hypotension. In the treatment of heart failure, hydralazine is usually combined with *isosorbide dinitrate*, a drug that dilates veins.

46.2.1.6 Preparations, Dosage, and Administration

46.2.1.6.1 Preparations.

Hydralazine [Apresoline] is available in tablets (10, 25, 50, and 100 mg) for oral use and in solution (20 mg/mL in 1-mL ampules) for parenteral administration. Hydralazine is also available in fixed-dose combination with (1) hydrochlorothiazide (a diuretic) under the trade name *Apresazide* and (2) isosorbide dinitrate (a vasodilator) under the trade name *BiDil*. As discussed in [Chapters 8](#) and [47](#), BiDil is the first drug product approved for treating a specific ethnic group—namely, African Americans.

46.2.1.6.2 Oral Therapy.

Dosage should be low initially (10 mg 4 times a day) and then gradually increased. Rapid increases may produce excessive hypotension. Usual maintenance dosages for adults range from 25 to 100 mg twice a day. Daily doses greater than 200 mg are associated with an increased incidence of adverse effects and should be avoided.

46.2.1.6.3 Parenteral Therapy.

Parenteral administration (IV and IM) is reserved for hypertensive crises. The usual dose is 20 to 40 mg, repeated as needed. Blood pressure should be monitored frequently to minimize excessive hypotension. In most cases, patients can be switched from parenteral hydralazine to oral therapy within 48 hours.

46.2.2 Minoxidil

Minoxidil, formerly available as Loniten, produces more intense vasodilation than hydralazine but also causes more severe adverse reactions. Because it is both very effective and very dangerous, minoxidil is reserved for patients with severe hypertension unresponsive to safer drugs.

46.2.2.1 Cardiovascular Effects

Like hydralazine, minoxidil produces selective dilation of *arterioles*. Little or no venous dilation occurs. Arteriolar dilation decreases peripheral resistance and arterial blood pressure. In response, reflex mechanisms increase heart rate and myocardial contractility. Both responses can increase cardiac oxygen demand, and can thereby exacerbate angina pectoris.

Vasodilation results from a direct action on VSM. In order to relax VSM, minoxidil must first be metabolized to minoxidil sulfate. This metabolite then causes potassium channels in VSM to open. The resultant efflux of potassium hyperpolarizes VSM cells, thereby reducing their ability to contract.

46.2.2.2 Pharmacokinetics

Minoxidil is rapidly and completely absorbed following oral administration. Vasodilation is maximal within 2 to 3 hours and then gradually declines. Residual effects may persist for 2 days or more. Minoxidil is extensively metabolized. Metabolites and parent drug are eliminated in the urine. The drug's half-life is 4.2 hours.

46.2.2.3 Therapeutic Uses

The only cardiovascular indication for minoxidil is *severe hypertension*. Because of its serious adverse effects, minoxidil is reserved for patients who have not responded to safer drugs. To minimize adverse responses (reflex tachycardia, expansion of blood volume, pericardial effusion), minoxidil should be used with a beta blocker plus intensive diuretic therapy.

Topical minoxidil [Rogaine, others] is used to promote hair growth in balding men and women (see [Chapter 104](#)).

46.2.2.4 Adverse Effects

46.2.2.4.1 Reflex Tachycardia.

Blood pressure reduction triggers reflex tachycardia, a serious effect that can be minimized by giving a beta blocker.

490

46.2.2.4.2 Sodium and Water Retention.

491

Fluid retention is both common and serious. Volume expansion may be so severe as to cause cardiac decompensation. Management of fluid retention requires a high-ceiling diuretic (eg, furosemide) used alone or in combination with a thiazide diuretic. If diuretics are inadequate, dialysis must be employed, or minoxidil must be withdrawn.

46.2.2.4.3 Hypertrichosis.

About 80% of patients taking minoxidil for 4 weeks or more develop hypertrichosis (excessive growth of hair). Hair growth begins on the face and later develops on the arms, legs, and back. Hypertrichosis appears to result from proliferation of epithelial cells at the base of the hair follicle; vasodilation may also be involved. Hairiness is a cosmetic problem that can be controlled by shaving or using a depilatory. However, many patients, primarily women, find hypertrichosis both unmanageable and intolerable and refuse to continue treatment.

46.2.2.4.4 Pericardial Effusion.

Rarely, minoxidil-induced fluid retention results in pericardial effusion (fluid accumulation beneath the pericardium). In most cases, pericardial effusion is asymptomatic. However, in some cases, fluid accumulation becomes so great as to cause cardiac tamponade (compression

of the heart with a resultant decrease in cardiac performance). If tamponade occurs, it must be treated by pericardiocentesis or surgical drainage.

46.2.2.4.5 Other Adverse Effects.

Minoxidil may cause *nausea, headache, fatigue, breast tenderness, glucose intolerance, thrombocytopenia*, and *skin reactions* (rashes, Stevens-Johnson syndrome). In addition, the drug has caused *hemorrhagic cardiac lesions* in experimental animals.

46.2.2.5 Preparations, Dosage, and Administration

Minoxidil is supplied in 2.5- and 10-mg tablets. The initial dosage is 5 mg once a day. The maximum dosage is 100 mg/day. The usual adult dosage is 10 to 40 mg/day administered in single or divided doses. When a rapid response is needed, a loading dose of 5 to 20 mg is given followed by doses of 2.5 to 10 mg every 4 hours.

A topical formulation [Rogaine, others] is available for treating baldness (see [Chapter 104](#)).

46.2.3 Diazoxide

Diazoxide [Hyperstat IV] is a close relative of the thiazide diuretics but lacks diuretic effects. The drug is indicated for hypertensive emergencies.

46.2.3.1 Cardiovascular Effects

Like hydralazine and minoxidil, diazoxide produces selective dilation of *arterioles*; the drug does not dilate veins. Intravenous diazoxide causes a rapid drop in diastolic and systolic pressure. Reduced arterial pressure triggers reflex tachycardia along with an increase in myocardial contractility; these effects combine to increase cardiac output. Arteriolar dilation also promotes substantial salt and water retention.

Vasodilation results from a direct effect on VSM. Diazoxide activates potassium channels in VSM, which results in hyperpolarization and a reduced ability to contract.

46.2.3.2 Pharmacokinetics

Diazoxide is administered IV, either as a bolus injection or by infusion. Bolus injection is generally preferred. Effects begin within minutes and may persist for hours. Most of the drug is eliminated unchanged in the urine.

46.2.3.3 Therapeutic Uses

Parenteral diazoxide is reserved for acute treatment of hypertensive emergencies (eg, malignant hypertension, hypertensive encephalopathy). Oral antihypertensive agents should be instituted as soon as possible. In most cases, diazoxide can be discontinued in 4 to 5 days.

46.2.3.4 Adverse Effects

46.2.3.4.1 Reflex Tachycardia.

Reflex tachycardia occurs in response to lowering blood pressure. Tachycardia can be blunted with a beta blocker.

46.2.3.4.2 Salt and Water Retention.

Diazoxide causes substantial retention of salt and water. The primary cause is reduced glomerular filtration. If fluid retention is severe, edema and even congestive heart failure can result. Edema and expansion of blood volume can be prevented with a diuretic, preferably a high-ceiling agent (eg, furosemide).

46.2.3.4.3 Hyperglycemia.

Like the thiazide diuretics, diazoxide can suppress release of insulin, and can thereby cause blood glucose to rise. For most patients, the degree of hyperglycemia is insignificant. However, for patients with diabetes, hyperglycemia may be substantial. If hyperglycemia develops, insulin dosage should be increased.

46.2.3.4.4 Hyperuricemia.

Like the thiazide diuretics, diazoxide can decrease renal excretion of uric acid, thereby raising uric acid levels in blood. For most patients, hyperuricemia is asymptomatic. However, in gout-prone individuals, uric acid retention may precipitate a gouty attack.

46.2.3.4.5 Other Adverse Effects.

Diazoxide may cause *GI effects* (nausea, vomiting, anorexia), *headache*, *flushing*, *hypotension*, and *temporary interruption of labor*. Rapid injection of large doses may produce *severe hypotension*, *anginal symptoms*, and *myocardial infarction*.

46.2.3.5 Drug Interactions

46.2.3.5.1 Diuretics.

High-ceiling diuretics are used to counteract diazoxide-induced retention of salt and water. Because *thiazide diuretics* might potentiate the hyperglycemic and hyperuricemic effects of diazoxide, these agents should be avoided.

46.2.3.5.2 Antihypertensive Drugs.

With the exception of high-ceiling diuretics, antihypertensive drugs should generally be avoided. Why? Because an excessive reduction of blood pressure could result.

46.2.3.6 Preparations, Dosage, and Administration

Diazoxide [Hyperstat IV] is available in solution (15 mg/mL) for IV administration. In the past, it was common to administer diazoxide as a single, large (300-mg) IV bolus. This is no longer recommended. Experts now consider it safer and more effective to use a series of “minibolus” injections, rather than one large injection. Accordingly, treatment should begin with a dose of 1 to 3 mg/kg injected by rapid IV push (30 seconds or less). Dosing is then repeated every 5 to 15 minutes until the desired drop in blood pressure has been achieved. Once hypertension has been controlled, injections can be made every 4 to 24 hours. Blood pressure should be monitored closely until an acceptable and stable level has been produced; hourly monitoring should be performed thereafter. The patient should remain recumbent for at least 30 minutes after diazoxide injection. After 4 or 5 days, the patient can usually be switched to oral antihypertensive therapy.

46.2.4 Sodium Nitroprusside

Sodium nitroprusside [Nitropress] is a potent and efficacious vasodilator. It is also the fastest acting antihypertensive agent available. Because of these qualities, nitroprusside is a drug of choice for hypertensive emergencies.

46.2.4.1 Cardiovascular Effects

In contrast to hydralazine, minoxidil, and diazoxide, nitroprusside causes *venous* dilation in addition to *arteriolar* dilation. Curiously, although nitroprusside is an effective arteriolar dilator, reflex tachycardia is minimal. Administration is by IV infusion, and effects begin at once. By adjusting the infusion rate, blood pressure can be depressed to almost any level desired. When

the infusion is stopped, blood pressure returns to pretreatment levels in minutes. Nitroprusside can trigger retention of sodium and water; furosemide can help offset this effect.

46.2.4.2 Mechanism of Action

Once in the body, nitroprusside breaks down to release *nitric oxide* (Fig. 45-1), which then activates *guanylate cyclase*, an enzyme present in VSM. Guanylate cyclase catalyzes the production of *cyclic GMP*, which, through a series of reactions, causes vasodilation. This mechanism is similar to that of nitroglycerin.

46.2.4.3 Metabolism

As shown in [Figure 45-1](#), nitroprusside contains five *cyanide groups*, which are split free in the first step of nitroprusside metabolism. *Nitric oxide*, the active component, is released

491

492

Figure 45-1 **Structure and metabolism of sodium nitroprusside.** Note the five cyanide (CN) groups in nitroprusside and their liberation during metabolism. Note also the release of nitric oxide (NO), the active component of nitroprusside.

next. Both reactions take place in smooth muscle. Once freed, the cyanide groups are converted to *thiocyanate* by the liver, using *thiosulfate* as a cofactor. Thiocyanate is eliminated by the kidneys over several days.

46.2.4.4 Therapeutic Uses

46.2.4.4.1 Hypertensive Emergencies.

Nitroprusside is used to lower blood pressure rapidly in hypertensive emergencies. Oral antihypertensive medication should be initiated simultaneously. During nitroprusside treatment, furosemide may be needed to prevent excessive retention of fluid.

46.2.4.4.2 Other Uses.

Nitroprusside is approved for producing controlled hypotension during surgery (to reduce bleeding in the surgical field). In addition, the drug has been employed investigationally to treat severe, refractory congestive heart failure and myocardial infarction.

46.2.4.5 Adverse Effects

46.2.4.5.1 Excessive Hypotension.

If administered too rapidly, nitroprusside can cause a precipitous drop in blood pressure, resulting in headache, palpitations, nausea, vomiting, and sweating. Blood pressure should be monitored continuously.

46.2.4.5.2 Cyanide Poisoning.

Rarely, lethal amounts of cyanide have accumulated. Cyanide buildup is most likely in patients with liver disease and in those with low stores of thiosulfate, the cofactor needed for cyanide detoxification. The chances of cyanide poisoning can be minimized by avoiding rapid infusion (faster than 5 mcg/kg/min) and by coadministering thiosulfate. If cyanide toxicity occurs, nitroprusside should be withdrawn.

46.2.4.5.3 Thiocyanate Toxicity.

When nitroprusside is given for several days, thiocyanate may accumulate. Although much less hazardous than cyanide, thiocyanate can also cause adverse effects. These effects, which involve the central nervous system (CNS), include disorientation, psychotic behavior, and delirium. To minimize toxicity, patients receiving nitroprusside for more than 3 days should undergo monitoring of plasma thiocyanate, which must be kept below 0.1 mg/mL.

46.2.4.6 Preparations, Dosage, and Administration

Sodium nitroprusside [Nitropress] is available in powdered form (50 mg) to be dissolved and then diluted for IV infusion. Fresh solutions may have a faint brown coloration. Solutions that are deeply colored (blue, green, dark red) should be discarded. Nitroprusside in solution can be degraded by light, and hence should be protected with an opaque material.

Blood pressure can be adjusted to practically any level by increasing or decreasing the rate of infusion. The initial infusion rate is 0.3 mcg/kg/min. The maximal rate is 10 mcg/kg/min. If infusion at the maximal rate for 10 minutes fails to produce an adequate drop in blood pressure, administration should stop. During the infusion, blood pressure should be monitored continuously, with either an arterial line or an electronic monitoring device. No other drugs should be mixed with the nitroprusside solution.

46.2.5 Drugs Acting on the Renin-AngiotensinAldosterone System

As discussed in [Chapter 43](#), the renin-angiotensin-aldosterone system (RAAS) plays an important role in the regulation of blood pressure, blood volume, and fluid and electrolyte balance. A key component of the system—angiotensin II—is a powerful vasoconstrictor that acts on arterioles and veins. Hence, by blocking either the formation or actions of angiotensin II, we can promote dilation of arterioles and veins.

46.2.5.1 Angiotensin-Converting Enzyme (ACE) Inhibitors.

Inhibitors of ACE promote vasodilation by blocking the conversion of angiotensin I (a weak vasoconstrictor) into angiotensin II (a powerful vasoconstrictor). The result is dilation of arterioles and veins. The primary indications for ACE inhibitors are essential hypertension and heart failure. In addition, these drugs can help preserve renal function in people with diabetes. The basic pharmacology of the ACE inhibitors is presented in [Chapter 43](#). Their use in hypertension and heart failure is discussed in [Chapters 46](#) and [47](#), respectively.

46.2.5.2 Angiotensin II Receptor Blockers (ARBs).

These drugs have effects much like those of the ACE inhibitors. However, instead of preventing formation of angiotensin II, these drugs block receptors for angiotensin II. Like the ACE inhibitors, ARBs dilate arterioles and veins. Currently, ARBs have three indications: hypertension, heart failure, and diabetic nephropathy. The basic pharmacology of the ARBs is discussed in [Chapter 43](#).

46.2.5.3 Direct Renin Inhibitors (DRIs).

Like ACE inhibitors, the DRIs prevent formation of angiotensin II. However, the mechanism is different: Rather than inhibiting ACE, the DRIs inhibit renin, the enzyme that forms angiotensin I; in the absence of angiotensin I, angiotensin II cannot be made. Like the ACE inhibitors and ARBs, the DRIs promote dilation of arterioles and veins. The only DRI currently available—aliskiren—is approved only for hypertension. The basic pharmacology of aliskiren is discussed in [Chapter 43](#).

46.2.6 Organic Nitrates

The organic nitrates (eg, nitroglycerin, isosorbide dinitrate) produce selective dilation of veins; dilation of arterioles is minimal. The primary indication for these drugs is angina pectoris. In addition, nitroglycerin is given to treat heart failure and myocardial infarction, and to provide controlled hypotension during surgery. The pharmacology of the organic nitrates is discussed in [Chapter 50](#).

46.2.7 Calcium Channel Blockers

The calcium channel blockers (eg, verapamil, nifedipine) produce vasodilation by preventing calcium entry into VSM. At therapeutic doses, these drugs produce selective dilation of arterioles. Primary indications are hypertension and angina pectoris. The calcium channel blockers are the subject of [Chapter 44](#).

46.2.8 Sympatholytic Drugs

Sympatholytic drugs promote vasodilation by preventing the sympathetic nervous system from causing vasoconstriction. Some of these drugs act by direct blockade of vascular adrenergic receptors. Others act on sympathetic ganglia, adrenergic neurons, or the CNS.

46.2.8.1 Alpha-Adrenergic Blocking Agents.

The alpha blockers (eg, phentolamine, prazosin) promote vasodilation by preventing activation of alpha adrenergic receptors on veins and arterioles. In their capacity as vasodilators, these drugs have multiple therapeutic applications, including hypertension, peripheral vascular disease, and pheochromocytoma. The alpha blockers are discussed in [Chapter 18](#).

46.2.8.2 Ganglionic Blocking Agents.

Ganglionic blocking agents interrupt impulse transmission through all ganglia of the autonomic nervous system. By doing so, they prevent sympathetic stimulation of arterioles and veins, and thereby cause vasodilation. Ganglionic blockers can be used for hypertensive emergencies and severe cases of essential hypertension. In addition, they can be given to produce hypotension during surgery. Prominent side effects—dry mouth, blurred vision, urinary retention, and paresis of the bowel—result from parasympathetic blockade. At this time, only one ganglionic blocker—mecamylamine—is available (see [Chapter 16](#)).

492

493

46.2.8.3 Adrenergic Neuron Blocking Agents.

Adrenergic neuron blockers (eg, reserpine) act within terminals of adrenergic neurons to reduce norepinephrine release. Vasodilation results from their effect on sympathetic nerves that innervate blood vessels. The adrenergic neuron blockers, which are used for hypertension, are discussed in [Chapter 19](#).

46.2.8.4 Centrally Acting Agents.

The centrally acting sympatholytics (eg, clonidine, methyldopa) act within the CNS to inhibit impulse outflow along sympathetic nerves. These agents are used primarily for hypertension. Their pharmacology is discussed in [Chapter 19](#).

46.2.9 Nesiritide

Nesiritide [Natrecor] is a synthetic form of B-natriuretic peptide. The drug dilates arterioles *and* veins. Three mechanisms are involved: suppression of the RAAS, suppression of CNS sympathetic outflow, and a direct effect on VSM. Nesiritide is indicated only for short-term therapy of acutely decompensated heart failure (see [Chapter 47](#)).

46.2.10 Drugs for Pulmonary Arterial Hypertension

Four vasodilators—ambrisentan [Letairis], bosentan [Tracleer], epoprostenol [Flolan], and treprostinil [Remodulin]—are used to dilate pulmonary blood vessels in patients with pulmonary arterial hypertension. Ambrisentan and bosentan block vascular receptors for endothelin-1, a powerful vasoconstrictor. Epoprostenol and treprostinil stimulate production of cyclic AMP in vascular smooth muscle. All four drugs are discussed in [Chapter 106](#).

46.2.10.1

KEY POINTS

- Some vasodilators are selective for arterioles, some are selective for veins, and some dilate both types of vessel.
- Drugs that dilate arterioles reduce cardiac afterload, and can thereby reduce cardiac work while increasing cardiac output and tissue perfusion.
- Drugs that dilate veins reduce cardiac preload, and can thereby reduce cardiac work, cardiac output, and tissue perfusion.
- Principal indications for vasodilators are essential hypertension, hypertensive crisis, angina pectoris, heart failure, and myocardial infarction.
- Drugs that dilate veins can cause orthostatic hypotension.
- Drugs that dilate arterioles or veins can cause reflex tachycardia, which increases cardiac work and elevates blood pressure. Reflex tachycardia can be blunted with a beta blocker.
- Drugs that dilate arterioles or veins can cause fluid retention, a response that can be blunted with a diuretic.
- Hydralazine causes selective dilation of arterioles.
- Hydralazine can cause a syndrome that resembles SLE.
- Minoxidil causes selective and profound dilation of arterioles.
- Minoxidil can cause hypertrichosis.
- Sodium nitroprusside dilates arterioles and veins.
- Prolonged infusion of nitroprusside can result in toxic accumulation of cyanide and thiocyanate.

⁴⁷CHAPTER 46 Drugs for Hypertension*

Hypertension (elevated blood pressure [BP]) is a common, chronic disorder that affects 65 million Americans and over 1 billion people worldwide. Left untreated, hypertension can lead to heart disease, kidney disease, and stroke. Conversely, a treatment program of lifestyle modifications and drug therapy can reduce both BP and the risk of long-term complications. However, it is important to appreciate that we cannot cure hypertension; we can only reduce symptoms. As a result, treatment must continue lifelong, making nonadherence a significant problem. Despite advances in management, hypertension remains underdiagnosed and undertreated: Among Americans with the disease, 70% have been diagnosed, 59% undergo treatment, and only 34% take sufficient medicine to bring their BP under control.

Fourteen drug classes are used for treatment. All have been introduced in previous chapters. Hence, in this chapter, rather than struggling with a huge array of new drugs, we simply discuss the antihypertensive applications of drugs you already know about.

In 2003, the National Heart, Lung, and Blood Institute issued revised clinical guidelines on hypertension. This document—*The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure*, known simply as JNC 7—was prepared by a special committee of the National High Blood Pressure Education Program. Recommendations in JNC 7 update and simplify those of JNC 6, released in 1997. Important changes include a new BP classification scheme, increased emphasis on controlling systolic BP, and the recommendation to use thiazide diuretics as initial therapy for most patients. Throughout this chapter, clinical practice recommendations reflect those in JNC 7.*

^{47.1}BASIC CONSIDERATIONS IN HYPERTENSION

In this section, we consider three issues: (1) classification of BP based on values for systolic and diastolic pressure, (2) types of hypertension, and (3) the damaging effects of chronic hypertension.

* Be aware that, although JNC 7 is the most influential guideline in the United States, it is not the only authoritative guideline available. Since the publication of JNC 7, updated treatment guidelines have been released by several organizations, including the American Society of Hypertension, the Canadian Hypertension Education Program, the European Society of Hypertension in conjunction with the European Society of Cardiology, and the World Health Organization in conjunction with the International Society of Hypertension. Recommendations in these guidelines generally parallel those in JNC 7. However, important differences do exist.

47.2 CLASSIFICATION OF BLOOD PRESSURE

JNC 7 defines four BP categories: normal, prehypertension, stage 1 hypertension, and stage 2 hypertension ([Table 46-1](#)). This scheme differs from that of JNC 6 in three ways:

- The cutoff values for normal BP have been reduced.
- A new category—prehypertension—has been added.
- Two classes of hypertension—stages 2 and 3 from JNC 6—have been combined into one—stage 2 in JNC 7—because management of both is much the same.

47.2.1 Normal.

In JNC 7, normal BP is defined as systolic BP below 120 mm Hg and diastolic BP below 80 mm Hg, compared with 130/85 in JNC 6. Why were the cutoff values reduced? Because the values from JNC 6 are not as safe as previously believed.

47.2.2 Prehypertension.

Prehypertension is defined as systolic BP of 120 to 139 mm Hg or diastolic BP of 80 to 89 mm Hg. BP in this range carries an increased risk of cardiovascular disease, even though outright hypertension has not yet developed. Data from the Framingham Heart Study show that, relative to people with normal BP, those with BP in the prehypertension range have a 2- to 3-fold increased risk of cardiovascular events. To reduce risk, these people should adopt certain health-promoting lifestyle changes (see below). Prehypertension affects about 30% of American adults (about 60 million people).

494
495

TABLE 46-1 Classification of Blood Pressure for Adults Age 18 and Older

Classification*	Systolic (mm Hg)		Diastolic (mm Hg)
Normal	<120	and	<80
Prehypertension	120–139	or	80–89
Stage 1 Hypertension	140–159	or	90–99
Stage 2 Hypertension	≥160	or	≥100
Data from The Seventh Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure. JAMA 289:2560–2572, 2003.			

- * Not taking any antihypertensive drugs and not acutely ill. When systolic and diastolic pressures fall into different categories, the higher category should be selected to classify BP status. For example, 160/92 mm Hg should be classified as stage 2 hypertension. Isolated systolic hypertension is defined as systolic BP of 140 mm Hg or higher and diastolic BP below 90 mm Hg and staged appropriately (eg, 170/82 is defined as stage 2 isolated systolic hypertension).

47.2.3 Hypertension.

Hypertension is defined as systolic BP above 140 mm Hg or diastolic BP above 90 mm Hg. If systolic BP is above 140 mm Hg and diastolic BP is below 90 mm Hg, a diagnosis of *isolated systolic hypertension* (ISH) applies. When systolic BP and diastolic BP fall in different categories, BP classification is based on the higher category. For example, a reading of 160/92 mm Hg indicates stage 2 hypertension, and a reading of 170/82 indicates stage 2 ISH.

Diagnosis of hypertension should be based on several BP readings, not just one. If an initial screen shows that BP is elevated (but does not represent an immediate danger), measurement should be repeated on two subsequent visits. At each visit, two measurements should be made, at least 5 minutes apart. The patient should be seated in a chair—not on an examination table—with his or her feet on the floor. High readings should be confirmed in the contralateral arm. If the mean of all readings shows that systolic BP is indeed greater than 140 mm Hg or that diastolic BP is greater than 90 mm Hg, a diagnosis of hypertension can be made.

47.3 TYPES OF HYPERTENSION

There are two broad categories of hypertension: *primary hypertension* and *secondary hypertension*. As indicated in [Table 46-2](#), primary hypertension is by far the most common form of hypertensive disease. Less than 10% of people with hypertension have a secondary form.

47.3.1 Primary (Essential) Hypertension

Primary hypertension is defined as hypertension that has no identifiable cause. A diagnosis of primary hypertension is made by ruling out probable specific causes of BP elevation. Primary hypertension is a chronic, progressive disorder. In the absence of treatment, patients will experience a continuous, gradual rise in BP over the rest of their lives.

TABLE 46-2 Types of Hypertension and Their Frequency

Type of Hypertension	Frequency (%)
Primary (Essential) Hypertension	92
Secondary Hypertension	
Chronic renal disease	4
Renovascular disease	2
Oral contraceptive–induced	1
Coarctation of the aorta	0.3
Primary aldosteronism	0.2
Cushing's syndrome	0.1
Pheochromocytoma	0.1
Sleep apnea	?
Thyroid or parathyroid disease	?

In the United States, primary hypertension affects about 30% of adults. However, not all groups are at equal risk: older people are at higher risk than younger people; African Americans and Hispanic Americans are at higher risk than white Americans; postmenopausal women are at higher risk than premenopausal women; and obese people are at higher risk than lean people.

Although the cause of primary hypertension is unknown, the condition can be successfully treated. It should be understood, however, that treatment is not curative: Drugs can lower BP, but they can't eliminate the underlying pathology. Consequently, treatment must continue lifelong.

Primary hypertension is also referred to as *essential hypertension*. This alternative name preceded the term *primary hypertension* and reflects our ignorance about the cause of the problem. Historically, it had been noted that, as people grew older, their BP rose. Why older people had elevated BP was (and remains) unknown. One hypothesis noted that, as people aged, their vascular systems offered greater resistance to blood flow. In order to move blood against this increased resistance, a compensatory increase in BP was required. Therefore, the hypertension that occurred with age was seen as being “essential” for providing adequate perfusion of tissues—hence, the term *essential hypertension*. Over time, the term came to be applied to all cases of hypertension for which an underlying cause could not be found.

47.3.2 Secondary Hypertension

Secondary hypertension is defined as an elevation of BP brought on by an identifiable primary cause. The most common are listed in [Table 46-2](#).

Because secondary hypertension results from an identifiable cause, it may be possible to treat that cause directly, rather than relying on antihypertensive drugs for symptomatic relief. As a result, some individuals can actually be cured. For example, if hypertension occurs secondary to pheochromocytoma (a catecholamine-secreting tumor), surgical removal of the tumor may produce permanent cure. When cure is not possible, secondary hypertension can be managed with the same drugs used for primary hypertension.

495

496

47.3.2.1

BOX 46-1 Special Interest Topic

47.3.2.1.1

ISOLATED SYSTOLIC HYPERTENSION: THE REAL KILLER OF AGING AMERICANS

Over the past 15 years, several large randomized clinical trials involving older hypertensive patients have produced unequivocal evidence that, compared with elevated *diastolic* BP, elevated *systolic* BP is the stronger predictor of cardiovascular disease, kidney disease, stroke, and death. Additional studies have shown that, when elevated systolic BP is reduced, there is a corresponding reduction in the incidence of kidney failure, heart failure, MI, stroke, and death. Accordingly, in 2000, the Coordinating Committee of the National High Blood Pressure Education Program issued a clinical advisory recommending that systolic BP—rather than diastolic BP—be used as the major clinical endpoint for the detection, evaluation, and treatment of hypertension, especially in middle-aged and older Americans. The importance of elevated systolic pressure is reflected in the recommendations of JNC 7, released in 2003.

Some readers may be asking, “What's new here? I mean, hasn't elevated systolic BP always been a concern?” Well, no, it hasn't. In fact, until recently, isolated systolic hypertension (ISH)—defined as systolic BP above 140 mm Hg and diastolic BP below 90 mm Hg—was considered a relatively benign condition that did not merit treatment. After all, most experts agreed that, in people with hypertension, elevated diastolic BP—not elevated systolic BP—was the principal cause of morbidity and mortality. Of course, this view has been proven dead wrong.

ISH is primarily a disease of the elderly. As we grow older, systolic BP gradually rises. The underlying cause is increased stiffness (reduced compliance) in large arteries—owing to progressive replacement of elastin with collagen in the arterial wall. Among older Americans, ISH is the most common form of hypertension: According to the National Health and Nutrition Examination Survey (NHANES), of all hypertensive individuals over the age of 60, fully 65% have ISH. Because of their ISH, older people are at increased risk,

as demonstrated in the Multiple Risk Factor Intervention Trial (MRFIT), which evaluated over 316,000 men and found a nearly linear relationship between increased systolic BP and increased risk of adverse cardiovascular events.

Does lowering elevated systolic BP reduce cardiovascular risk? Yes indeed! The benefits of treating ISH have been documented in several large, randomized controlled trials. Important among these are the Systolic Hypertension in the Elderly Program (SHEP) and the Systolic Hypertension in Europe (Syst-Eur) trial. An analysis of the results of these trials indicated that lowering systolic BP decreased overall mortality by 13%, cardiovascular mortality by 18%, cardiovascular complications by 26%, coronary events by 23%, and stroke by 30%.

Unfortunately, among people with ISH, control of BP is generally poor. For most hypertensive people, the target BP is 140/90 mm Hg. However, among elderly African Americans, only 25% achieve this goal. And among white Americans, the success rate is even worse: Only 18% achieve the goal. This low success rate is both sad and troubling, in that it means many people will experience unnecessary morbidity and mortality.

The low rate of BP control in the elderly, coupled with our heightened appreciation of the dangers of ISH, led the Coordinating Committee to issue its advisory. As noted, the Committee recommended that systolic BP, rather than diastolic BP, be the major consideration in the detection, evaluation, and treatment of hypertension—especially in older Americans. The Committee recommended using either a low-dose thiazide diuretic (with or without a beta blocker) or a long-acting dihydropyridine CCB for initial treatment. These recommendations were based in part on the successful use of these drugs in the SHEP and Syst-Eur trials. Although ACE inhibitors were not recommended by the Committee, recent evidence indicates that these drugs too can reduce the risk of stroke, MI, heart failure, and death in older hypertensive people.

^{47.4} CONSEQUENCES OF HYPERTENSION

Chronic hypertension is associated with increased morbidity and mortality. Left untreated, prolonged elevation of BP can lead to heart disease (myocardial infarction [MI], heart failure, angina pectoris), kidney disease, and stroke. The degree of injury is directly related to the degree of pressure elevation: the higher the pressure, the greater the risk. Among people 40 to 70 years old, the risk of cardiovascular disease is doubled for each 20 mm Hg increase in systolic BP or each 10 mm Hg increase in diastolic BP—beginning at 115/75 mm Hg and continuing through 185/155 mm Hg. For people over the age of 50, elevated *systolic* BP poses a greater risk than elevated diastolic BP ([Box 46-1](#)). For patients of all ages, hypertension-related deaths result largely from cerebral hemorrhage, renal failure, heart failure, and MI.

Unfortunately, despite its potential for serious harm, hypertension usually remains asymptomatic until long after injury has begun to develop. As a result, the disease can exist for years before overt pathology is evident. Because injury develops slowly and progressively, and because hypertension rarely causes discomfort, many people who have the disease don't know it. Furthermore, many who do know it forgo treatment, largely because hypertension doesn't make them feel bad—that is, until it's too late.

47.5 MANAGEMENT OF CHRONIC HYPERTENSION

In this section we consider treatments for chronic hypertension. We begin by addressing patient evaluation and other basic issues, after which we discuss the two modes of management: lifestyle modifications and drug therapy.

47.6 BASIC CONSIDERATIONS

47.6.1 Benefits of Lowering Blood Pressure

Multiple clinical trials have demonstrated unequivocally that, when the BP of hypertensive individuals is lowered, morbidity is decreased and life is prolonged. Treatment reduces the incidence of stroke by 35% to 40%, MI by 20% to 25%, and heart failure by more than 50%.

496

497

Although reductions in morbidity are not as dramatic, they are nonetheless significant: Among patients with stage 1 hypertension plus additional cardiovascular risk factors, one death would be prevented for every 11 patients who reduced systolic pressure by 12 mm Hg for a period of 10 years—and among those with hypertension plus cardiovascular disease or target-organ damage, one death would be prevented for every 9 patients who achieved a sustained 12 mm Hg reduction in pressure.

47.6.2 Patient Evaluation

Evaluation of patients with hypertension has two major objectives. Specifically, we must assess for (1) identifiable causes of hypertension, and (2) factors that increase cardiovascular risk. To aid evaluation, diagnostic tests are required.

47.6.2.1 Hypertension with a Treatable Cause.

As discussed above, some forms of hypertension result from a treatable cause, such as Cushing's syndrome, pheochromocytoma, and oral contraceptive use (see [Table 46-2](#)). Patients should be evaluated for these causes and managed appropriately. In many cases, direct treatment of the underlying cause can control BP, thereby eliminating the need for further antihypertensive therapy.

47.6.2.2 Factors That Increase Cardiovascular Risk.

Two types of factors—existing target-organ damage and major cardiovascular risk factors—increase the risk of cardiovascular events in patients with hypertension. When these factors are present, aggressive therapy is indicated. Accordingly, in order to select appropriate interventions, we must identify patients with the following types of *target-organ damage*:

- Heart disease
 - Left ventricular hypertrophy
 - Angina pectoris
 - Prior MI
 - Prior coronary revascularization
 - Heart failure
- Stroke or transient ischemic attack
- Chronic kidney disease
- Peripheral arterial disease
- Retinopathy

as well as patients with the following *major cardiovascular risk factors* (other than hypertension):

- Cigarette smoking
- Obesity
- Inadequate exercise
- Dyslipidemia
- Diabetes
- Microalbuminuria
- Advancing age (above 55 years for men, above 65 years for women)
- Family history of premature cardiovascular disease

47.6.2.3 Diagnostic Tests.

The following tests should be done in all patients: electrocardiogram; complete urinalysis; hemoglobin and hematocrit; and blood levels of sodium, potassium, calcium, creatinine, glucose, uric acid, triglycerides, and cholesterol (total, LDL, and HDL cholesterol).

47.6.3 Treatment Goals

The ultimate goal in treating hypertension is to reduce cardiovascular and renal morbidity and mortality. Hopefully, this can be accomplished without decreasing quality of life with the drugs employed. For most patients with stage 1 or stage 2 hypertension, the goal is to maintain systolic BP below 140 mm Hg and diastolic BP below 90 mm Hg. For patients with diabetes or chronic kidney disease, the target BP is lower: 130/80 mm Hg. For patients over the age of 50, reducing *systolic* pressure is the primary goal. However, although treatment focuses on systolic pressure, interventions that achieve the systolic goal will likely achieve the diastolic goal too.

47.6.4 Therapeutic Interventions

We can reduce BP in two ways: We can implement healthy lifestyle changes and we can treat with antihypertensive drugs. As shown in [Table 46-3](#), for people with *prehypertension*, lifestyle changes are all that is needed. In contrast, for those with *hypertension*—either stage 1 or stage 2—a *combination* of lifestyle changes and drugs is indicated. Lifestyle changes and drug therapy are discussed in detail below.

TABLE 46-3 Overview of Blood Pressure Management in Adults 18 Years and Older

Blood Pressure Classification	Therapeutic Interventions	Blood Pressure Goal	
		Patients Without Diabetes or Chronic Kidney Disease	Patients With Diabetes or Chronic Kidney Disease
Normal	Encourage lifestyle changes	Prevent increase	Prevent increase
Prehypertension	Initiate lifestyle changes	Prevent increase/ promote decrease	Prevent increase/ promote decrease
Stage 1 hypertension	Initiate or continue lifestyle changes and begin antihypertensive drug therapy	<140/<90 mm Hg	<130/<80 mm Hg
Stage 2 hypertension	Initiate or continue lifestyle changes and begin or intensify antihypertensive drug therapy	<140/<90 mm Hg	<130/<80 mm Hg
Recommendations from The Seventh Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure. JAMA 289:2560–2572, 2003.			

497

47.7 LIFESTYLE MODIFICATIONS

498

Lifestyle changes offer multiple cardiovascular benefits—and they do so with little cost and minimal risk. When implemented before hypertension develops, they may actually prevent hypertension. When implemented after hypertension has developed, they can lower BP, thereby decreasing or eliminating the need for drugs. Lastly, lifestyle modifications can decrease other cardiovascular risk factors. Accordingly, all patients should be strongly encouraged to adopt a healthy lifestyle. Key components are discussed below.

47.7.1 Weight Loss.

There is a direct relationship between obesity and elevation of BP. Studies indicate that weight loss can reduce BP in 60% to 80% of overweight hypertensive individuals. In addition, weight loss can enhance responses to antihypertensive drugs. Consequently, a program of calorie restriction and exercise is recommended for all patients who are overweight. The goal is to achieve a body mass index in the normal range (18.5 to 24.9).*

* The definition and calculation of body mass index are presented in [Chapter 81](#) (Drugs for Obesity).

47.7.2 Sodium Restriction.

Reducing sodium chloride (salt) intake can lower BP in people with hypertension, and can help prevent overt hypertension in those with prehypertension. In addition, salt restriction can enhance the hypotensive effects of drugs. However, the benefits of sodium restriction are short lasting: Over time, BP returns to its original level, despite continued salt restriction. Nonetheless, JNC 7 recommends that all people with hypertension consume no more than 6 gm of sodium chloride (2.4 gm of sodium) a day. The Institute of Medicine recommends even lower salt consumption: 3.8 gm/day for adults age 50 and younger, 3.2 gm/day for adults age 51 to 70, and 2.9 gm/day for adults age 71 and older. To facilitate salt restriction, patients should be given information on the salt content of foods.

Experts disagree about the relationship between salt intake and BP in *normotensive* patients. In particular, they disagree as to whether a high-salt diet *causes* hypertension. Hence, for people with normal BP, a low-salt diet may be considered healthy or unnecessary, depending on the expert you consult.

47.7.3 The DASH Eating Plan.

Two studies have shown that we can reduce BP by adopting a healthy diet, known as the Dietary Approaches to Stop Hypertension (DASH) eating plan. This diet is rich in fruits, vegetables, and low-fat dairy products, and low in total fat, saturated fats, and cholesterol. In addition, the plan encourages intake of whole-grain products, fish, poultry, and nuts, and recommends minimal intake of red meat and sweets. Details are available online at www.nhlbi.nih.gov/health/public/heart/hbp/dash.

47.7.4 Alcohol Restriction.

Excessive alcohol consumption can raise BP and create resistance to antihypertensive drugs. Accordingly, patients should limit alcohol intake: Most men should consume no more than 1 ounce/day; women and lighter weight men should consume no more than 0.5 ounce/day. (One ounce of ethanol is equivalent to about two mixed drinks, two glasses of wine, or two cans of beer.)

47.7.5 Aerobic Exercise.

Regular aerobic exercise (eg, jogging, walking, swimming, bicycling) can reduce BP by about 10 mm Hg. In addition, exercise facilitates weight loss, reduces the risk of cardiovascular disease, and reduces all-cause mortality. In normotensive people, exercise decreases the risk of developing hypertension. Accordingly, all people with a sedentary lifestyle should be encouraged to develop

an exercise program. An activity as simple as brisk walking 30 to 45 minutes most days of the week is beneficial.

47.7.6 Smoking Cessation.

Smoking is a major risk factor for cardiovascular disease. Each time a cigarette is smoked, BP rises. In patients with hypertension, smoking can reduce the effects of antihypertensive drugs. Clearly, all patients who smoke should be strongly encouraged to quit. (Pharmacologic aids to smoking cessation are discussed in [Chapter 39](#).) As a rule, use of nicotine replacement products (eg, nicotine gum, nicotine patch) does not elevate BP. The cardiovascular benefits of quitting become evident within 1 year.

47.7.7 Maintenance of Potassium and Calcium Intake.

Potassium has a beneficial effect on BP. In patients with hypertension, potassium can lower BP. In normotensive people, high potassium intake helps protect against hypertension, whereas low intake elevates BP. For optimal cardiovascular effects, all people should take in 50 to 90 mmol of potassium a day. Preferred sources are fresh fruits and vegetables. If hypokalemia develops secondary to diuretic therapy, dietary intake may be insufficient to correct the problem. In this case, the patient may need to use a potassium supplement, a potassium-sparing diuretic, or a potassium-containing salt substitute.

Although adequate calcium is needed for overall good health, the impact of calcium on BP is only modest. In epidemiologic studies, high calcium intake is associated with a reduced incidence of hypertension. Among patients with hypertension, a few may be helped by increasing calcium intake. To maintain good health, calcium intake should be 1000 mg/day for adults under the age of 50, and 1200 mg/day for those 51 and older.

47.8 DRUG THERAPY

Drug therapy, together with lifestyle modifications, can control BP in all patients with chronic hypertension. The decision to use drugs should be the result of collaboration between prescriber and patient. A wide range of antihypertensive drugs is available, permitting versatility in the regimen. Consequently, for the majority of patients, it should be possible to establish a program that is effective and yet devoid of objectionable side effects.

47.8.1 Review of Blood Pressure Control

Before discussing the antihypertensive drugs, we need to review the major mechanisms by which BP is controlled. This information will help us understand the mechanisms by which drugs lower BP.

47.8.1.1 Principal Determinants of Blood Pressure

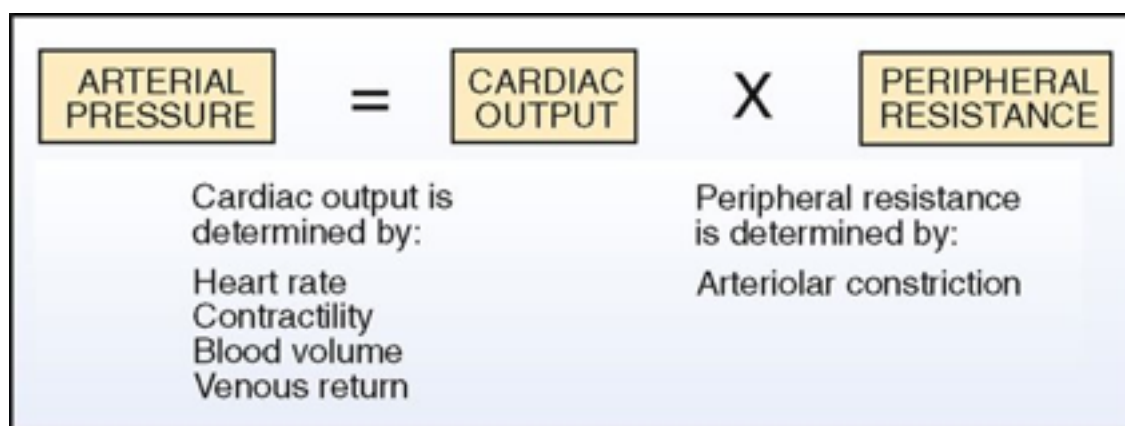

The principal determinants of BP are summarized in [Figure 46-1](#). As indicated, arterial pressure is the product of cardiac output and peripheral resistance. An increase in either will increase BP.

As shown in the figure, *cardiac output* is influenced by four factors: (1) heart rate, (2) myocardial contractility (force of contraction), (3) blood volume, and (4) venous return of blood to the heart. An increase in any of these will increase cardiac output, thereby causing BP to rise. Conversely, by

498

499

Figure 46-1 Primary determinants of arterial blood pressure.

reducing these factors, we can make BP fall. Drugs that affect these factors are (1) beta blockers, verapamil, and diltiazem and other drugs that decrease heart rate and contractile force; (2) diuretics and other drugs that decrease blood volume; and (3) venodilators, which reduce venous return.

Peripheral vascular resistance is regulated by arteriolar constriction. Accordingly, we can reduce BP with drugs that promote arteriolar dilation.

47.8.1.2 Systems That Help Regulate Blood Pressure

Having established that BP is determined by heart rate, myocardial contractility, blood volume, venous return, and arteriolar constriction, we can now examine how these factors are regulated. Three regulatory systems are of particular significance: (1) the sympathetic nervous system, (2) the reninangiotensin-aldosterone system (RAAS), and (3) the kidney.

47.8.1.2.1 Sympathetic Baroreceptor Reflex.

The sympathetic nervous system employs a reflex circuit—the baroreceptor reflex—to keep BP at a preset level. This circuit operates as follows: (1) Baroreceptors in the aortic arch and carotid sinus sense BP and relay this information to the brainstem. (2) When BP is perceived as too low, the brainstem sends impulses along sympathetic nerves to stimulate the heart and blood vessels. (3) BP is then elevated by (a) activation of β_1 receptors in the heart, resulting in increased cardiac output; and (b) activation of vascular α_1 receptors, resulting in vasoconstriction. (4) When BP has been restored to an acceptable level, sympathetic stimulation of the heart and vascular smooth muscle subsides.

The baroreceptor reflex frequently opposes our attempts to reduce BP with drugs. Opposition occurs because the “set point” of the baroreceptors is high in people with hypertension. That is, the baroreceptors are set to perceive excessively high BP as “normal” (ie, appropriate). As a result, the system operates to maintain BP at pathologic levels. Consequently, when we attempt to lower BP using drugs, the reduced (healthier) pressure is interpreted by the baroreceptors as below what it should be, and, in response, signals are sent along sympathetic nerves to “correct” the reduction. These signals produce reflex tachycardia and vasoconstriction—responses that can counteract the hypotensive effects of drugs. Clearly, if treatment is to succeed, the regimen must compensate for the resistance offered by this reflex. Taking a *beta blocker*, which will block reflex tachycardia, can be an effective method of compensation. Fortunately, when BP has been suppressed with drugs for an extended time, the baroreceptors become reset at a lower level. Consequently, as therapy proceeds, sympathetic reflexes offer progressively less resistance to the hypotensive effects of medication.

47.8.1.2.2 Renin-Angiotensin-Aldosterone System.

The RAAS can elevate BP, thereby negating the hypotensive effects of drugs. The RAAS is discussed at length in [Chapter 43](#) and reviewed briefly here.

How does the RAAS elevate BP? The process begins with the release of renin from juxtaglomerular cells of the kidney. These cells release renin in response to reduced renal blood flow, reduced blood volume, reduced BP, and activation of β_1 -adrenergic receptors on the cell surface. Following its release, *renin* catalyzes the conversion of angiotensinogen into angiotensin I, a weak vasoconstrictor. After this, *angiotensin-converting enzyme* (ACE) acts on angiotensin I to form *angiotensin II*, a compound that constricts systemic and renal blood vessels. Constriction of systemic blood vessels elevates BP by increasing peripheral

resistance. Constriction of renal blood vessels elevates BP by reducing glomerular filtration, which causes retention of salt and water, which in turn increases blood volume and BP. In addition to causing vasoconstriction, angiotensin II causes release of *aldosterone* from the adrenal cortex. Aldosterone acts on the kidney to further increase retention of sodium and water.

Since drug-induced reductions in BP can activate the RAAS, this system can counteract the effect we are trying to achieve. We have five ways to cope with this problem. First, we can suppress renin release with *beta blockers*. Second, we can prevent conversion of angiotensinogen to angiotensin I with a *direct renin inhibitor*. Third, we can prevent the conversion of angiotensin I into angiotensin II with an *ACE inhibitor*. Fourth, we can block receptors for angiotensin II with an *angiotensin II receptor blocker*. And fifth, we can block receptors for aldosterone with an *aldosterone antagonist*.

47.8.1.2.3 Renal Regulation of Blood Pressure.

As discussed in [Chapter 42](#), the kidney plays a central role in long-term regulation of BP. When BP falls, glomerular filtration rate (GFR) falls as well, thereby promoting retention of sodium, chloride, and water. The resultant increase in blood volume increases venous return to the heart, causing an increase in cardiac output, which in turn increases arterial pressure. We can neutralize renal effects on BP with *diuretics*.

47.8.2 Antihypertensive Mechanisms: Sites of Drug Action and Effects Produced

As discussed above, drugs can lower BP by reducing heart rate, myocardial contractility, blood volume, venous return, and the tone of arteriolar smooth muscle. In this section we survey the principal mechanisms by which drugs produce these effects.

The major mechanisms for lowering BP are summarized in [Figure 46-2](#) and [Table 46-4](#). The figure depicts the principal sites at which antihypertensive drugs act. The table summarizes the effects elicited when drugs act at these sites. The numbering system used below corresponds with the system used in [Figure 46-2](#) and [Table 46-4](#).

47.8.2.1 1—Brainstem.

Antihypertensive drugs acting in the brainstem suppress sympathetic outflow to the heart and blood vessels, resulting in decreased heart rate, decreased myocardial contractility, and vasodilation. Vasodilation contributes the most to reducing BP. Dilation of arterioles reduces BP by decreasing vascular resistance. Dilation of veins reduces BP by decreasing venous return to the heart.

47.8.2.2 2—Sympathetic Ganglia.

Ganglionic blockade reduces sympathetic stimulation of the heart and blood vessels.
Antihypertensive

499

500

Figure 46-2 **Sites of action of antihypertensive drugs.** Note that some antihypertensive agents act at more than one site: beta blockers act at sites 4 and 8a, and thiazides act at sites 6 and 7. The hemodynamic consequences of drug actions at the sites depicted are summarized in [Table 46-4](#). (ACE = angiotensin-converting enzyme, ARB = angiotensin II receptor blocker.)

effects result primarily from dilation of arterioles and veins. Ganglionic blocking agents (eg, mecamylamine) produce such a profound reduction in BP that they are used rarely, and then only for hypertensive emergencies.

47.8.2.3 3—Terminals of Adrenergic Nerves.

Antihypertensive agents that act at adrenergic nerve terminals decrease the release of norepinephrine, resulting in decreased sympathetic stimulation of the heart and blood vessels.

47.8.2.4 4—Beta₁-Adrenergic Receptors on the Heart.

Blockade of cardiac beta₁ receptors prevents sympathetic stimulation of the heart. As a result, heart rate and myocardial contractility decline.

47.8.2.5 5—Alpha₁-Adrenergic Receptors on Blood Vessels.

Blockade of vascular alpha₁ receptors promotes dilation of arterioles and veins. Arteriolar dilation reduces peripheral resistance. Venous dilation reduces venous return to the heart.

47.8.2.6 6—Vascular Smooth Muscle.

Several antihypertensive drugs (see [Fig. 46-2](#)) act directly on vascular smooth muscle to cause relaxation. Two of these agents—sodium nitroprusside and diazoxide—are used only for hypertensive emergencies. The rest are used for chronic hypertension.

47.8.2.7 7—Renal Tubules.

Diuretics act on renal tubules to promote salt and water excretion. As a result, blood volume declines, causing BP to fall.

TABLE 46-4 Summary of Antihypertensive Effects Elicited by Drug Actions at Specific Sites

Site of Drug Action*	Representative Drug	Drug Effects
1. Brainstem	Clonidine	Suppression of sympathetic outflow decreases sympathetic stimulation of the heart and blood vessels.
2. Sympathetic ganglia	Mecamylamine	Ganglionic blockade reduces sympathetic stimulation of the heart and blood vessels.
3. Adrenergic nerve terminals	Guanethidine	Reduced norepinephrine release decreases sympathetic stimulation of the heart and blood vessels.
4. Cardiac β_1 receptors	Propranolol	β_1 blockade decreases heart rate and myocardial contractility.
5. Vascular α_1 receptors	Prazosin	α_1 blockade causes vasodilation.
6. Vascular smooth muscle	Hydralazine	Relaxation of vascular smooth muscle causes vasodilation.
7. Renal tubules	Chlorothiazide	Promotion of diuresis results in decreased blood volume.
<i>Components of the renin-angiotensin-aldosterone system (8a to 8e)</i>		
8a. β_1 receptors on juxtaglomerular cells	Propranolol	β_1 blockade suppresses renin release, resulting in (1) vasodilation secondary to reduced production of angiotensin II, and (2) prevention of aldosterone-mediated volume expansion.
8b. Renin	Aliskiren	Inhibition of renin suppresses formation of angiotensin I, which in turn decreases formation of angiotensin II, and thereby reduces (1) vasoconstriction and (2) aldosterone-mediated volume expansion.
8c. Angiotensin-converting enzyme (ACE)	Captopril	Inhibition of ACE decreases formation of angiotensin II and thereby prevents (1) vasoconstriction and (2) aldosterone-mediated volume expansion.
8d. Angiotensin II receptors	Losartan	Blockade of angiotensin II receptors prevents angiotensin-mediated vasoconstriction and aldosterone-mediated volume expansion.
8e. Aldosterone receptors	Eplerenone	Blockade of aldosterone receptors in the kidney promotes excretion of sodium and water, and thereby reduces blood volume.

* Site numbers in this table correspond with site numbers in [Figure 46-2](#).

47.8.2.8 Components of the Renin-Angiotensin-Aldosterone System (8a to 8e)

47.8.2.9 8a—Beta₁ Receptors on Juxtaglomerular Cells.

Blockade of beta₁ receptors on juxtaglomerular cells suppresses release of renin. The resultant decrease in angiotensin II levels has three effects: peripheral vasodilation, renal vasodilation, and suppression of aldosterone-mediated volume expansion.

47.8.2.10 8b—Renin.

Inhibition of renin decreases conversion of angiotensinogen into angiotensin I, and thereby suppresses the entire RAAS. The result is peripheral vasodilation, renal vasodilation, and suppression of aldosterone-mediated volume expansion.

47.8.2.11 8c—Angiotensin-Converting Enzyme.

Inhibitors of ACE suppress formation of angiotensin II. The result is peripheral vasodilation, renal vasodilation, and suppression of aldosterone-mediated volume expansion.

47.8.2.12 8d—Angiotensin II Receptors.

Blockade of angiotensin II receptors prevents the actions of angiotensin II. Hence blockade results in peripheral vasodilation, renal vasodilation, and suppression of aldosterone-mediated volume expansion.

47.8.2.13 8e—Aldosterone Receptors.

Blockade of aldosterone receptors in the kidney promotes excretion of sodium and water, and thereby reduces blood volume.

47.8.3 Classes of Antihypertensive Drugs

In this section we consider the principal drugs employed to treat *chronic* hypertension. Drugs for hypertensive emergencies and hypertensive disorders of pregnancy are considered separately.

Individual antihypertensive drugs and their classes are summarized in [Table 46-5](#). Combination products are summarized in [Table 46-6](#). All of these drugs have been discussed in previous

chapters. Accordingly, discussion here is limited to their use in hypertension. Of primary interest are mechanisms of antihypertensive action and major adverse effects.

47.8.3.1 Diuretics

Diuretics are a mainstay of antihypertensive therapy. These drugs reduce BP when used alone, and they can enhance the effects of other hypotensive drugs. The basic pharmacology of the diuretics is discussed in [Chapter 40](#).

47.8.3.1.1 Thiazide Diuretics.

The thiazide diuretics (eg, hydrochlorothiazide, chlorthalidone) are among the most commonly used antihypertensive drugs. Thiazides reduce BP by two mechanisms: reduction of blood volume and reduction of arterial resistance. Reduced blood volume is responsible for initial antihypertensive effects. Reduced vascular resistance develops over time and is responsible for long-term antihypertensive effects. The mechanism by which thiazides reduce vascular resistance has not been determined.

The principal adverse effect of thiazides is *hypokalemia*. This can be minimized by consuming potassium-rich foods (eg, bananas, citrus fruits) and using potassium supplements or a potassium-sparing diuretic. Other side effects include *dehydration*, *hyperglycemia*, and *hyperuricemia*.

As discussed in [Box 46-2](#), thiazides are superior to calcium channel blockers and ACE inhibitors, and hence are preferred to these more expensive drugs.

501

TABLE 46-5 Drugs for Chronic Hypertension

502

Diuretics	Sympatholytics	RAAS Suppressants	Others
-----------	----------------	-------------------	--------

Pharmacology for Nursing Care, 7th Edition

Thiazides and Related Diuretics	Beta Blockers	ACE Inhibitors	Direct-Acting Vasodilators
Bendroflumethiazide	Acebutolol (has ISA)	Benazepril	Hydralazine
Benzthiazide	Atenolol	Captopril	Minoxidil
Chlorothiazide	Betaxolol	Enalapril	Calcium Channel Blockers
Chlorthalidone	Bisoprolol	Fosinopril	Amlodipine
Cyclothiazide	Carteolol (has ISA)	Lisinopril	Diltiazem (non-DHP)
Hydrochlorothiazide	Metoprolol	Moexipril	Felodipine
Hydroflumethiazide	Nadolol	Quinapril	Isradipine
Indapamide	Nebivolol	Ramipril	Nicardipine
Methyclothiazide	Penbutolol (has ISA)	Trandolapril	Nifedipine
Metolazone	Pindolol (has ISA)	Angiotensin II Receptor Blockers	Nimodipine
Polythiazide	Propranolol	Candesartan	Nisoldipine
Quinethazone	Timolol	Eprosartan	Verapamil (non-DHP)
Trichlormethiazide	Alpha₁ Blockers	Irbesartan	
Loop Diuretics	Doxazosin	Losartan	
Bumetanide	Prazosin	Olmesartan	
Ethacrynic acid	Terazosin	Telmisartan	
Furosemide	Alpha/Beta Blockers	Valsartan	
Torsemide	Carvedilol	Direct Renin Inhibitor	
Potassium-Sparing Diuretics	Labetalol	Aliskiren	
Amiloride	Centrally Acting Alpha₂ Agonists	Aldosterone Antagonists	
Spironolactone	Clonidine	Eplerenone	
Triamterene	Guanabenz	Spironolactone	
	Guanfacine		
	Methyldopa		
	Adrenergic Neuron Blockers		
	Guanadrel		

Guanethidine
Reserpine
DHP = dihydropyridine; ISA = intrinsic sympathomimetic activity; RAAS = renin-angiotensin-aldosterone system.

47.8.3.1.2 High-Ceiling (Loop) Diuretics.

High-ceiling diuretics (eg, furosemide) produce much greater diuresis than the thiazides. For most individuals with chronic hypertension, the amount of fluid loss that loop diuretics can produce is greater than needed or desirable. Consequently, loop diuretics are not used routinely. Rather, they are reserved for (1) patients who need greater diuresis than can be achieved with thiazides and (2) patients with a low GFR (because thiazides won't work when GFR is low). Like the thiazides, the loop diuretics lower BP by reducing blood volume and promoting vasodilation.

Most adverse effects are like those of the thiazides: *hypokalemia*, *dehydration*, *hyperglycemia*, and *hyperuricemia*. In addition, high-ceiling agents can cause *hearing loss*.

47.8.3.1.3 Potassium-Sparing Diuretics.

The degree of diuresis induced by the potassium-sparing agents (eg, spironolactone) is small. Consequently, these drugs have only modest hypotensive effects. However, because of their ability to conserve potassium, these drugs can play an important role in an antihypertensive regimen. Specifically, they can balance potassium loss caused by thiazides or loop diuretics. The most significant adverse effect of the potassium-sparing agents is *hyperkalemia*. Because of the risk of hyperkalemia, potassium-sparing diuretics must not be used in combination with one another or with potassium supplements. Also, they should not be used routinely with ACE inhibitors, angiotensin II receptor blockers, or aldosterone antagonists, all of which promote significant hyperkalemia.

47.8.3.2 Sympatholytics (Antiadrenergic Drugs)

Sympatholytic drugs suppress the influence of the sympathetic nervous system on the heart, blood vessels, and other structures. These drugs are used widely for hypertension.

As indicated in [Table 46-5](#), there are five subcategories of sympatholytic drugs: (1) beta blockers, (2) α_1 blockers, (3) α / β blockers, (4) centrally acting α_2 agonists, and (5) adrenergic neuron blockers.

47.8.3.2.1 Beta-Adrenergic Blockers.

The beta blockers (eg, propranolol, metoprolol) are among the most widely used antihypertensive drugs. However, despite their efficacy and frequent use, the exact mechanism by which they reduce BP is somewhat uncertain. Beta blockers are less effective in African Americans than in whites.

The beta blockers have at least four useful actions in hypertension. First, blockade of cardiac β_1 receptors decreases heart rate and contractility, thereby causing cardiac output to decline. Second, beta blockers can suppress reflex tachycardia caused by vasodilators. Third, blockade of β_1 receptors on juxtaglomerular cells of the kidney reduces release of renin, thereby reducing angiotensin II–mediated vasoconstriction and aldosterone-mediated volume expansion. 502
Fourth, long-term use of beta blockers reduces peripheral vascular resistance—by 503
a mechanism that is unknown. This action could readily account for most of their antihypertensive effects.

TABLE 46-6 Combination Products for Chronic Hypertension

Generic Name	Trade Name
Combinations with a Thiazide Diuretic	
Thiazide Plus a Beta Blocker	
Hydrochlorothiazide + propranolol	Inderide
Hydrochlorothiazide + metoprolol	Lopressor HCT
Hydrochlorothiazide + timolol	Timolide
Hydrochlorothiazide + bisoprolol	Ziac
Bendroflumethiazide + nadolol	Corzide
Chlorthalidone + atenolol	Tenoretic
Thiazide Plus an ACE Inhibitor	
Hydrochlorothiazide + captopril	Capozide
Hydrochlorothiazide + benazepril	Lotensin HCT
Hydrochlorothiazide + enalapril	Vaseretic
Hydrochlorothiazide + fosinopril	Monopril HCT
Hydrochlorothiazide + lisinopril	Prinzide, Zestoretic
Hydrochlorothiazide + moexipril	Uniretic
Hydrochlorothiazide + quinapril	Accuretic, Quinaretic
Thiazide Plus an ARB	
Hydrochlorothiazide + losartan	Hyzaar
Hydrochlorothiazide + valsartan	Diovan HCT
Hydrochlorothiazide + candesartan	Atacand HCT
Hydrochlorothiazide + eprosartan	Teveten HCT
Hydrochlorothiazide + irbesartan	Avalide
Hydrochlorothiazide + telmisartan	Micardis HCT
Hydrochlorothiazide + olmesartan	Benicar HCT
Thiazide Plus a Direct Renin Inhibitor	
Hydrochlorothiazide + aliskiren	Tekturna HCT
Thiazide Plus an Alpha₂ Agonist	
Chlorthalidone + clonidine	Clorpres
Hydrochlorothiazide + methyldopa	generic only
Thiazide Plus a Direct-Acting Vasodilator	

Hydrochlorothiazide + hydralazine	generic only
Thiazide Plus a Potassium-Sparing Diuretic	
Hydrochlorothiazide + spironolactone	Aldactazide
Hydrochlorothiazide + triamterene	Dyazide, Maxzide
Hydrochlorothiazide + amiloride	Moduretic
Combinations with a CCB	
CCB Plus an ACE Inhibitor	
Amlodipine + benazepril	Lotrel
Verapamil + trandolapril	Tarka
CCB Plus an ARB	
Amlodipine + valsartan	Exforge
Amlodipine + olmesartan	Azor
ACE = angiotensin-converting enzyme; CCB = calcium channel blocker; ARB = angiotensin II receptor blocker.	

Four beta blockers have *intrinsic sympathomimetic activity* (see [Table 46-5](#)). That is, they can produce mild activation of beta receptors while blocking receptor activation by strong agonists (eg, norepinephrine). As a result, heart rate at rest is slowed less than with other beta blockers. Accordingly, if a patient develops symptomatic bradycardia with another beta blocker, switching to one of these may help.

Beta blockers can produce a variety of adverse effects. Blockade of cardiac beta₁ receptors can produce *bradycardia*, *decreased atrioventricular (AV) conduction*, and *reduced contractility*. Consequently, beta blockers should not be used by patients with sick sinus syndrome or second- or third-degree AV block—and must be used with care in patients with heart failure. Blockade of beta₂ receptors in the lung can promote *bronchoconstriction*.

Accordingly, beta blockers should be avoided by patients with asthma. If an asthmatic individual absolutely must use a beta blocker, a beta₁-selective agent (eg, metoprolol) should be employed. Beta blockers can mask signs of hypoglycemia, and therefore must be used with caution in patients with diabetes. Although conventional wisdom has it that beta blockers can cause depression, insomnia, bizarre dreams, and sexual dysfunction, a review of older clinical trials indicated that the risk is small or nonexistent.

503

504

47.8.3.2.1.1

BOX 46-2 Special Interest Topic

47.8.3.2.1.1.1

AND THE BEST DRUG IS ... THE CHEAP ONE!

Results from the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT),¹ published in 2002, show unequivocally that the least expensive drugs for hypertension, the thiazide diuretics, are also the most effective—a welcome revelation in these cost-conscious times. ALLHAT is an important trial that should have a profound impact on clinical practice.

ALLHAT was a large, double-blind trial that compared the impact of four antihypertensive drugs—chlorthalidone (a thiazide diuretic), amlodipine (a CCB), lisinopril (an ACE inhibitor), and doxazosin (an alpha blocker)—on the incidence of adverse cardiovascular (CV) events. The study enrolled 33,357 patients, including more women (47%), blacks (32%), and Hispanics (19%) than most earlier trials. All participants had stage 1 or stage 2 hypertension plus at least one additional risk factor for coronary heart disease (CHD). The mean follow-up time was 4.9 years.

The results? With one drug—doxazosin—the incidence of adverse CV events was substantially higher than with the others, and hence this arm of the study was terminated early. Effects of the remaining three drugs—chlorthalidone, amlodipine, and lisinopril—were similar in some respects but significantly different in others. With all three, rates of (1) fatal CHD or nonfatal heart attacks and (2) all-cause mortality were identical. However, in other ways, chlorthalidone was clearly superior. Specifically, chlorthalidone was slightly better at reducing systolic BP. More importantly, chlorthalidone was associated with fewer adverse CV events: Compared with patients taking chlorthalidone, those taking amlodipine experienced a higher 6-year rate of heart failure (10.2% vs. 7.7%), and those taking lisinopril experienced higher 6-year rates of stroke (6.3% vs. 5.6%), heart failure (8.7% vs. 7.7%), and combined CV disease (33.3% vs. 30.9%).

You might ask “Can the results seen with chlorthalidone, lisinopril, and amlodipine be extended to other members of the drug families they represent?” The answer is a qualified “Yes.” All thiazide diuretics are very similar, and hence the results seen with chlorthalidone are likely to be seen with other thiazides. Similarly, all ACE inhibitors are much the same, and hence the results seen with lisinopril are probably representative. The story with amlodipine is different. Amlodipine belongs to a subclass of CCBs known as dihydropyridines (DHPs), which differ significantly from CCBs in

other subclasses. Accordingly, extrapolation of the results seen with amlodipine should probably be limited to CCBs in the DHP subclass.

How do thiazides compare with beta blockers? Unfortunately, beta blockers were not included in ALLHAT. However, data from other large studies indicate that beta blockers are certainly no more effective than thiazides, and may well be less effective.

The message from ALLHAT is both clear and compelling: Thiazide diuretics should be the initial drugs of choice for most patients with hypertension. These drugs are at least as effective as the alternatives, and they cost *much* less. Hydrochlorothiazide, for example, costs about 10 cents a day, compared with about \$1 a day for amlodipine. Clearly, if most patients were to switch from amlodipine (and other expensive drugs) to the thiazides, the savings for our health system would be huge—and would quickly offset the \$120 million that taxpayers invested on ALLHAT. Wouldn't it be great if more clinical studies led to the same good news: The best drug for what ails you is also the cheapest.

47.8.3.2.1.1.1.1

Postscript

Do the results of the Anglo-Scandinavian Cardiac Outcomes Trial–Blood Pressure Lowering Arm (ASCOT-BPLA)² refute the results of ALLHAT? Not really. Although ASCOT-BPLA is an important clinical trial that may well lead to changes in hypertension treatment, the trial does not directly challenge the superiority of thiazides—at least when thiazides are used alone. ASCOT-BPLA enrolled 19,257 patients, most of whom were treated with either (1) a *combination* of amlodipine plus perindopril (nearly identical to the CCB/ACE inhibitor combination used in ALLHAT) or (2) a *combination* of atenolol (a beta blocker) plus bendroflumethiazide (a thiazide diuretic). The result? After a median follow-up of 5.5 years, patients taking the CCB/ACE inhibitor combination experienced significantly fewer adverse CV events than did patients taking the beta blocker/thiazide combination, indicating that one *combination* is better than the other. The results do not say, however, that the CCB *alone* or the ACE inhibitor *alone* is superior to the thiazide *alone*. Hence we cannot compare these results directly with those of ALLHAT (which showed that, when used alone, a thiazide *is* better than a CCB or an ACE inhibitor). What ASCOT-BPLA *does* suggest is that a CCB/ACE inhibitor combination would be better as first-line therapy of hypertension than the currently recommended beta blocker/thiazide combination. Whether a thiazide/CCB combination or a thiazide/ACE inhibitor combination would be better still has yet to be determined.

- 2 Dahlof B, Sever PS, Poulter NR, for the ASCOT Investigators: Prevention of cardiovascular events with an antihypertensive regimen of amlodipine adding perindopril as required versus atenolol adding bendroflumethiazide as required, in the Anglo-Scandinavian Cardiac Outcomes Trial–Blood Pressure Lowering Arm (ASCOT-BPLA): A multicenter randomized controlled trial. Lancet 366:895–906, 2005.

The basic pharmacology of the beta blockers is discussed in [Chapter 18](#).

47.8.3.2.2

Alpha₁ Blockers.

The alpha₁ blockers (eg, doxazosin, terazosin) prevent stimulation of alpha₁ receptors on arterioles and veins, thereby preventing sympathetically mediated vasoconstriction. The resultant vasodilation reduces both peripheral resistance and venous return to the heart.

504

505

The most disturbing side effect of alpha blockers is *orthostatic hypotension*. Hypotension can be especially severe with the initial dose. Significant hypotension continues with subsequent doses but is less profound.

The American College of Cardiology recommends that alpha blockers *not* be used as first-line therapy for hypertension. Why? Because in a huge clinical trial known as ALLHAT, in which doxazosin was compared with chlorthalidone (a thiazide diuretic), patients taking doxazosin experienced 25% more cardiovascular events and were twice as likely to be hospitalized for heart failure. It is not clear whether doxazosin *increased* cardiovascular risk or chlorthalidone *decreased* risk. Either way, the diuretic is clearly preferred to the alpha blocker.

The basic pharmacology of the alpha blockers is discussed in [Chapter 18](#).

47.8.3.2.3

Alpha/Beta Blockers: Carvedilol and Labetalol.

Carvedilol and labetalol are unusual in that they can block alpha₁ receptors as well as beta receptors. Blood pressure reduction results from a combination of actions: (1) alpha₁ blockade

promotes dilation of arterioles and veins, (2) blockade of cardiac β_1 receptors reduces heart rate and contractility, and (3) blockade of β_1 receptors on juxtaglomerular cells suppresses release of renin. Presumably, these drugs also share the ability of other beta blockers to reduce peripheral vascular resistance. Like other nonselective beta blockers, labetalol and carvedilol can exacerbate bradycardia, AV heart block, and asthma. Blockade of venous α_1 receptors can produce postural hypotension.

47.8.3.2.4 Centrally Acting α_2 Agonists.

As discussed in [Chapter 19](#), these drugs (eg, clonidine, methyldopa) act within the brainstem to suppress sympathetic outflow to the heart and blood vessels. The result is vasodilation and reduced cardiac output, both of which help lower BP. All central α_2 agonists can cause *dry mouth* and *sedation*. In addition, clonidine can cause severe *rebound hypertension* if treatment is abruptly discontinued. Additional adverse effects of methyldopa are *hemolytic anemia* (accompanied by a positive direct Coombs' test) and *liver disorders*.

47.8.3.2.5 Adrenergic Neuron Blockers.

This group consists of three drugs: guanethidine, guanadrel, and reserpine. All three drugs decrease BP through actions in the terminals of postganglionic sympathetic neurons. Guanethidine and guanadrel inhibit release of norepinephrine, whereas reserpine causes norepinephrine depletion. Both actions result in decreased sympathetic stimulation of the heart and blood vessels.

The major adverse effect of *guanethidine* and *guanadrel* is *severe orthostatic hypotension* resulting from decreased sympathetic tone to veins. Because of this risk, these drugs are last-choice agents for chronic hypertension.

The major adverse effect of *reserpine* is *depression*. Accordingly, reserpine is absolutely contraindicated for patients with a history of depressive illness.

The basic pharmacology of reserpine, guanethidine, and guanadrel is discussed in [Chapter 19](#).

47.8.3.3 Direct-Acting Vasodilators: Hydralazine and Minoxidil

Hydralazine and minoxidil reduce BP by promoting dilation of *arterioles*. Neither drug causes significant dilation of veins. Because venous dilation is minimal, the risk of orthostatic hypotension is low. With both drugs, lowering of BP may be followed by reflex tachycardia, renin release, and fluid retention. Reflex tachycardia and release of renin can be prevented with a beta blocker. Fluid retention can be prevented with a diuretic.

The most disturbing adverse effect of *hydralazine* is a syndrome resembling *systemic lupus erythematosus* (SLE). Fortunately, this reaction is rare at recommended doses. If an SLE–like reaction occurs, hydralazine should be withdrawn. Hydralazine is considered a third-choice drug for chronic hypertension.

Minoxidil is substantially more dangerous than hydralazine. By causing fluid retention, minoxidil can promote *pericardial effusion* (accumulation of fluid beneath the myocardium) that in some cases progresses to *cardiac tamponade* (compression of the heart). A less serious effect is *hypertrichosis* (excessive hair growth). Because of its capacity for significant harm, minoxidil is not used routinely for chronic hypertension. Instead, the drug is reserved for patients with severe hypertension that has not responded to safer drugs.

The basic pharmacology of hydralazine and minoxidil is discussed in [Chapter 45](#).

47.8.3.4 Calcium Channel Blockers

The calcium channel blockers (CCBs) fall into two groups: dihydropyridines (eg, nifedipine) and nondihydropyridines (verapamil and diltiazem). Drugs in both groups promote dilation of arterioles. In addition, verapamil and diltiazem have direct suppressant effects on the heart.

Like other vasodilators, CCBs can cause *reflex tachycardia*. This reaction is greatest with the dihydropyridines and minimal with verapamil and diltiazem. Reflex tachycardia is low with verapamil and diltiazem because of cardiosuppression. Since dihydropyridines do not block cardiac calcium channels, reflex tachycardia with these drugs can be substantial.

Because of their ability to compromise cardiac performance, verapamil and diltiazem must be used cautiously in patients with bradycardia, heart failure, or AV heart block. These precautions do not apply to dihydropyridines.

The *rapid-acting* formulation of *nifedipine* has been associated with increased mortality in patients with MI and unstable angina. As a result, the National Heart, Lung, and Blood Institute has recommended that rapid-acting nifedipine be used with great caution, if at all.

The basic pharmacology of the CCBs is discussed in [Chapter 44](#).

47.8.3.5 Drugs that Suppress the RAAS

Because the RAAS plays an important role in controlling BP, drugs that suppress the system—especially the ACE inhibitors—have a significant role in controlling hypertension. The basic pharmacology of these drugs is discussed in [Chapter 43](#).

47.8.3.5.1 ACE Inhibitors.

The ACE inhibitors (eg, captopril, enalapril) lower BP by preventing formation of angiotensin II, and thereby prevent angiotensin II–mediated vasoconstriction and aldosterone-mediated volume expansion. In hypertensive diabetic patients with renal damage, these actions slow progression of kidney injury. Like the beta blockers, ACE inhibitors are less effective in African Americans than in white patients. Principal adverse effects are *persistent cough, first-dose hypotension, angioedema, and hyperkalemia* (secondary to suppression of aldosterone release). Because of the risk of hyperkalemia, combined use with potassium supplements or potassium-sparing diuretics is generally avoided. ACE inhibitors can cause serious *fetal harm*, especially during the second and third trimesters of pregnancy, and hence must not be given to pregnant women. ACE inhibitors—along with angiotensin receptor blockers (ARBs) and direct renin inhibitors (DRIs)—are the only antihypertensive drugs specifically contraindicated during pregnancy.

505

506

47.8.3.5.2 Angiotensin II Receptors Blockers.

ARBs lower BP in much the same way as do ACE inhibitors. Like the ACE inhibitors, ARBs prevent angiotensin II–mediated vasoconstriction and release of aldosterone. The only difference is that ARBs do so by blocking the *actions* of angiotensin II, whereas ACE inhibitors block the *formation* of angiotensin II. Both groups lower BP to the same extent. Like the ACE inhibitors, ARBs can cause *fetal harm* and must not be used during pregnancy. In contrast to ACE inhibitors, ARBs do not induce cough or significant hyperkalemia but they do cause angioedema.

47.8.3.5.3 Direct Renin Inhibitors.

DRIs act directly on renin to inhibit conversion of angiotensinogen into angiotensin II. As a result, DRIs can suppress the entire RAAS. At this time, only one DRI—*aliskiren* [Tekturna]—is available. Antihypertensive effects equal those of ACE inhibitors, ARBs, and CCBs. Compared with ACE inhibitors, aliskiren causes less hyperkalemia, cough, or angioedema—but poses a similar risk of *fetal harm*. In addition, aliskiren causes *diarrhea* in 2.3% of patients. Although we know that aliskiren can lower BP, we don't yet know if it reduces adverse outcomes (eg, stroke, kidney failure, MI). Accordingly, until experience with the drug is more extensive, other antihypertensives should be considered first.

47.8.3.5.4 Aldosterone Antagonists.

Aldosterone antagonists lower BP by promoting renal excretion of sodium and water. Only two agents are available: *eplerenone* and *spironolactone*. (In case you're confused about spironolactone, yes, it's the same drug we discussed above under *potassium-sparing diuretics*. We're discussing it here because it produces diuresis through aldosterone receptor blockade.) Both spironolactone and eplerenone promote renal retention of potassium, and hence pose a risk of *hyperkalemia*. Accordingly, they should not be given to patients with existing hyperkalemia, and should not be combined with potassium-sparing diuretics or potassium supplements. Combined use with ACE inhibitors, ARBs, and DRIs is permissible, but must be done with caution. Spironolactone is discussed in [Chapter 40](#) (Diuretics), eplerenone is discussed in [Chapter 43](#) (Drugs Acting on the Renin-Angiotensin-Aldosterone System), and both are discussed again in [Chapter 47](#) (Drugs for Heart Failure).

47.8.4 Fundamentals of Hypertension Drug Therapy

47.8.4.1 Treatment Algorithm

The basic approach to treating hypertension is outlined in [Figure 46-3](#). As shown, lifestyle changes should be instituted first. If these fail to lower BP enough, drug therapy should be started—and the lifestyle changes should continue. Treatment often begins with a single drug. If needed, another drug may be *added* (if the initial drug was well tolerated but inadequate) or *substituted* (if the initial drug was poorly tolerated). However, before another drug is considered, possible reasons for failure of the initial drug should be assessed. Among these are insufficient dosage, poor adherence, excessive salt intake, and the presence of secondary hypertension. If treatment with two drugs is unsuccessful, a third and even fourth may be added.

47.8.4.2 Initial Drug Selection

Initial drug selection is determined by the presence or absence of a *compelling indication*, defined as a comorbid condition for which a specific class of antihypertensive drugs has been shown to improve outcomes. Initial drugs for patients with and without compelling indications are discussed below.

47.8.4.2.1 Patients WITHOUT Compelling Indications.

For initial therapy in the absence of a compelling indication, a *thiazide diuretic* is recommended for most patients. This preference is based on long-term controlled trials showing conclusively that thiazides can reduce morbidity and mortality in hypertensive

patients, and are well tolerated and inexpensive too (see [Box 46-2](#)). Other options for initial therapy—*ACE inhibitors*, *ARBs*, *DRIs*, *CCBs*, and *alpha/beta blockers*—equal diuretics in their ability to lower BP. However, they may not be as effective at reducing morbidity and mortality. Accordingly, these drugs should be reserved for special indications and for patients who have not responded to thiazides. Certain other alternatives—*centrally acting sympatholytics*, *adrenergic neuron blockers*, and *direct-acting vasodilators*—are associated with a high incidence of undesirable effects, and hence are not well suited for initial monotherapy. One last alternative—*alpha₁ blockers*—is no longer recommended as first-line therapy. As noted above, when the alpha blocker doxazosin was compared with the diuretic chlorthalidone, doxazosin was associated with a much higher incidence of adverse cardiovascular events.

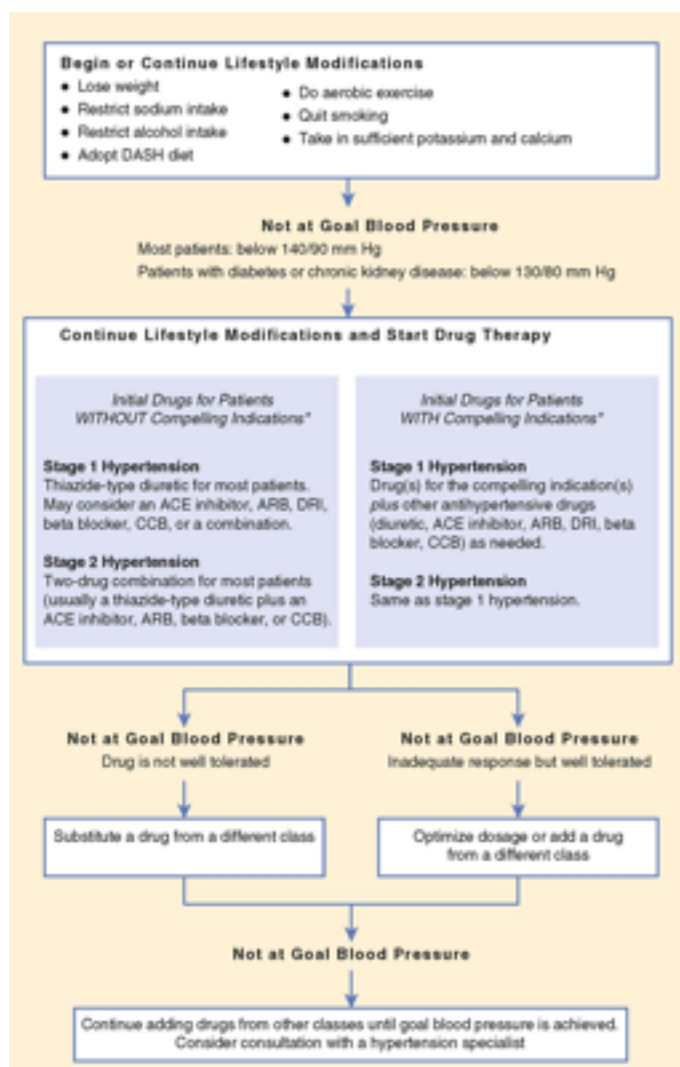

Beta blockers require special comment. In JNC 7, these drugs are recommended as first-line alternatives to thiazides for initial therapy of uncomplicated hypertension. However, several studies have shown that newer drugs—ACE inhibitors, ARBs, and CCBs—are superior to beta blockers at preventing stroke and cardiac events in this population. Accordingly, the American Heart Association now recommends against using beta blockers as first-line therapy in patients without compelling indications. On the other hand, if a patient already *has* heart disease (eg, angina pectoris, systolic heart failure, tachydysrhythmias, prior myocardial infarction), beta blockers clearly improve outcomes, and hence remain first-choice drugs for these patients.

How many drugs should be used for initial therapy? The answer depends on the hypertension stage. For patients with stage 1 hypertension, treatment with just one drug—usually a thiazide diuretic—is recommended. For patients with stage 2 hypertension, initial therapy should consist of two drugs—typically a thiazide combined with either an ACE inhibitor, ARB, or CCB.

47.8.4.2.2 Patients WITH Compelling Indications.

For patients with hypertension plus certain comorbid conditions (eg, heart failure, diabetes), there is strong evidence that specific antihypertensive drugs can reduce morbidity and mortality. Drugs shown to improve outcomes for six comorbid conditions are indicated in [Table 46-7](#). Clearly, these drugs should be used for initial therapy. If needed, other antihypertensive agents can be added to the regimen. Management of hypertension in patients with diabetes and renal disease—two specific comorbid conditions—is discussed further under *Individualizing Therapy*.

Figure 46-3 **Algorithm for treating hypertension.** (ACE = angiotensin-converting enzyme; ARB = angiotensin II receptor blocker; CCB = calcium channel blocker; DASH = Dietary Approaches to Stop Hypertension; DRI = direct renin inhibitor.) *A “compelling indication” is a comorbid condition (eg, heart failure, diabetes) for which a specific class of antihypertensive drugs has been shown to improve outcomes. See text for details.

* ACE = angiotensin-converting enzyme; ARB = angiotensin II receptor blocker; CCB = calcium channel blocker.

47.8.4.3 Adding Drugs to the Regimen

47.8.4.3.1 Rationale for Drug Selection.

When using two or more drugs to treat hypertension, each drug should come from a different class. That is, each drug should have a different mechanism of action. In accord with this guideline, it would be appropriate to combine a beta blocker, a diuretic, and a vasodilator, since each lowers BP by a different mechanism. In contrast, it would be inappropriate to combine two thiazide diuretics or two beta blockers or two vasodilators.

47.8.4.3.2 Benefits of Multidrug Therapy.

Treatment with multiple drugs offers significant benefits. First, by employing drugs that have different mechanisms, we can increase the chance of success: Attacking BP control at several sites is likely to be more effective than attacking at one site. Second, when drugs are used in combination, each can be administered in a lower dosage than would be possible if it were used alone. As a result, both the frequency and the intensity of side effects are reduced. Third,

when proper combinations are selected, one agent can offset the adverse effects of another. For example, if a vasodilator is used alone, reflex tachycardia is likely. However, if a vasodilator is combined with a beta blocker, reflex tachycardia will be minimal.

47.8.4.4 Dosing

For each drug in the regimen, *dosage should be low initially and then gradually increased*. There are several reasons for this approach. First, for most people with chronic hypertension, the disease poses no immediate threat. Hence, there is no need to lower BP rapidly using large doses. Second, when BP is reduced slowly, baroreceptors gradually reset to the new, lower pressure. As a result, sympathetic reflexes offer less resistance to the hypotensive effects of therapy. Third, since there is no need to drop BP rapidly, and since higher doses carry a higher risk of adverse effects, use of high initial doses would needlessly increase the risk of unpleasant responses.

47.8.4.5 Step-Down Therapy

After BP has been controlled for at least 1 year, an attempt should be made to reduce dosages and the number of drugs in the regimen. Of course, lifestyle modifications should continue. When reductions are made slowly and progressively, many patients are able to maintain BP control with less medication—and some can be maintained with no medication at all. If drugs are discontinued, regular follow-up is essential, because BP usually returns to hypertensive levels—although it may take years to do so.

47.8.5 Individualizing Therapy

47.8.5.1 Patients with Comorbid Conditions

Comorbid conditions complicate treatment. Two conditions that are especially problematic—renal disease and diabetes—are discussed below. Preferred drugs for patients with these and other comorbid conditions are summarized in [Table 46-7](#). Drugs to avoid in patients with specific comorbid conditions are summarized in [Table 46-8](#).

47.8.5.1.1 Renal Disease.

Nephrosclerosis (hardening of the kidney) secondary to hypertension is among the most common causes of progressive renal disease. Pathophysiologic changes include degeneration of renal tubules and fibrotic thickening of the glomeruli, both of which contribute to renal insufficiency. Nephrosclerosis sets the stage for a downward spiral: Renal insufficiency causes water retention, which in turn causes BP to rise higher, which in turn promotes even

more renal injury, and so forth. Accordingly, early detection and treatment are essential. To retard progression of renal damage, the most important action is to lower BP. The target BP is 130/80 mm Hg or lower. Achieving this goal often requires three or more drugs. Although all classes of antihypertensive agents are effective in nephrosclerosis, ACE inhibitors and ARBs work best. Hence, in the absence of contraindications, all patients should get one of these drugs. As a rule, a diuretic is used too. In patients with advanced renal insufficiency, thiazide diuretics are ineffective, hence a loop diuretic should be employed. Potassium-sparing diuretics should be avoided.

47.8.5.1.2 Diabetes.

In patients with diabetes, the target BP is 130/80 mm Hg or less. Preferred antihypertensive drugs are ACE inhibitors, ARBs, CCBs, and diuretics (in low doses). In patients with diabetic nephropathy, ACE inhibitors and ARBs can slow progression of renal damage and reduce albuminuria. In diabetic patients, as in nondiabetics, beta blockers and diuretics can decrease morbidity and mortality. Keep in mind, however, that beta blockers can suppress glycogenolysis and mask early signs of hypoglycemia, and therefore must be used with caution. Thiazides and high-ceiling diuretics promote hyperglycemia, and hence should be used with care.

508

TABLE 46-8 Comorbid Conditions That Require Cautious Use or Complete Avoidance of Certain Antihypertensive Drugs

Comorbid Condition	Drugs to Be Avoided or Used with Caution	Reason for Concern
Cardiovascular Disorders		
Heart failure	Verapamil	These drugs act on the heart to decrease myocardial contractility and can thereby further reduce cardiac output.
	Diltiazem	
AV heart block	Beta blockers	These drugs act on the heart to suppress AV conduction and can thereby intensify AV block.
	Labetalol	
	Verapamil	
	Diltiazem	
Coronary artery disease	Guanethidine	Reflex tachycardia induced by these drugs can precipitate an anginal attack.
	Hydralazine	
Post–myocardial infarction	Guanethidine	Reflex tachycardia induced by these drugs can increase cardiac work and oxygen demand.
	Hydralazine	
Other Disorders		
Dyslipidemia	Beta blockers	These drugs may exacerbate dyslipidemia.
	Diuretics	
Renal insufficiency	K ⁺ -sparing diuretics	Use of these agents can lead to dangerous accumulations of potassium.
	K ⁺ supplements	
Asthma	Beta blockers	Beta ₂ blockade promotes bronchoconstriction.
	Labetalol	
Depression	Reserpine	These drugs can cause depression.
	Beta blockers	
Diabetes mellitus	Thiazides	Thiazides and furosemide promote hyperglycemia, and beta blockers suppress glycogenolysis and can mask signs of hypoglycemia.
	Furosemide	
	Beta blockers	

Pharmacology for Nursing Care, 7th Edition

Gout	Thiazides	These diuretics promote hyperuricemia.
	Furosemide	
Hyperkalemia	K ⁺ -sparing diuretics	These drugs cause potassium accumulation.
	ACE inhibitors	
	Aldosterone antagonists	
Hypokalemia	Thiazides	These drugs cause potassium loss.
	Furosemide	
Collagen diseases	Hydralazine	Hydralazine can precipitate a lupus erythematosus–like syndrome.
Liver disease	Methyldopa	Methyldopa is hepatotoxic.
Preeclampsia	ACE inhibitors	These drugs can injure the fetus.
	ARBs	
	Direct renin inhibitors	

ACE = angiotensin-converting enzyme; ARBs = angiotensin II receptor blockers; AV = atrioventricular.

How do ACE inhibitors compare with CCBs in patients with hypertension and diabetes? In one large study, patients taking nisoldipine (a CCB) had a higher incidence of MI than did patients taking enalapril (an ACE inhibitor). Because the study was not placebo controlled, it was impossible to distinguish between two possible interpretations: (1) the CCB increased the risk of MI or (2) the ACE inhibitor protected against MI. Either way, it seems clear that ACE inhibitors are better than CCBs for patients with hypertension and diabetes.

47.8.5.2 Patients in Special Populations

47.8.5.2.1 African Americans.

Hypertension is a major health problem for African American adults. Hypertension develops earlier in blacks than in whites, has a much higher incidence, and is likely to be more severe. As a result, African Americans face a greater risk of heart disease, end-stage renal disease, and stroke. Compared with the general population, African Americans experience a 50% higher rate of death from heart disease, an 80% higher rate of death from stroke, and a 320% higher rate of hypertension-related end-stage renal disease.

With timely treatment, the disparity between blacks and nonblacks can be greatly reduced, if not eliminated. We know that blacks and whites respond equally to treatment (although not always to the same drugs). The problem is that, among blacks, hypertension often goes untreated until after significant organ damage has developed. If hypertension were diagnosed and treated earlier, the prognosis would be greatly improved. Accordingly, it is important that African Americans undergo routine monitoring of BP. If hypertension is diagnosed, treatment should begin at once. Because African Americans have a high incidence of salt sensitivity, obesity, and cigarette use, lifestyle modifications are an important component of treatment.

509

510

African Americans respond better to some antihypertensive drugs than to others. Controlled trials have shown that *diuretics* can decrease morbidity and mortality in blacks. Accordingly, diuretics are drugs of first choice. *CCBs* and *alpha/beta blockers* are also effective. In contrast, monotherapy with *beta blockers* or *ACE inhibitors* is less effective in blacks than in whites. Nonetheless, beta blockers and ACE inhibitors should be used if they are strongly indicated for a comorbid condition. For example, ACE inhibitors should be used in black patients who have type 1 diabetes with proteinuria. Also, ACE inhibitors should be used in patients with hypertensive nephrosclerosis, a condition for which ACE inhibitors are superior to CCBs.

47.8.5.2.2

Children and Adolescents.

The incidence of secondary hypertension in children is much higher than in adults. Accordingly, efforts to diagnose and treat an underlying cause should be especially diligent. For children with primary hypertension, treatment is the same as for adults—although doses are lower and should be adjusted with care. Because ACE inhibitors and ARBs can cause fetal harm, they should be avoided in girls who are sexually active or pregnant.

47.8.5.2.3

The Elderly.

The incidence of hypertension in people over age 60 is about 65%, and the prevalence of isolated systolic hypertension is greater than in younger adults. In clinical trials, antihypertensive treatment has reduced the incidence of stroke by 36% and MI by 27%. Although all antihypertensive drugs are effective in older adults, only *beta blockers* and *diuretics* have been shown in controlled trials to reduce morbidity and mortality. Hence, these drugs are generally preferred. In patients with isolated systolic hypertension, diuretics are preferred. Because cardiovascular reflexes are blunted in the elderly, treatment carries a significant risk of orthostatic hypotension. Accordingly, initial doses should be low—about one-half those used for younger adults. Drugs that are especially likely to cause orthostatic hypotension (eg, guanethidine, α_1 blockers, alpha/beta blockers) should be used with

caution, as should clonidine and methyldopa (central α_2 agonists), both of which can impair cognitive function.

47.8.6 Minimizing Adverse Effects

Antihypertensive drugs can produce many unwanted effects, including hypotension, sedation, and sexual dysfunction. (Although not stressed previously, practically all antihypertensive drugs can interfere with sexual feelings or performance.)

The fundamental strategy for decreasing side effects is to tailor the regimen to the sensitivities of the patient. Simply put, if one drug causes effects that are objectionable, a more acceptable drug should be substituted. The best way to identify unacceptable responses is to encourage patients to report them.

Adverse effects caused by exacerbation of comorbid diseases are both predictable and avoidable. We know, for example, that beta blockers can intensify asthma and AV block, and hence should not be taken by people with these disorders. Other conditions that can be aggravated by antihypertensive drugs are listed in [Table 46-8](#). To help avoid drug-disease mismatches, the medical history should identify all comorbid conditions. With this information, the prescriber can choose drugs that are least likely to make the comorbid condition worse.

High initial doses and rapid dosage escalation can increase the incidence and severity of adverse effects. Accordingly, doses should be low at first and then gradually increased. Remember, there is usually no need to reduce BP rapidly. Hence, it makes no sense to give large initial doses that can produce a rapid fall in BP but that also produce intense undesired responses.

47.8.7 Promoting Adherence

The major cause of treatment failure in patients with chronic hypertension is lack of adherence to the prescribed regimen. In this section we consider the causes of nonadherence and discuss some solutions.

47.8.7.1 Why Adherence Is Often Hard to Achieve

Much of the difficulty in promoting adherence stems from the nature of hypertension itself. Hypertension is a chronic, slowly progressing disease that, through much of its course, is devoid of overt symptoms. Because symptoms are absent, it can be difficult to convince patients that they are ill and need treatment. In addition, since there are no symptoms to relieve, drugs cannot produce an obvious therapeutic response. In the absence of such a response, it can be difficult for patients to believe that their medication is doing anything useful.

Because hypertension progresses very slowly, the disease tends to encourage procrastination. For most people, the adverse effects of hypertension will not become manifest for many years. Realizing this, patients may reason (incorrectly) that they can postpone therapy without significantly increasing risk.

The negative aspects of treatment also contribute to nonadherence. Antihypertensive regimens can be complex and expensive. In addition, treatment must continue lifelong. Lastly, antihypertensive drugs can cause a number of adverse effects, ranging from sedation to hypotension to impaired sexual function. It is difficult to convince people who are feeling good to take drugs that may make them feel worse. Some people may decide that exposing themselves to the negative effects of therapy today is paying too high a price to avoid the adverse consequences of hypertension at some indefinite time in the future.

47.8.7.2 Ways to Promote Adherence

47.8.7.2.1 Patient Education.

Adherence requires motivation, and patient education can help provide it. Patients should be taught about the consequences of hypertension and the benefits of treatment. Because hypertension does not cause discomfort, it may not be clear to patients that their condition is indeed serious. Patients must be made to understand that, left untreated, hypertension can cause heart disease, kidney disease, and stroke. In addition, patients should appreciate that, with proper therapy, the risks of these long-term complications can be minimized, resulting in a longer and healthier life. Lastly, patients must understand that drugs do not cure hypertension—they only control symptoms. Hence, for treatment to be effective, medication must be taken lifelong.

47.8.7.2.2 Teach Self-Monitoring.

Patients should be taught the goal of treatment (usually maintenance of BP below 140/90 mm Hg), and they should be taught to monitor and record their BP daily. This increases patient involvement and provides positive feedback that can help promote adherence.

510

47.8.7.2.3 Minimize Side Effects.

511

Common sense dictates that, if we expect patients to comply with long-term treatment, we must keep undesired effects to a minimum. As discussed above, adverse effects can be minimized by (1) encouraging patients to report side effects, (2) discontinuing objectionable drugs and substituting more acceptable ones, (3) avoiding drugs that can exacerbate comorbid conditions, and (4) using doses that are low initially and then gradually increased.

47.8.7.2.4 Establish a Collaborative Relationship.

The patient who feels like a collaborative partner in the treatment program is more likely to comply than is the patient who feels that treatment is being imposed. Collaboration allows the patient to help set treatment goals, create the treatment program, and evaluate progress. In addition, a collaborative relationship facilitates communication about side effects. This is especially important with respect to drug-induced sexual dysfunction, which patients may be reluctant to disclose.

47.8.7.2.5 Simplify the Regimen.

Antihypertensive regimens may consist of several drugs taken multiple times a day. Such complex regimens deter adherence. Therefore, in order to promote adherence, the dosing schedule should be as simple as possible. Once an effective regimen has been established, dosing just once or twice daily should be tried. If an appropriate combination product is available (eg, a fixed-dose combination of a thiazide diuretic plus an ACE inhibitor), the combination product may be substituted for its components.

47.8.7.2.6 Other Measures.

Adherence can be promoted by giving positive reinforcement when therapeutic goals are achieved. Involvement of family members can be helpful. Also, adherence can be promoted by scheduling office visits at convenient times and by following up when appointments are missed. For many patients, antihypertensive therapy represents a significant economic burden; devising a regimen that is effective but inexpensive will help.

47.9 DRUGS FOR HYPERTENSIVE EMERGENCIES

A hypertensive emergency exists when diastolic BP exceeds 120 mm Hg. The severity of the emergency is determined by the likelihood of organ damage. When excessive BP is associated with papilledema (edema of the retina), intracranial hemorrhage, MI, or acute congestive heart failure, a severe emergency exists—and BP must be lowered rapidly (within 1 hour). If severe hypertension is present but does not yet pose an immediate threat of organ damage, it is preferable to reduce BP more slowly (over 24 to 48 hours). Why? Because rapid reductions can cause cerebral ischemia, MI, and renal failure. Hence, pressure should be reduced gradually whenever possible.

The major drugs used for hypertensive emergencies are discussed below. All reduce BP by causing vasodilation, and all are administered IV.

47.9.1 Sodium Nitroprusside.

When acute, severe hypertension demands a rapid but controlled reduction in BP, IV nitroprusside [Nitropress] is usually the drug of first choice. Nitroprusside is a direct-acting vasodilator that relaxes smooth muscle of arterioles and veins. Effects begin in seconds and then fade rapidly when administration ceases. Nitroprusside is administered by continuous IV infusion using a pump to control the rate. The usual rate is 0.5 to 8 mcg/kg/min. To avoid overshoot, continuous BP monitoring is required. Because nitroprusside has an extremely short duration of action, overshoot can be corrected quickly by reducing the rate of the infusion. Prolonged infusion (longer than 72 hours) can produce toxic accumulation of thiocyanate and should be avoided. The basic pharmacology of nitroprusside is discussed in [Chapter 45](#).

47.9.2 Fenoldopam.

Fenoldopam [Corlopan] is an IV drug indicated for short-term management of hypertensive emergencies. Benefits equal those of nitroprusside. Fenoldopam lowers BP by activating dopamine₁ receptors on arterioles, and thereby promotes vasodilation. In animal models, the drug dilates renal, coronary, mesenteric, and peripheral vessels.

Fenoldopam differs from other antihypertensives in that it helps maintain (or even improve) renal function. Two mechanisms are involved. First, the drug dilates renal blood vessels, and thereby increases renal blood flow (despite reducing arterial pressure). Second, fenoldopam promotes sodium and water excretion through direct effects on renal tubules.

Fenoldopam has a rapid onset and short duration. Effects begin in less than 5 minutes. The drug undergoes rapid hepatic metabolism followed by renal excretion. Its plasma half-life is only 5 minutes.

Fenoldopam is generally well tolerated. The most common side effects are hypotension, headache, flushing, dizziness, and reflex tachycardia—all of which occur secondary to vasodilation. Tachycardia may cause ischemia in patients with angina. Combined use with a beta blocker can minimize tachycardia, but may also result in excessive lowering of BP. Fenoldopam can elevate intraocular pressure, and hence should be used with caution in patients with glaucoma.

Fenoldopam is administered by continuous IV infusion. To minimize tachycardia, the initial dosage should be low. The typical infusion rate is 0.1 to 0.3 mcg/kg/min. With continuous 24-hour infusion, no tolerance develops to antihypertensive effects, and there is no rebound increase in BP when the infusion is stopped. With a 48-hour infusion, some tolerance may develop. Oral antihypertensive therapy can be added as soon as BP has stabilized.

47.9.3 Labetalol.

Labetalol [Trandate] blocks alpha- and beta-adrenergic receptors. BP is reduced by arteriolar dilation secondary to alpha blockade. Beta blockade prevents reflex tachycardia in response to reduced arterial pressure, and hence the drug is probably safe for patients with angina or MI. Beta blockade can aggravate bronchial asthma, heart failure, AV block, cardiogenic shock, and bradycardia. Accordingly, labetalol should not be given to patients with these disorders. Administration is by slow IV injection.

47.9.4 Diazoxide.

Diazoxide [Hyperstat IV] causes selective dilation of arterioles. Effects begin within minutes and may persist for hours. The drug can be administered by IV bolus or slow IV infusion (over 15 to 30 minutes). Diazoxide can cause reflex tachycardia and hence should be avoided in patients with angina. Reflex tachycardia can be reduced with a beta blocker. Fluid retention may occur and can be controlled with a diuretic. Hyperglycemia may be a complication for patients with diabetes. The basic pharmacology of diazoxide is discussed in [Chapter 45](#).

47.9.5 Clevidipine.

Clevidipine [Cleviprex], approved in 2008, is a dihydropyridine CCB with an ultrashort half-life (about 1 minute). Administration is by IV infusion. As with nitroprusside, effects begin rapidly and then fade rapidly when the infusion is slowed or stopped. As a result, BP can be easily titrated. For patients with severe hypertension, the infusion rate is 1 to 2 mg/hr initially, and can be doubled every 3 minutes up to a maximum of 32 mg/hr. In clinical trials, the average time to reach the target BP was 10.9 minutes. The most common side effects are headache, nausea, and vomiting. The basic pharmacology of clevidipine is discussed in [Chapter 44](#).

47... DRUGS FOR HYPERTENSIVE DISORDERS OF PREGNANCY

Hypertension is the most common complication of pregnancy, with an incidence of about 10%. When hypertension develops, it is essential to distinguish between chronic hypertension and preeclampsia. Why? Because chronic hypertension is relatively benign, whereas preeclampsia can lead to life-threatening complications for the mother and fetus.

511

47... CHRONIC HYPERTENSION

512

Chronic hypertension, which occurs in 5% of pregnancies, is defined as hypertension that was present before pregnancy or that developed prior to the 20th week of gestation. Persistent *severe* hypertension carries a risk to both the mother and fetus. Potential adverse outcomes include

placental abruption, maternal cardiac decompensation, premature birth, fetal growth retardation, central nervous system hemorrhage, and renal failure. The goal of treatment is to minimize the risk of hypertension to the mother and fetus while avoiding drug-induced harm to the fetus. With the exception of ACE inhibitors, ARBs, and DRIs, antihypertensive drugs that were being taken before pregnancy can be continued. *ACE inhibitors, ARBs, and DRIs are contraindicated because of their potential for harm* (fetal growth retardation, congenital malformations, neonatal renal failure, neonatal death). When drug therapy is initiated *during* pregnancy, *methyldopa* is the traditional agent of choice. The drug has limited effects on uteroplacental and fetal hemodynamics, and does not adversely affect the fetus or neonate. Regardless of the drug selected, treatment should not be too aggressive. Why? Because an excessive drop in BP could compromise uteroplacental blood flow.

How high can BP rise before drug therapy is indicated? According to guidelines issued in 2001 by the American College of Obstetricians and Gynecologists (ACOG), “severe” hypertension requires treatment, whereas “mild” hypertension generally does not. (The ACOG defines severe hypertension as systolic BP above 180 mm Hg or diastolic BP above 110 mm Hg, and mild hypertension as systolic BP 140 to 179 mm Hg or diastolic BP 90 to 109 mm Hg.) There is good evidence that treating severe hypertension reduces risk. In contrast, there is little evidence that treating mild hypertension offers significant benefit.

Women who have chronic hypertension during pregnancy are at increased risk of developing preeclampsia (see below). Unfortunately, reducing BP does *not* lower this risk.

^{47...} PREECLAMPSIA AND ECLAMPSIA

Preeclampsia is a multisystem disorder characterized by the combination of elevated BP (above 140/90 mm Hg) and proteinuria (300 mg or more in 24 hours) that develop after the 20th week of gestation. The disorder occurs in about 5% of pregnancies. Rarely, women with preeclampsia develop seizures. If seizures do develop, the condition is then termed *eclampsia*. Risk factors for preeclampsia include obesity, black race, chronic hypertension, diabetes, collagen vascular disorders, and previous preeclampsia. The etiology of preeclampsia is complex and incompletely understood.

Preeclampsia poses serious risks for the fetus and mother. Risks for the fetus include intrauterine growth restriction, premature birth, and even death. The mother is at risk for seizures (eclampsia), renal failure, pulmonary edema, stroke, and death.

Management of preeclampsia is based on the severity of the disease, the status of mother and fetus, and the length of gestation. The objective is to preserve the health of the mother and deliver an

infant that will not require intensive and prolonged neonatal care. Success requires close maternal and fetal monitoring. Although drugs can help reduce BP, delivery is the only cure.

Management of *mild* preeclampsia is controversial and depends on the duration of gestation. If preeclampsia develops near term, and if fetal maturity is certain, induction of labor is advised. However, if mild preeclampsia develops earlier in gestation, experts disagree about what to do. Suggested measures include bed rest, prolonged hospitalization, treatment with antihypertensive drugs, and prophylaxis with an anticonvulsant. Studies to evaluate these strategies have generally failed to demonstrate benefits from any of them, including treatment with antihypertensive drugs.

The definitive intervention for *severe* preeclampsia is delivery. However, making the choice to induce labor presents a dilemma. Since preeclampsia can deteriorate rapidly, with grave consequences for mother and fetus, immediate delivery is recommended. However, if the fetus is not sufficiently mature, immediate delivery could threaten its life. Hence the dilemma: Do we deliver the fetus immediately, which would eliminate risk for the mother but present a serious risk for the fetus—or do we postpone delivery, which would reduce risk for the fetus but greatly increase risk for the mother? If the woman elects to postpone delivery, then BP can be lowered with drugs. Because severe preeclampsia can be life threatening, treatment must be done in a tertiary care center to permit close monitoring of mother and fetus. The major objective is to prevent maternal cerebral complications (eg, hemorrhage, encephalopathy). The drug of choice for lowering BP is *hydralazine* (5 mg by IV bolus); dosing may be repeated 3 times at 20-minute intervals.

Because preeclampsia can (rarely) evolve into eclampsia, an anticonvulsant may be given for prophylaxis. *Magnesium sulfate* is the drug of choice. In one study, prophylaxis with magnesium sulfate reduced the risk of eclampsia by 58% and the risk of death by 45%. Dosing consists of a 10-gm IM loading dose followed by 5 gm IM every 4 hours for maintenance.

If eclampsia develops, magnesium sulfate is the preferred drug for seizure control. Dosing consists of a 4-gm IV loading dose followed by 5 gm IM injected into alternate buttocks every 4 hours for maintenance. To ensure therapeutic effects and prevent toxicity, blood levels of magnesium should be monitored. The target range is 4 to 7 mEq/L (the normal range for magnesium is 1.5 to 2 mEq/L).

Efforts to prevent preeclampsia with drugs have been disappointing. Low-dose aspirin may offer modest protection. Several other preparations—magnesium, zinc, vitamin C, vitamin E, fish oil, and diuretics—appear to offer no protection at all.

512

513

47.12.1

KEY POINTS

- Hypertension is defined as systolic BP greater than 140 mm Hg or diastolic BP greater than 90 mm Hg.

- Primary hypertension (essential hypertension), defined as hypertension with no identifiable cause, is the most common form of hypertension.
- Untreated hypertension can lead to heart disease, kidney disease, and stroke.
- In patients older than 50, elevated *systolic* BP represents a greater cardiovascular risk than elevated *diastolic* BP.
- The goal of antihypertensive therapy is to decrease morbidity and mortality without decreasing quality of life. For most patients, this goal is achieved by maintaining BP below 140/90 mm Hg, or below 130/80 mm Hg for those with diabetes or chronic kidney disease.
- To reduce BP, two kinds of treatment may be used: drug therapy and lifestyle modification (weight reduction, smoking cessation, reduction of salt and alcohol intake, following the DASH diet, and increasing aerobic exercise).
- The baroreceptor reflex, the kidneys, and the RAAS can oppose our attempts to lower BP with drugs. We can counteract the baroreceptor reflex with a beta blocker, the kidneys with a diuretic, and the RAAS with an ACE inhibitor, ARB, DRI, or aldosterone antagonist.
- Thiazide diuretics (eg, hydrochlorothiazide) and loop diuretics (eg, furosemide) reduce BP in two ways: they reduce blood volume (by promoting diuresis) and they reduce arterial resistance (by an unknown mechanism).
- Loop diuretics should be reserved for (1) patients who need greater diuresis than can be achieved with thiazides and (2) patients with a low GFR (because thiazides don't work when GFR is low).
- Beta blockers (eg, propranolol) appear to lower BP primarily by reducing peripheral vascular resistance; the mechanism is unknown. They may also lower BP by decreasing myocardial contractility and suppressing reflex tachycardia (through beta₁ blockade in the heart), and by decreasing renin release (through beta₁ blockade in the kidney).
- Calcium channel blockers (eg, diltiazem, nifedipine) reduce BP by promoting dilation of arterioles.
- ACE inhibitors, ARBs, and DRIs lower BP by preventing angiotensin II–mediated vasoconstriction and aldosterone-mediated volume expansion. ACE inhibitors work by

blocking the formation of angiotensin II, whereas ARBs block the actions of angiotensin II. DRIs prevent formation of angiotensin I, and thereby shut down the entire RAAS.

- Aldosterone antagonists lower BP by preventing aldosterone-mediated retention of sodium and water in the kidney.
- Patients with stage 1 hypertension can often be treated with one drug, whereas those with stage 2 hypertension usually require two or more drugs.
- Thiazide diuretics are preferred drugs for initial therapy of uncomplicated hypertension.
- When a combination of drugs is used for hypertension, each drug should have a different mechanism of action.
- Dosages of antihypertensive drugs should be low initially and then gradually increased. This approach minimizes adverse effects and permits baroreceptors to reset to a lower pressure.
- Lack of patient adherence is the major cause of treatment failure in antihypertensive therapy.
- Adherence is difficult to achieve because (1) hypertension has no symptoms (so drug benefits aren't obvious); (2) hypertension progresses slowly (so patients think they can postpone treatment); and (3) treatment is complex and expensive, continues lifelong, and can cause adverse effects.
- A severe hypertensive emergency exists when diastolic BP exceeds 120 mm Hg and there is ongoing end-organ damage.
- Nitroprusside (IV) is a drug of choice for hypertensive emergencies.
- Hypertension is the most common complication of pregnancy.
- Methyldopa is a drug of choice for treating chronic hypertension of pregnancy.

47.12.2 Summary of Major Nursing Implications*

47.1... ANTIHYPERTENSIVE DRUGS

47.1... Preadministration Assessment

47.1... Therapeutic Goal

The goal of antihypertensive therapy is to prevent the long-term sequelae of hypertension (heart disease, kidney disease, stroke) while minimizing drug effects that can reduce quality of life. For most patients, BP should be reduced to less than 140/90 mm Hg or less than 130/80 mm Hg for those with diabetes or chronic kidney disease.

47.1... Baseline Data

The following tests should be done in all patients: BP; electrocardiogram; complete urinalysis; hemoglobin and hematocrit; and blood levels of sodium, potassium, calcium, creatinine, glucose, uric acid, triglycerides, and cholesterol (total, LDL, and HDL cholesterol).

47.1... Identifying High-Risk Patients

When taking the patient's drug history, attempt to identify drugs that can raise BP or that can interfere with the effects of antihypertensive drugs. Some drugs of concern are listed below under *Minimizing Adverse Interactions*.

513

514

The patient history should identify comorbid conditions that either contraindicate use of specific agents (eg, asthma and AV block contraindicate use of beta blockers) or require that drugs be used with special caution (eg, thiazide diuretics must be used with caution in patients with gout or diabetes). For risk factors that pertain to specific antihypertensive drugs, refer to the chapters in which those drugs are discussed.

47.1... Implementation: Administration

47.1... Routes

All drugs for chronic hypertension are administered orally. None is injected.

47.1...

Dosage

To minimize adverse effects, dosages should be low initially and then gradually increased. It is counterproductive to employ high initial dosages that produce a rapid fall in pressure while also producing intense undesired responses that can discourage adherence. After 12 months of successful treatment, dosage reductions should be tried.

47.1...

Implementation: Measures to Enhance Therapeutic Effects

47.1...

Lifestyle Modifications

In hypertensive patients, lifestyle changes can reduce BP and increase responsiveness to antihypertensive drugs. These changes should be tried for 6 to 12 months before implementing drug therapy and should continue even if drug therapy is required.

47.1...

Weight Reduction.

Help overweight patients develop an exercise program and a restricted-calorie diet. The goal is a body mass index in the normal range (18.5 to 24.9).

47.1...

Sodium Restriction.

Encourage patients to consume no more than 6 gm of salt (2.4 gm of sodium) daily and provide them with information on the salt content of foods.

47.1...

DASH Diet.

Encourage patients to adopt a diet rich in fruits, vegetables, and low-fat dairy products, and low in total fat, unsaturated fat, and cholesterol.

47.1...

Alcohol Restriction.

Encourage patients to limit alcohol consumption to 1 ounce/day (for most men) and 0.5 ounce/day (for women and lighter weight men). One ounce of ethanol is equivalent to about two mixed drinks, two glasses of wine, or two cans of beer.

47.1...

Exercise.

Encourage patients with a sedentary lifestyle to perform 30 to 45 minutes of aerobic exercise (eg, walking, jogging, swimming, bicycling) most days of the week.

47.1...

Smoking Cessation.

Strongly encourage patients to quit smoking. Teach patients about aids for smoking cessation (eg, nicotine patch, bupropion, varenicline).

47.1...

Promoting Adherence

Nonadherence is the major cause of treatment failure. Achieving adherence is difficult for several reasons: hypertension is devoid of overt symptoms; drugs do not make people feel better—and may make them feel worse; regimens can be complex and expensive; complications of hypertension take years to develop, thereby providing a misguided rationale for postponing treatment; and treatment usually lasts lifelong.

47.1...

Provide Patient Education.

Educate patients about the long-term consequences of hypertension and the ability of lifestyle changes and drug therapy to decrease morbidity and prolong life. Inform patients that drugs do not cure hypertension, and therefore must usually be taken lifelong.

47.1...

Encourage Self-Monitoring.

Make certain that patients know the treatment goal (usually reduction of BP to less than 140/90 mm Hg) and teach them to monitor and chart their own BP. This will increase their involvement and help them see the benefits of treatment.

47.1...

Minimize Adverse Effects.

Adverse drug effects are an obvious deterrent to adherence. Measures to reduce undesired effects are discussed below, under *Minimizing Adverse Effects*.

47.1...

Establish a Collaborative Relationship.

Encourage patients to be active partners in setting treatment goals, creating a treatment program, and evaluating progress.

47.1...

Simplify the Regimen.

An antihypertensive regimen can consist of several drugs taken multiple times a day. Once an effective regimen has been established, attempt to switch to once-a-day or twice-a-day dosing. If an appropriate combination product is available (eg, a fixed-dose

combination of a thiazide diuretic plus an ACE inhibitor), substitute the combination product for its components.

47.1...

Other Measures.

Additional measures to promote adherence include providing positive reinforcement when treatment goals are achieved, involving family members in the treatment program, scheduling office visits at convenient times, following up on patients who miss an appointment, and devising a program that is effective but keeps costs low.

47.1...

Ongoing Evaluation and Interventions

47.1...

Evaluating Treatment

Monitor BP periodically. The usual goal is to reduce it to less than 140/90 mm Hg. **Teach patients to self-monitor their BP and to maintain a BP record.**

47.1...

Minimizing Adverse Effects

47.1...

General Considerations.

The fundamental strategy for decreasing adverse effects is to tailor the regimen to the sensitivities of the patient. If a drug causes objectionable effects, a more acceptable drug should be substituted.

Inform patients about the potential side effects of treatment and encourage them to report objectionable responses.

Avoid drugs that can exacerbate comorbid conditions. For example, don't give beta blockers to patients who have bradycardia, AV block, or asthma. [Table 46-8](#) lists drugs to avoid in patients with specific disorders.

Initiate therapy with low doses and increase them gradually.

514

47.1...

Adverse Effects of Specific Drugs.

For measures to minimize adverse effects of specific antihypertensive drugs (eg, beta blockers, diuretics, ACE inhibitors), refer to the chapters in which those drugs are discussed.

515

47.1...

Minimizing Adverse Interactions

When taking the patient history, identify drugs that can raise BP or interfere with the effects of antihypertensive drugs. Drugs of concern include oral contraceptives, nasal decongestants and other cold remedies, nonsteroidal anti-inflammatory drugs, glucocorticoids, appetite suppressants, tricyclic antidepressants, monoamine oxidase inhibitors, cyclosporine, erythropoietin, and alcohol (in large quantities).

Antihypertensive regimens frequently contain two or more drugs, thereby posing a potential risk of adverse interactions (eg, ACE inhibitors can increase the risk of hyperkalemia caused by potassium-sparing diuretics). For interactions that pertain to specific antihypertensive drugs, refer to the chapters in which those drugs are discussed.

* Patient education information is highlighted as **blue text**.

⁴⁸CHAPTER 47 Drugs for Heart Failure

Heart failure is a disease with two major forms: (1) heart failure with left ventricular (LV) systolic dysfunction, and (2) diastolic heart failure, also known as heart failure with preserved LV ejection fraction. In this chapter, discussion is limited to the first form. Accordingly, from this point in the chapter on, the term *heart failure* (HF) will be used to denote the first form only.

Heart failure is a progressive, often fatal disorder characterized by ventricular dysfunction, reduced cardiac output, insufficient tissue perfusion, and signs of fluid retention (eg, peripheral edema, shortness of breath). The disease affects nearly 5 million Americans and, every year, is responsible for 12 to 15 million office visits, 6.5 million hospital days, and about 300,000 deaths. Of those who have HF, 24% are likely to die within 1 year, and 65% within 5 years. Heart failure is primarily a disease of the elderly, affecting 2% to 3% of those at age 65 and more than 80% of those over 80. In 2008, direct and indirect healthcare costs of HF were estimated at more than \$35 billion. With improved evaluation and care, many hospitalizations could be prevented, quality of life could be improved, and life expectancy could be extended.

In the past, HF was commonly referred to as *congestive heart failure*. This term was used because HF frequently causes fluid accumulation (congestion) in the lungs and peripheral tissues. However, because many patients do not have signs of pulmonary or systemic congestion, the term *heart failure* is now preferred.

Drugs recommended for treatment include diuretics, inhibitors of the renin-angiotensin-aldosterone system (RAAS), beta blockers, and digoxin. In this chapter, only digoxin is discussed at length. The other drugs are presented at length in previous chapters, and hence discussion here is limited to their use in heart failure.

In order to understand HF and its treatment, you need a basic understanding of hemodynamics. In particular, you need to understand the role of venous pressure, afterload, and Starling's mechanism in determining cardiac output. You also need to understand the roles of the baroreceptor reflex, the RAAS, and the kidneys in regulating arterial pressure. If your understanding of these concepts is a little hazy, you can refresh your memory by reading [Chapter 42](#) (Review of Hemodynamics).

^{48.1} PATHOPHYSIOLOGY OF HEART FAILURE

Heart failure is a syndrome in which the heart is unable to pump sufficient blood to meet the metabolic needs of tissues. The syndrome is characterized by signs of *inadequate tissue perfusion* (fatigue, shortness of breath, exercise intolerance) and/or signs of *volume overload* (venous distention, peripheral and pulmonary edema). The major underlying causes of HF are chronic

hypertension and myocardial infarction. Other causes include valvular heart disease, coronary artery disease, congenital heart disease, dysrhythmias, and aging of the myocardium. In its earliest stage, HF is asymptomatic. As failure progresses, fatigue and shortness of breath develop. As cardiac performance declines further, blood backs up behind the failing ventricles, causing venous distention, peripheral edema, and pulmonary edema. Heart failure is a chronic disorder that requires continuous treatment with drugs.

48.1.1 Cardiac Remodeling

In the initial phase of failure, the heart undergoes remodeling, a process in which the ventricles dilate (grow larger), hypertrophy (increase in wall thickness), and become more spherical (less cylindrical). These alterations in cardiac geometry increase wall stress and reduce LV ejection fraction. Remodeling occurs in response to cardiac injury, brought on by infarction and other causes. The remodeling process is driven primarily by neurohormonal systems, including the sympathetic nervous system (SNS) and the RAAS. In addition to promoting remodeling, neurohormonal factors promote cardiac fibrosis and myocyte death. The net result of these pathologic changes—remodeling, fibrosis, and cell death—is progressive decline in cardiac output. As a rule, cardiac remodeling precedes development of symptoms, and continues after they appear. As a result, cardiac performance continues to decline.

48.1.2 Physiologic Adaptations to Reduced Cardiac Output

In response to reductions in cardiac pumping ability, the body undergoes several adaptive changes. Some of these help improve tissue perfusion; others compound existing problems.

516

48.1.2.1 Cardiac Dilation.

517

Dilation of the heart is characteristic of HF. Cardiac dilation results from a combination of increased venous pressure (see below) and reduced contractile force. Reduced contractility lowers the amount of blood ejected during systole, causing end-systolic volume to rise. The increase in venous pressure increases diastolic filling, which causes the heart to expand even further.

Because of Starling's mechanism, the increase in heart size that occurs in HF helps improve cardiac output. That is, as the heart fails and its volume expands, contractile force increases, causing a corresponding increase in stroke volume. However, please note that the maximal contractile force that can be developed by the failing heart is considerably lower than the maximal force of the healthy heart. This limitation is reflected in the curve for the failing heart shown in [Figure 47-1](#).

If cardiac dilation is insufficient to maintain cardiac output, other factors come into play. As discussed below, these are not always beneficial.

48.1.2.2 Increased Sympathetic Tone.

Heart failure causes arterial pressure to fall. In response, the baroreceptor reflex increases sympathetic output to the heart, veins, and arterioles. At the same time, parasympathetic effects on the heart are reduced. The consequences of increased sympathetic tone are summarized below.

- *Increased heart rate.* Acceleration of heart rate increases cardiac output, thereby helping improve tissue perfusion. However, if heart rate increases too much, there will be insufficient time for complete ventricular filling, and hence cardiac output will fall.
- *Increased contractility.* Increased myocardial contractility has the obvious benefit of increasing cardiac output. The only detriment is an increase in cardiac oxygen demand.
- *Increased venous tone.* Elevation of venous tone increases venous pressure, and thereby increases ventricular filling. Because of Starling's mechanism, increased filling increases stroke volume. Unfortunately, if venous pressure is excessive, blood will back up behind the failing ventricles, thereby aggravating pulmonary and peripheral edema. Furthermore, excessive filling pressure can dilate the heart so much that stroke volume will begin to decline (see [Fig. 47-1](#)).
- *Increased arteriolar tone.* Elevation of arteriolar tone increases arterial pressure, thereby increasing perfusion of vital organs. Unfortunately, increased arterial pressure also means the heart must pump against greater resistance. Since cardiac reserve is minimal in HF, the heart may be unable to meet this challenge, and output may fall.

48.1.2.3 Water Retention and Increased Blood Volume.

48.1.2.3.1 Mechanisms.

Water retention results from two mechanisms. First, reduced cardiac output causes a reduction in renal blood flow, which in turn decreases glomerular filtration rate (GFR). As a result, urine production is decreased and water is retained. Retention of water increases blood volume.

Second, HF activates the RAAS. Activation occurs in response to reduced blood pressure and reduced renal blood flow. Once activated, the RAAS promotes water retention by increasing circulating levels of *aldosterone* and *angiotensin II*. Aldosterone acts directly on the kidneys

to promote retention of sodium and water. Angiotensin II causes constriction of renal blood vessels, which decreases renal blood flow, and thereby further decreases urine production. In addition,

Figure 47-1 Relationship of ventricular diameter to contractile force. In the normal heart and the failing heart, increased fiber length produces increased contractile force. However, for any given fiber length, contractile force in the failing heart is much less than in the healthy heart. By increasing cardiac contractility, digoxin shifts the relationship between fiber length and stroke volume in the failing heart toward that in the normal heart.

angiotensin II causes constriction of systemic arterioles and veins, and thereby increases venous and arterial pressure.

48.1.2.3.2 Consequences.

As with other adaptive responses to HF, increased blood volume can be beneficial or harmful. Increased blood volume increases venous pressure, and thereby increases venous return. As a result, ventricular filling and stroke volume are increased. The resultant increase in cardiac output can improve tissue perfusion. However, as noted, if venous pressure is too high, edema of the lungs and periphery may result. More importantly, *if the increase in cardiac output is insufficient to maintain adequate kidney function, renal retention of water will progress unabated. The resultant accumulation of fluid will cause severe cardiac, pulmonary, and peripheral edema—and, ultimately, death.*

48.1.2.4 Natriuretic Peptides.

In response to stretching of the atria and dilation of the ventricles, the heart releases two natriuretic peptides: atrial natriuretic peptide (ANP) and B-natriuretic peptide (BNP). As discussed in [Chapter 42](#), these hormones promote dilation of arterioles and veins, and also promote loss of sodium and water through the kidneys. Hence, they tend to counterbalance vasoconstriction caused by the SNS and angiotensin II, as well as retention of sodium and water caused by the RAAS. However, as HF progresses, the effects of ANP and BNP eventually become overwhelmed by the effects of the SNS and RAAS.

48.1.3 The Vicious Cycle of “Compensatory” Physiologic Responses

As discussed above, reduced cardiac output leads to compensatory responses: (1) cardiac dilation, (2) activation of the SNS, (3) activation of the RAAS, and (4) retention of water and expansion of blood volume. Although these responses represent the body's attempt to compensate for reduced cardiac output, they can actually make matters worse:

517

518

Figure 47-2 The vicious cycle of maladaptive compensatory responses to a failing heart.

excessive heart rate can reduce ventricular filling; excessive arterial pressure can lower cardiac output; and excessive venous pressure can cause pulmonary and peripheral edema. Hence, as depicted in [Figure 47-2](#), the “compensatory” responses can create a self-sustaining cycle of maladaptation that further impairs cardiac output and tissue perfusion. If cardiac output becomes too low to maintain sufficient production of urine, the resultant accumulation of water will eventually be fatal. The actual cause of death is complete cardiac failure secondary to excessive cardiac dilation and cardiac edema.

48.1.4 Signs and Symptoms of Heart Failure

The prominent signs and symptoms of HF are a direct consequence of the pathophysiology just described. Decreased tissue perfusion results in reduced exercise tolerance, fatigue, and shortness of breath; shortness of breath may also reflect pulmonary edema. Increased sympathetic tone produces tachycardia. Increased ventricular filling, reduced systolic ejection, and myocardial hypertrophy result in cardiomegaly (increased heart size). The combination of increased venous tone plus increased blood volume helps cause pulmonary edema, peripheral edema, hepatomegaly (increased liver size), and distention of the jugular veins. Weight gain results from fluid retention.

48.1.5 Classification of Heart Failure Severity

There are two major schemes for classifying HF severity. One scheme, established by the New York Heart Association (NYHA), classifies HF based on the functional limitations it causes. A newer scheme, proposed jointly by the American College of Cardiology (ACC) and the American Heart Association (AHA), is based on the observation that HF is a progressive disease that moves through stages of increasing severity.

The NYHA scheme, which has four classes, can be summarized as follows:

- Class I—No limitation of ordinary physical activity
- Class II—Slight limitation of physical activity: normal activity produces fatigue, dyspnea, palpitations, or angina
- Class III—Marked limitation of physical activity: even mild activity produces symptoms
- Class IV—Symptoms occur at rest

The ACC/AHA scheme, which also has four stages, can be summarized as follows:

- Stage A—At high risk for HF but without structural heart disease or symptoms of HF
- Stage B—Structural heart disease but without symptoms of HF

- Stage C—Structural heart disease with prior or current symptoms of HF
- Stage D—Advanced structural heart disease with marked symptoms of HF at rest, and requiring specialized interventions (eg, heart transplant, mechanical assist device)

The ACC/AHA scheme was unveiled in treatment guidelines issued in 2001. The 2005 version of that document—*ACC/AHA 2005 Guideline Update for the Evaluation and Management of Chronic Heart Failure in the Adult*—and its 2009 focused update are discussed below under *Management of Heart Failure*.

Please note that the ACC/AHA scheme is intended to complement the NYHA scheme, not replace it. The relationship between the two is shown graphically in [Figure 47-3](#).

48.2 OVERVIEW OF DRUGS USED TO TREAT HEART FAILURE

For routine therapy, heart failure is treated with three types of drugs: (1) diuretics, (2) agents that inhibit the RAAS, and (3) beta blockers. Other agents (eg, digoxin, dopamine, hydralazine, nesiritide) may be used as well.

48.2.1 Diuretics

Diuretics are first-line drugs for all patients with signs of volume overload or with a history of volume overload. By reducing blood volume, these drugs can decrease venous pressure, arterial pressure (afterload), pulmonary edema, peripheral edema, and cardiac dilation. However, excessive diuresis must be avoided: If blood volume drops too low, cardiac output and blood pressure may fall precipitously, thereby further compromising tissue perfusion. For the most part, benefits of diuretics are limited to symptom reduction. As a rule, these drugs do not prolong survival. The basic pharmacology of the diuretics is discussed in [Chapter 40](#).

48.2.1.1 Thiazide Diuretics.

The thiazide diuretics (eg, hydrochlorothiazide) produce moderate diuresis. These oral agents are used for long-term therapy of HF when edema is not too great. Since thiazides are ineffective when GFR is low, these drugs cannot be used if cardiac output is greatly reduced. The principal adverse effect of the thiazides is *hypokalemia*, which increases the risk of *digoxin-induced dysrhythmias* (see below).

48.2.1.2 High-Ceiling (Loop) Diuretics.

The loop diuretics (eg, furosemide) produce profound diuresis. In contrast to the thiazides, these drugs can promote fluid loss even when GFR

Figure 47-3 American College of Cardiology/American Heart Association (ACC/AHA) Stage and New York Heart Association (NYHA) Classification of Heart Failure.

ACC/AHA Stage	NYHA Functional Classification
A At high risk for HF but without structural heart disease or symptoms of HF	
B Structural heart disease but without symptoms of HF	I Asymptomatic
C Structural heart disease with prior or current symptoms of HF	II Symptomatic with moderate exertion
	III Symptomatic with minimal exertion
D Advanced structural heart disease with marked symptoms of HF at rest despite maximal medical therapy. Specialized interventions (e.g., heart transplant, mechanical assist device) required	IV Symptomatic at rest

is low. Hence, loop diuretics are preferred to thiazides when cardiac output is greatly reduced. Administration may be oral or IV. Because they can mobilize large volumes of water, and because they work when GFR is low, loop diuretics are drugs of choice for patients with severe HF. Like the thiazides, these drugs can cause *hypokalemia*, thereby increasing the risk of *digoxin toxicity*. In addition, loop diuretics can cause severe *hypotension* secondary to excessive volume reduction.

48.2.1.3 Potassium-Sparing Diuretics.

In contrast to the thiazides and loop diuretics, the potassium-sparing diuretics (eg, spironolactone, triamterene) promote only scant diuresis. In patients with HF, these drugs are employed to counteract potassium loss caused by thiazide and loop diuretics, thereby lowering the risk of digoxin-induced dysrhythmias. Not surprisingly, the principal adverse effect of the potassium-sparing drugs is *hyperkalemia*. Because *angiotensin-converting enzyme (ACE) inhibitors* and *angiotensin II receptor blockers (ARBs)* also carry a risk of hyperkalemia, caution is needed if these drugs are combined with a potassium-sparing diuretic. Accordingly, when

therapy with an ACE inhibitor or ARB is initiated, the potassium-sparing diuretic should be discontinued. It can be resumed later if needed.

One potassium-sparing diuretic—spironolactone—prolongs survival in patients with HF primarily by blocking receptors for aldosterone, not by causing diuresis. This drug and a related agent—eplerenone—are discussed below under *Aldosterone Antagonists*.

48.2.2 Drugs That Inhibit the RAAS

The RAAS plays an important role both in cardiac remodeling and in the hemodynamic changes that occur in response to reduced cardiac output. Accordingly, agents that inhibit the RAAS can be highly beneficial. Four groups of drugs are available: ACE inhibitors, ARBs, direct renin inhibitors (DRIs), and aldosterone antagonists. Of the four, the ACE inhibitors have been studied most thoroughly in HF. The basic pharmacology of the RAAS inhibitors is presented in [Chapter 43](#).

48.2.2.1 ACE Inhibitors

ACE inhibitors (eg, captopril, enalapril) are a cornerstone of HF therapy. These drugs can improve functional status and prolong life. In one trial, the 2-year mortality rate for patients taking enalapril was 47% lower than the rate for patients taking placebo. Other large, controlled trials have shown similar benefits. Accordingly, in the absence of specific contraindications, all patients with HF should receive one of these drugs. Although ACE inhibitors can be used alone, they are usually combined with a beta blocker and a diuretic.

How do ACE inhibitors help? They block production of angiotensin II, decrease release of aldosterone, and suppress degradation of kinins. As a result, they improve hemodynamics and favorably alter cardiac remodeling.

48.2.2.1.1 Hemodynamic Benefits.

By suppressing production of angiotensin II, ACE inhibitors cause dilation of arterioles and veins and they decrease release of aldosterone. Resulting benefits in HF are as follows:

- *Arteriolar dilation* improves regional blood flow in the kidneys and other tissues and, by reducing afterload, it increases stroke volume and cardiac output. Increased renal blood flow promotes excretion of sodium and water.
- *Venous dilation* reduces venous pressure, and thereby reduces pulmonary congestion, peripheral edema, preload, and cardiac dilation.

- *Suppression of aldosterone release* enhances excretion of sodium and water, while causing retention of potassium.

Interestingly, suppression of angiotension II production diminishes over time, suggesting that long-term benefits are the result of some other action.

48.2.2.1.2 Impact on Cardiac Remodeling.

With continued use, ACE inhibitors have a favorable impact on cardiac remodeling. Elevation of kinins is largely responsible. This statement is based in part on the observation that, in experimental models, giving a kinin receptor blocker decreases beneficial effects on remodeling. Also, we know that suppression of angiotensin II production diminishes over time, and hence reduced angiotensin II cannot fully explain long-term benefits.

519

520

48.2.2.1.3 Adverse Effects.

The principal adverse effects of the ACE inhibitors are *hypotension* (secondary to arteriolar dilation), *hyperkalemia* (secondary to decreased aldosterone release), *intractable cough*, and *angioedema*. In addition, these drugs can cause *renal failure in patients with bilateral renal artery stenosis*. If taken during pregnancy—especially the second and third trimesters—ACE inhibitors can cause *fetal injury*. Accordingly, if pregnancy occurs, these drugs should be discontinued. Because of their ability to elevate potassium levels, ACE inhibitors should be used with caution in patients taking potassium supplements or a potassium-sparing diuretic (eg, spironolactone, triamterene).

48.2.2.1.4 Dosage.

Adequate dosage is critical: Higher dosages are associated with increased survival. Results of the Assessment of Treatment with Lisinopril and Survival (ATLAS) trial indicate that the doses needed to increase survival are higher than those needed to produce hemodynamic changes. Unfortunately, in everyday practice, dosages are often too low: Providers frequently prescribe dosages that are large enough to produce hemodynamic benefits, but are still too low to prolong life. Target dosages associated with increased survival are summarized in [Table 47-1](#). These dosages should be used unless side effects make them intolerable.

48.2.2.2 Angiotensin II Receptor Blockers

In patients with HF, the effects of ARBs are similar to those of ACE inhibitors—but not identical. Hemodynamic effects of both groups are much the same. Clinical trials have shown that ARBs improve LV ejection fraction, reduce HF symptoms, increase exercise tolerance,

decrease hospitalization, enhance quality of life, and, most importantly, reduce mortality. However, because ARBs do not increase levels of kinins, their effects on cardiac remodeling are less favorable than those of ACE inhibitors. For this reason, and because clinical experience with ACE inhibitors is much greater than with ARBs, ACE inhibitors are generally preferred. For now, ARBs should be reserved for HF patients who cannot tolerate ACE inhibitors, usually owing to intractable cough. (Because ARBs do not increase bradykinin levels, they do not cause cough.)

48.2.2.3 Aldosterone Antagonists

In patients with HF, aldosterone antagonists—*spironolactone* [Aldactone] and *eplerenone* [Inspra]—can reduce symptoms, decrease hospitalizations, and prolong life. These benefits were first demonstrated with spironolactone in the Randomized Aldactone Evaluation Study (RALES). Similar results were subsequently obtained with eplerenone. Current guidelines recommend adding an aldosterone antagonist to standard HF therapy (ie, a diuretic, an ACE inhibitor or ARB, and a beta blocker), but only in patients with moderately severe or severe symptoms.

How do aldosterone antagonists help? Primarily by blocking aldosterone receptors in the heart and blood vessels. To understand these effects, we need to review the role of aldosterone in HF. In the past, researchers believed that all aldosterone did was promote renal retention of sodium (and water) in exchange for excretion of potassium. However, we now know that aldosterone has additional—and more harmful—effects. Among these are

- Promotion of myocardial remodeling (which impairs pumping)
- Promotion of myocardial fibrosis (which increases the risk of dysrhythmias)
- Activation of the SNS and suppression of norepinephrine uptake in the heart (both of which can promote dysrhythmias and ischemia)
- Promotion of vascular fibrosis (which decreases arterial compliance)
- Promotion of baroreceptor dysfunction

During HF, activation of the RAAS causes levels of aldosterone to rise. In some patients, levels reach 20 times normal. As aldosterone levels grow higher, harmful effects increase, and prognosis becomes progressively worse.

Drugs can reduce the impact of aldosterone by either decreasing aldosterone production or blocking aldosterone receptors. ACE inhibitors, ARBs, and DRIs decrease aldosterone

520

521

production; spironolactone and eplerenone block aldosterone receptors. Although ACE inhibitors and ARBs can reduce aldosterone production, they do not block it entirely. Furthermore, production is suppressed only for a relatively short time. Hence, when ACE inhibitors or ARBs are used alone, detrimental effects of aldosterone can persist. However, when an aldosterone antagonist is added to the regimen, any residual effects are eliminated. As a result, symptoms of HF are improved and life is prolonged.

**TABLE 47-1 Inhibitors of the Renin-Angiotensin-Aldosterone System
Used in Heart Failure**

Drug	Initial Daily Dose	Maximum Daily Dose
ACE Inhibitors		
Captopril [Capoten]	6.25 mg 3 times	50 mg 3 times
Enalapril [Vasotec]	2.5 mg twice	10–20 mg twice
Fosinopril [Monopril]	5–10 mg once	40 mg once
Lisinopril [Zestril, Prinvil]	2.5–5 mg once	20–40 mg once
Perindopril [Aceon]	2 mg once	8–16 mg once
Quinapril [Accupril]	5 mg twice	20 mg twice
Ramipril [Altace]	1.25–2.5 mg once	10 mg once
Trandolapril [Mavik]	1 mg once	4 mg once
Angiotensin II Receptor Blockers		
Candesartan [Benicar]	4–8 mg once	32 mg once
Losartan [Cozaar]	25–50 mg once	50–100 mg once
Valsartan [Diovan]	20–40 mg twice	160 mg twice
Aldosterone Antagonists		
Eplerenone [Inspra]	25 mg once	50 mg once
Spironolactone [Aldactone]	12.5–25 mg once	25 mg once or twice

Aldosterone antagonists have one major adverse effect: *hyperkalemia*. The underlying cause is renal retention of potassium. Risk is increased by renal impairment and by using an ACE inhibitor or ARB. To minimize risk, potassium levels and renal function should be measured at baseline and periodically thereafter. Potassium supplements should be discontinued.

Spironolactone—but not eplerenone—poses a significant risk of *gynecomastia* (breast enlargement) in men, a condition that can be both cosmetically troublesome and painful. In the RALES trial, 10% of males experienced painful breast enlargement.

48.2.2.4 Direct Renin Inhibitors

As discussed in [Chapter 43](#), DRIs can shut down the entire RAAS. In theory, their benefits in HF should equal those of the ACE inhibitors and ARBs. At this time, only one DRI is available. This drug—*aliskiren* [Tekturna]—is being tested in HF, but is not yet approved for the disorder.

48.2.3 Beta Blockers

The role of beta blockers in HF continues to evolve. Until the mid-1990s, HF was considered an absolute contraindication to these drugs. After all, blockade of cardiac β_1 -adrenergic receptors *reduces* contractility—an effect that is clearly detrimental, given that contractility is already compromised in the failing heart. However, it is now clear that, with careful control of dosage, beta blockers can improve patient status. Controlled trials have shown that three beta blockers—*carvedilol* [Coreg], *bisoprolol* [Zebeta], and *sustained-release metoprolol* [Toprol XL]—when added to conventional therapy, can improve LV ejection fraction, increase exercise tolerance, slow progression of HF, reduce the need for hospitalization, and, most importantly, prolong survival. Accordingly, beta blockers are now recommended for most patients. These drugs can even be used in patients with severe disease (NYHA Class IV), provided the patient is euvolemic and hemodynamically stable. Although the mechanism underlying benefits is uncertain, likely possibilities include protecting the heart from excessive sympathetic stimulation and protecting against dysrhythmias. Because excessive beta blockade can reduce contractility, doses must be very low initially and then gradually increased. Full benefits may not be seen for 1 to 3 months. Among patients with HF, the principal adverse effects are (1) fluid retention and worsening of HF, (2) fatigue, (3) hypotension, and (4) bradycardia or heart block. The basic pharmacology of the beta blockers is discussed in [Chapter 18](#).

48.2.4 Digoxin and Other Cardiac Glycosides

Digoxin and the other cardiac glycosides are best known for their *positive inotropic actions*, that is, their ability to increase myocardial contractile force. By increasing contractile force, these drugs can increase cardiac output. In addition, cardiac glycosides can alter the electrical activity of the heart, and they can favorably affect neurohormonal systems. Unfortunately, although these drugs can reduce symptoms of HF, they do not prolong life. Used widely in the past, cardiac glycosides are considered second-line agents today. The pharmacology of these drugs is discussed at length later.

48.2.5 Inotropic Agents (Other Than Cardiac Glycosides)

In addition to the cardiac glycosides, we have two other groups of inotropic drugs: sympathomimetics and phosphodiesterase (PDE) inhibitors. Unlike the cardiac glycosides, which can be taken orally, these other inotropics must be given by IV infusion. Accordingly, their use is restricted to acute care of hospitalized patients. Because the cardiac glycosides can be given PO, they are the only inotropics suited for long-term therapy.

48.2.5.1 Sympathomimetic Drugs: Dopamine and Dobutamine

The basic pharmacology of dopamine and dobutamine is presented in [Chapter 17](#). Discussion here is limited to their use in HF. Both drugs are administered by IV infusion.

48.2.5.1.1 Dopamine.

Dopamine (formerly available as Intropin) is a catecholamine that can activate (1) β_1 -adrenergic receptors in the heart, (2) dopamine receptors in the kidney, and (3) at high doses, α_1 -adrenergic receptors in blood vessels. Activation of β_1 receptors increases myocardial contractility, thereby improving cardiac performance. β_1 activation also increases heart rate, creating a risk of tachycardia. Activation of dopamine receptors dilates renal blood vessels, thereby increasing renal blood flow and urine output. Activation of α_1 receptors increases vascular resistance (afterload), and can thereby reduce cardiac output. Dopamine is administered by continuous infusion. Constant monitoring of blood pressure, the electrocardiogram (ECG), and urine output is required. Dopamine is employed as a short-term rescue measure for patients with severe, acute cardiac failure.

48.2.5.1.2 Dobutamine.

Dobutamine (formerly available as Dobutrex) is a synthetic catecholamine that causes selective activation of β_1 -adrenergic receptors. By doing so, the drug can increase myocardial contractility, and can thereby improve cardiac performance. Like dopamine, dobutamine can cause tachycardia. In contrast to dopamine, dobutamine does not activate α_1 receptors, and therefore does not increase vascular resistance. As a result, the drug is generally preferred to dopamine for short-term treatment of acute HF. Administration is by continuous infusion.

48.2.5.2 Phosphodiesterase Inhibitors

48.2.5.2.1 Inamrinone.

Inamrinone, formerly known as *amrinone*, has been called an *inodilator* because it increases myocardial contractility *and* promotes vasodilation. Increased contractility results from intracellular accumulation of cyclic AMP (cAMP) secondary to inhibition of PDE3, an enzyme that degrades cAMP. The mechanism underlying vasodilation is unclear.

Comparative studies indicate that improvements in cardiac function elicited by inamrinone are superior to those elicited by dopamine or dobutamine. Like dopamine and dobutamine, inamrinone is administered by IV infusion, and hence is not suited for outpatient use.

Inamrinone is indicated only for short-term (2- to 3-day) treatment of HF in patients who have not responded to RAAS inhibitors, diuretics, and digoxin. The drug should be protected from light and should not be mixed with glucose-containing solutions. Constant monitoring is required. The initial dose is 0.75 mg/kg IV administered over 2 to 3 minutes. The maintenance infusion is 5 to 10 mcg/kg/min.

48.2.5.2.2 Milrinone.

Like inamrinone, milrinone (formerly available as Primacor) is an inodilator. Increased contractility results from accumulation of cAMP secondary to inhibition of PDE3. Milrinone is administered by IV infusion and is indicated only for short-term therapy of severe HF. Dosing is complex.

48.2.6 Vasodilators (Other Than ACE Inhibitors and ARBs)

48.2.6.1 Isosorbide Dinitrate Plus Hydralazine

For treatment of HF, isosorbide dinitrate (ISDN) and hydralazine are usually combined. The combination represents an alternative to ACE inhibitors or ARBs. However, ACE inhibitors and ARBs are generally preferred.

Isosorbide dinitrate [Isordil, others] belongs to the same family as nitroglycerin. Like nitroglycerin, ISDN causes selective dilation of *veins*. In patients with severe, refractory HF, the drug can reduce congestive symptoms and improve exercise capacity. In addition to its hemodynamic actions, ISDN may inhibit abnormal myocyte growth, and hence may retard cardiac remodeling. Principal adverse effects are *orthostatic hypotension* and *reflex tachycardia*.

The basic pharmacology of ISDN and other organic nitrates is discussed in [Chapter 50](#) (Drugs for Angina Pectoris).

521

522

Hydralazine [Apresoline] causes selective dilation of *arterioles*. By doing so, the drug can improve cardiac output and renal blood flow. For treatment of HF, hydralazine is always used in combination with ISDN, since hydralazine by itself is not very effective. Principal adverse effects are *hypotension*, *tachycardia*, and a syndrome that resembles *systemic lupus erythematosus*. The basic pharmacology of hydralazine is discussed in [Chapter 45](#) (Vasodilators).

In 2005, the Food and Drug Administration approved *BiDil*, a fixed-dose combination of hydralazine and isosorbide dinitrate, for treating HF—but only in African Americans, making BiDil the first medication approved for a specific ethnic group. Can BiDil help people in other ethnic groups? Probably, but data are lacking: The manufacturer only tested the product in blacks. As discussed in [Chapter 8](#) (under the heading *Race*), testing was limited to blacks primarily because of regulatory and market incentives, not because there were data suggesting it wouldn't work for others. Of course, now that BiDil is approved, clinicians may prescribe it for anyone they see fit. Each BiDil tablet contains 37.5 mg hydralazine and 20 mg isosorbide dinitrate. The recommended dosage is 1 or 2 tablets 3 times a day.

48.2.6.2 Intravenous Vasodilators for Acute Care

48.2.6.2.1 Nitroglycerin.

Intravenous nitroglycerin is a powerful *venodilator* that produces a dramatic reduction in venous pressure. Effects have been described as being equivalent to “pharmacologic phlebotomy.” In HF, nitroglycerin is used to relieve acute severe pulmonary edema. Principal adverse effects are *hypotension* and resultant *reflex tachycardia*. The basic pharmacology of nitroglycerin is discussed in [Chapter 50](#) (Drugs for Angina Pectoris).

48.2.6.2.2 Sodium Nitroprusside.

Sodium nitroprusside [Nitropress] acts rapidly to dilate *arterioles* and *veins*. Arteriolar dilation reduces afterload and thereby increases cardiac output. Venodilation reduces venous pressure and thereby decreases pulmonary and peripheral congestion. The drug is indicated for short-term therapy of severe refractory HF. The principal adverse effect is *profound hypotension*. Blood pressure must be monitored continuously. The basic pharmacology of nitroprusside is discussed in [Chapter 45](#) (Vasodilators).

48.2.6.2.3 Nesiritide.

Nesiritide [Natrekor] is a synthetic form of human BNP indicated only for short-term, IV therapy of hospitalized patients with acutely decompensated HF, characterized by increased

pulmonary capillary wedge pressure (PCWP) and dyspnea at rest. Nesiritide is produced by recombinant DNA technology and has the same amino acid sequence as naturally occurring BNP. Hemodynamic benefits equal those of nitroglycerin. However, nesiritide costs much more than nitroglycerin, and hypotension, which can be caused by both drugs, lasts much longer.

In 2005, two meta-analyses of older data suggested that nesiritide may *increase* the risk of renal injury and death. The resulting controversy is not yet resolved. Although there is debate as to whether nesiritide actually increases mortality, one thing is nonetheless clear: There are no data to show that it *reduces* mortality. Until more is known, an expert panel, convened by the drug's manufacturer, has recommended that use of nesiritide be strictly limited to inpatients with acutely decompensated HF (and that it *not* be used for unlabeled indications, including intermittent outpatient infusions or scheduled repetitive use). The panel also noted the need for large-scale trials to assess the benefits and risks of nesiritide compared with standard therapy.

48.2.6.2.3.1 Mechanism of Action.

Nesiritide affects hemodynamics by three mechanisms: suppression of the RAAS, suppression of sympathetic outflow from the central nervous system (CNS), and direct dilation of arterioles and veins. In patients with HF, benefits derive primarily from direct vasodilation. To promote vasodilation, nesiritide binds with receptors on vascular smooth muscle (VSM), and thereby stimulates production of cyclic GMP (cGMP), a second messenger that causes VSM to relax. This mechanism is similar to that of nitroglycerin, which also stimulates cGMP production. However, whereas nitroglycerin acts primarily on veins, nesiritide dilates arterioles as well. By dilating arterioles and veins, nesiritide reduces both preload and afterload. The net result is a decrease in PCWP and increased cardiac output. Also, by dilating afferent renal arterioles, nesiritide increases GFR, and thereby increases excretion of sodium and water. The result is a reduction in blood volume, which further reduces cardiac preload.

48.2.6.2.3.2 Clinical Effects.

Nesiritide has been studied in several clinical trials, including the Vasodilation in the Management of Acute Congestive Heart Failure (VMAC) trial, which compared nesiritide with IV nitroglycerin and placebo. The result? Three hours after the start of treatment, nesiritide produced a significant reduction in PCWP and a significant improvement in dyspnea. The effect was equivalent to that of IV nitroglycerin and superior to that of placebo. To date, there are no data to show that nesiritide prolongs life.

48.2.6.2.3.3 Pharmacokinetics.

With continuous infusion, nesiritide achieves steady-state levels that are 3 to 6 times greater than the level of endogenous BNP present at baseline. Nesiritide is eliminated by three mechanisms: (1) proteolytic cleavage by endopeptidases present on the luminal surface of blood vessels; (2) binding to clearance receptors on the surface of cells, followed by cellular uptake and proteolytic cleavage; and (3) renal filtration. The drug's half-life is short, about 18 minutes.

48.2.6.2.3.4 Adverse Effects.

The principal adverse effect is symptomatic *hypotension*. In the VMAC trial, hypotension developed in 4% of patients, about the same rate seen with nitroglycerin. However, because nesiritide has a longer half-life than nitroglycerin, the duration of hypotension was also longer (2.2 hours vs. 0.7 hours with nitroglycerin). The risk of hypotension is increased by high doses of nesiritide and by concurrent use of ACE inhibitors and other vasodilators. In addition to causing hypotension, nesiritide can cause ventricular tachycardia (3%), headache (8%), back pain (4%), dizziness (3%), and nausea (4%). An analysis of several clinical trials suggested that nesiritide may cause renal damage.

48.2.6.2.3.5 Preparations, Dosage, and Administration.

Nesiritide [Natrekor] is available in 1.5-mg, single-use vials. The powder must be dissolved and then diluted to a final concentration of 6 mcg/mL. Dosing consists of an initial IV bolus (2 mcg/kg) followed by continuous infusion (0.01 mcg/kg/min), typically lasting 48 hours or less. If symptomatic hypotension develops, the infusion should be slowed or stopped.

48.3 CARDIAC (DIGITALIS) GLYCOSIDES

The cardiac glycosides are naturally occurring compounds that have profound effects on the mechanical and electrical properties of the heart. In addition, they have important neurohormonal effects. Because these drugs are prepared by extraction from *Digitalis purpurea* (purple foxglove) and *Digitalis lanata* (Grecian foxglove), the cardiac glycosides are also known as *digitalis glycosides*.

How do cardiac glycosides help people with HF? For many decades, benefits were ascribed solely to increased myocardial contractility. It is now clear, however, that effects on neurohormonal systems are also important.

Cardiac glycosides are dangerous drugs. Why? Because, at doses close to therapeutic, they can cause severe dysrhythmias. Because of their prodysrhythmic actions, these drugs must be used with respect, caution, and skill.

In the United States, digoxin is the only cardiac glycoside available. Glycosides available in the past include digitoxin, deslanoside, and powdered digitalis leaf. For patients with HF, cardiac glycosides are now considered second-line drugs.

48.3.1 Digoxin

Digoxin [Lanoxin, Lanoxicaps] is indicated for HF and control of dysrhythmias (see [Chapter 48](#)). When used for HF, digoxin can reduce symptoms, increase exercise tolerance, and decrease hospitalizations. However, the drug does not prolong life. Furthermore, when used by *women*, it may actually *shorten* life ([Box 47-1](#)).

48.3.1.1 Chemistry

Digoxin consists of three components: a steroid nucleus, a lactone ring, and three molecules of digitoxose (a sugar). It is because of the sugars that digoxin is known as a glycoside. The region of the molecule composed of the steroid nucleus plus the lactone ring (ie, the region without the sugar molecules) is responsible for the pharmacologic effects of digoxin. The sugars only increase solubility.

48.3.1.2 Mechanical Effects on the Heart

Digoxin exerts a *positive inotropic action* on the heart. That is, the drug *increases the force of ventricular contraction*, and can thereby increase cardiac output.

522

48.3.1.2.1 BOX 47-1 Special Interest Topic

523

48.3.1.2.1.1 ATTENTION LADIES: DIGOXIN MAY BE HAZARDOUS TO YOUR HEALTH

Researchers who conducted a re-analysis of older data discovered that, for *women* with heart failure, digoxin may do more harm than good. In 1997, the Digitalis Investigation Group¹ (DIG) reported the results of a large, randomized, placebocontrolled trial designed to assess the impact of digoxin on morbidity and mortality in patients with heart failure. The study enrolled 6801 patients (men and women) with heart failure and followed them for an average of 37 months. They all took an ACE inhibitor and a diuretic; half also received digoxin and the other half received a placebo. The result? Digoxin improved

symptoms and decreased hospitalizations, but did not reduce mortality. The overall death rate was 35%, regardless of whether patients took digoxin or placebo. However, the data were not analyzed for possible gender-related effects. Accordingly, in 2002, Rathore et al.^{*} performed a retrospective analysis of the DIG data to determine whether digoxin had different effects in men and women. What did their analysis reveal? Among men, digoxin had no significant impact on mortality, mirroring the overall mortality seen in 1997. However, among *women*, digoxin produced a small, but significant *increase* in mortality: After 37 months, the death rate was 28.9% for women taking placebo compared with 33.1% for those taking digoxin—an increase of 4.2%.

Why did digoxin increase the mortality rate in women, but not in men? The answer is unknown. Theoretical possibilities include sex-based differences in autonomic function, muscle metabolism, signal transduction, or myocardial cell growth and function. However, there may be a more simple answer: In the women who died, digoxin plasma levels may have been excessive. It is well established that digoxin can be lethal at high levels. In the DIG trial, digoxin levels were measured only in randomly selected patients, and hence Rathore et al. lacked the data needed to determine whether deaths were related to high drug levels. If high digoxin levels were indeed responsible for the observed mortality increase, then the take-home message is obvious: We must keep digoxin doses low.

The Rathore et al. study suggests that, for female patients, the benefits of digoxin therapy (primarily a small [4%] decrease in the risk of hospitalization) may not justify the risk (possible drug-induced death). Until more is known, prudence dictates using digoxin in women with increased caution. As a rule, the drug should be reserved for patients who have not responded adequately to first-line medicines: ACE inhibitors or ARBs, diuretics, and beta blockers. Furthermore, digoxin levels should be kept as low as possible (0.5 to 0.8 ng/mL is a reasonable initial target). Finally, although the re-analysis underscores the potential dangers of digoxin, we mustn't forget that the drug *can* benefit many patients—especially those with heart failure combined with atrial fibrillation. Accordingly, we shouldn't withhold digoxin indiscriminately. Nor should we discontinue it without careful consideration, since doing so might lead to hemodynamic decompensation.

* Rathore SS, Wang Y, Krumholz H: Sex-based differences in the effect of digoxin for the treatment of heart failure. *N Engl J Med* 347:1403–1411, 2002.

48.3.1.2.2 Mechanism of Inotropic Action.

Digoxin increases myocardial contractility by inhibiting an enzyme known as *sodium, potassium-ATPase* (Na^+, K^+ -ATPase). By way of an indirect process described below, inhibition of Na^+, K^+ -ATPase promotes calcium accumulation within myocytes. The calcium then augments contractile force by facilitating the interaction of myocardial contractile proteins: actin and myosin.

To understand how inhibition of Na^+, K^+ -ATPase causes intracellular calcium to rise, we must first understand the normal role of Na^+, K^+ -ATPase in myocytes. That role is illustrated in [Figure 47-4](#). As indicated, when an action potential passes along the myocyte membrane (sarcolemma), Na^+ ions and Ca^{++} ions enter the cell, and K^+ ions exit. Once the action potential has passed, these ion fluxes must be reversed, so that the original ionic balance of the cell can be restored. Na^+, K^+ -ATPase is critical to this process. As shown in [Figure 47-4](#), Na^+, K^+ -ATPase acts as a “pump” to draw extracellular K^+ ions into the cell, while simultaneously extruding intracellular Na^+ . The energy required for pumping Na^+ and K^+ is provided by the breakdown of ATP—hence the name Na^+, K^+ -ATPase. To complete the normalization of cellular ionic composition, Ca^{++} ions must leave the cell. Extrusion of Ca^{++} is accomplished through an exchange process in which extracellular Na^+ ions are taken into the cell while Ca^{++} ions exit. This exchange of Na^+ for Ca^{++} is a passive (energy-independent) process.

We can now answer the question, how does inhibition of Na^+, K^+ -ATPase increase intracellular Ca^{++} ? By inhibiting Na^+, K^+ -ATPase, digoxin prevents the myocyte from restoring its proper ionic composition following the passage of an action potential. Inhibition of Na^+, K^+ -ATPase blocks uptake of K^+ and extrusion of Na^+ . Hence, with each successive action potential, intracellular K^+ levels decline and intracellular Na^+ levels rise. It is this rise in Na^+ that leads to the rise in intracellular Ca^{++} . In the presence of excess intracellular Na^+ , further Na^+ entry is suppressed. Since Na^+ entry is suppressed, the passive exchange of Ca^{++} for Na^+ cannot take place, and hence Ca^{++} accumulates within the cell.

48.3.1.2.3 Relationship of Potassium to Inotropic Action.

Potassium ions compete with digoxin for binding to Na^+, K^+ -ATPase. This competition is of great clinical significance. Because potassium competes with digoxin, when potassium levels are low, binding of digoxin to Na^+, K^+ -ATPase increases. This increase can produce excessive

inhibition of Na^+, K^+ -ATPase with resultant toxicity. Conversely, when levels of potassium are high, inhibition of Na^+, K^+ -ATPase by digoxin is reduced, causing a reduction in the therapeutic response. Because an increase in potassium can impair therapeutic responses, whereas a decrease in potassium can cause toxicity, it is imperative that potassium levels be kept within the normal physiologic range: 3.5 to 5 mEq/L.

48.3.1.3 Hemodynamic Benefits in Heart Failure

48.3.1.3.1 Increased Cardiac Output.

In patients with HF, increased myocardial contractility increases cardiac output. As shown in [Figure 47-1](#), by increasing contractility, digoxin shifts the relationship of fiber length to stroke volume in the failing heart toward that in the healthy heart. Consequently, at any given heart size, the stroke volume of the failing heart increases, causing cardiac output to rise.

523

524

Figure 47-4 Ion fluxes across the cardiac cell membrane.

During the action potential, Na^+ and Ca^{++} enter the cardiac cell and K^+ exits. Following the action potential, Na^+, K^+ -ATPase pumps Na^+ out of the cell and takes up K^+ . Ca^{++} leaves the cell in exchange for the uptake of Na^+ . By inhibiting Na^+, K^+ -ATPase, digoxin prevents the extrusion of Na^+ , causing Na^+ to accumulate inside the cell. The resulting buildup of intracellular Na^+ suppresses the $\text{Na}^+-\text{Ca}^{++}$ exchange process, thereby causing intracellular levels of Ca^{++} to rise.

48.3.1.3.2 Consequences of Increased Cardiac Output.

As a result of increased cardiac output, three major secondary responses occur: (1) sympathetic tone declines, (2) urine production increases, and (3) renin release declines. These responses can reverse virtually all signs and symptoms of HF. However, they do not correct the underlying problem of cardiac remodeling.

48.3.1.3.2.1 Decreased Sympathetic Tone.

By increasing contractile force and cardiac output, digoxin increases arterial pressure. In response, sympathetic nerve traffic to the heart and blood vessels is reduced via the baroreceptor reflex. (Recall that a compensatory *increase* in sympathetic tone had taken place because of HF.)

The decrease in sympathetic tone has several beneficial effects. First, heart rate is reduced, thereby allowing more complete ventricular filling. Second, afterload is reduced (because of reduced arteriolar constriction), thereby allowing more complete ventricular emptying. Third, venous pressure is reduced (because of reduced venous constriction), thereby reducing cardiac distention, pulmonary congestion, and peripheral edema.

48.3.1.3.2.2 Increased Urine Production.

The increase in cardiac output increases renal blood flow, and thereby increases production of urine. The resultant loss of water reduces blood volume, which in turn reduces cardiac distention, pulmonary congestion, and peripheral edema.

48.3.1.3.2.3 Decreased Renin Release.

In response to increased arterial pressure, renin release declines, causing levels of aldosterone and angiotensin II to decline as well. The decrease in angiotensin II decreases vasoconstriction, thereby further reducing afterload and venous pressure. The decrease in aldosterone reduces retention of sodium and water, which reduces blood volume, which in turn further reduces venous pressure.

48.3.1.3.3 Summary of Hemodynamic Effects.

In summary, we can see that, through direct and indirect mechanisms, digoxin has the potential to reverse all of the overt manifestations of HF: cardiac output improves, heart rate decreases, heart size declines, constriction of arterioles and veins decreases, water retention reverses, blood volume declines, peripheral and pulmonary edema decrease, and weight is lost

(owing to water loss). In addition, exercise tolerance improves and fatigue is reduced. There is, however, one important caveat: Although digoxin can produce substantial improvement in HF symptoms, it does not prolong life.

48.3.1.4 Neurohormonal Benefits in Heart Failure

At dosages below those needed for positive inotropic effects, digoxin can modulate the activity of neurohormonal systems. The underlying mechanism is inhibition of Na^+, K^+ -ATPase.

In the kidney, digoxin can suppress renin release. How? By inhibiting Na^+, K^+ -ATPase in renal tubules, digoxin decreases tubular absorption of sodium. As a result, less sodium is presented to the distal tubule, and hence renin release is suppressed.

Through effects on the vagus nerve, digoxin can decrease sympathetic outflow from the CNS. Specifically, by inhibiting Na^+, K^+ -ATPase in vagal afferent fibers, digoxin increases the sensitivity of cardiac baroreceptors. As a result, these receptors discharge more readily, thereby signaling the CNS to reduce sympathetic traffic to the periphery.

How important are these effects on renin and sympathetic tone? No one knows for sure. However, they are probably just as important as inotropic effects, and perhaps even more important.

48.3.1.5 Electrical Effects on the Heart

The effects of digoxin on the electrical activity of the heart are of therapeutic and toxicologic importance. It is because of its electrical effects that digoxin is useful for treating dysrhythmias (see [Chapter 48](#)). Ironically, these same electrical effects are responsible for *causing* dysrhythmias, the most serious adverse effect of digoxin.

The electrical effects of digoxin can be bewildering in their complexity. Through a combination of actions, digoxin can alter the electrical activity in noncontractile tissue (sinoatrial [SA] node, atrioventricular [AV] node, Purkinje fibers) as well as in ventricular muscle. In these various regions, digoxin can alter automaticity, refractoriness, and impulse conduction. Whether these parameters are increased or decreased depends on cardiac status, digoxin dosage, and the particular region involved.

Although the electrical effects of digoxin are many and varied, only a few are clinically significant. These are discussed below.

48.3.1.5.1 Mechanisms for Altering Electrical Activity of the Heart.

Digoxin alters the electrical properties of the heart by *inhibiting Na^+ , K^+ -ATPase* and by *enhancing vagal influences on the heart*. By inhibiting Na^+ , K^+ -ATPase, digoxin alters the distribution of ions (Na^+ , K^+ , Ca^{++}) across the cardiac cell membrane. This change in ion distribution can alter the electrical responsiveness of the cells involved. Since hypokalemia intensifies inhibition of Na^+ , K^+ -ATPase, hypokalemia intensifies alterations in cardiac electrical properties.

Digoxin acts in two ways to enhance vagal effects on the heart. First, the drug acts in the CNS to increase the firing rate of vagal fibers that innervate the heart. Second, digoxin increases the responsiveness of the SA node to acetylcholine (the neurotransmitter released by the vagus). The net result of these vagotonic effects is (1) decreased automaticity of the SA node, and (2) decreased conduction through the AV node.

48.3.1.5.2 Effects on Specific Regions of the Heart.

In the SA node, digoxin decreases automaticity (by the vagotonic mechanisms just mentioned). In the AV node, digoxin decreases conduction velocity and prolongs the effective refractory period. These effects, which can promote varying degrees of AV block, result primarily from the drug's vagotonic actions. In Purkinje fibers, digoxin-induced inhibition of Na^+ , K^+ -ATPase results in increased automaticity; this increase can generate ectopic foci that, in turn, can cause ventricular dysrhythmias. In the ventricular myocardium, digoxin acts to shorten the effective refractory period and (possibly) increase automaticity.

48.3.1.6 Adverse Effects I: Cardiac Dysrhythmias

Dysrhythmias are the most serious adverse effect of digoxin. The drug causes dysrhythmias by altering the electrical properties of the heart. Fortunately, when used in the dosages recommended today, dysrhythmias are uncommon.

What kinds of dysrhythmias can occur? Digoxin can mimic practically all types of dysrhythmias. Atrioventricular block with escape beats is among the most common. Ventricular flutter and ventricular fibrillation are the most dangerous.

Because serious dysrhythmias are a potential consequence of therapy, all patients should be evaluated frequently for changes in heart rate and rhythm. If significant changes occur, digoxin should be withheld and the prescriber consulted. Outpatients should be taught to monitor their pulses and instructed to report any significant changes in rate or regularity.

48.3.1.6.1 Mechanism of Ventricular Dysrhythmia Generation.

Digoxin-induced ventricular dysrhythmias result from a combination of four factors:

- Decreased automaticity of the SA node
- Decreased impulse conduction through the AV node
- Spontaneous discharge of Purkinje fibers (caused in part by increased automaticity)
- Shortening of the effective refractory period in ventricular muscle

Increased Purkinje fiber discharge and shortening of the ventricular effective refractory period predispose the ventricles to developing ectopic beats. Potential ectopic beats become manifest because the effects of digoxin on the SA and AV nodes decrease the ability of the normal pacemaker to drive the ventricles, thereby allowing ventricular ectopic beats to take over.

48.3.1.6.2 Predisposing Factors.

48.3.1.6.2.1 Hypokalemia.

The most common cause of dysrhythmias in patients receiving digoxin is hypokalemia secondary to the use of diuretics. Less common causes include vomiting and diarrhea.

Hypokalemia promotes dysrhythmias by increasing digoxin-induced inhibition of Na^+, K^+ -ATPase, which in turn leads to increased automaticity of Purkinje fibers. Because low potassium can precipitate dysrhythmias, *it is imperative that serum potassium levels be kept within a normal range.* If diuretic therapy causes potassium levels to fall, a potassium-sparing diuretic (eg, spironolactone) can be prescribed to correct the problem. Potassium supplements may also be used. Patients should be taught to recognize symptoms of hypokalemia (eg, muscle weakness) and instructed to notify the prescriber if these develop.

48.3.1.6.2.2 Elevated Digoxin Levels.

Digoxin has a narrow therapeutic range: Drug levels only slightly higher than therapeutic greatly increase the risk of toxicity. Possible causes of excessive digoxin levels include (1) intentional or accidental overdose, (2) increased digoxin absorption, and (3) decreased digoxin elimination.

If digoxin levels are kept within the optimal therapeutic range—now considered to be 0.5 to 0.8 ng/mL—the chances of a dysrhythmia will be reduced. However, it is important to note that careful control over drug levels does not eliminate the risk. As discussed above, there is

only a loose relationship between digoxin levels and clinical effects. As a result, some patients may experience dysrhythmias even when drug levels are within what is normally considered the therapeutic range.

48.3.1.6.2.3 Heart Disease.

The ability of digoxin to cause dysrhythmias is greatly increased by the presence of heart disease. Doses of digoxin that have no adverse effects on healthy volunteers can precipitate serious dysrhythmias in patients with HF. The probability and severity of a dysrhythmia are directly related to the severity of the underlying disease. Since heart disease is the reason for taking digoxin, it should be no surprise that people taking the drug are at risk of dysrhythmias.

48.3.1.6.3 Diagnosing Digoxin-Induced Dysrhythmias.

Diagnosis is not easy. Why? Largely because the failing heart is prone to spontaneous dysrhythmias. Hence, when a dysrhythmia occurs, we cannot simply assume that digoxin is the cause: The possibility that the dysrhythmia is the direct result of heart disease must be considered. Compounding diagnostic difficulties is the poor correlation between plasma digoxin levels and dysrhythmia onset. Because of this loose association, the presence of an apparently excessive digoxin level does not necessarily indicate that digoxin is responsible for the problem. Laboratory data required for diagnosis include digoxin level, serum electrolytes, and an ECG. Ultimately, diagnosis is based on experience and clinical judgment. Resolution of the dysrhythmia following digoxin withdrawal confirms the diagnosis.

48.3.1.6.4 Managing Digoxin-Induced Dysrhythmias.

With proper treatment, digoxin-induced dysrhythmias can almost always be controlled. Basic management measures are as follows:

- *Withdraw digoxin and potassium-wasting diuretics.* For many patients, no additional treatment is needed. To help ensure that medication is stopped, a written order to withhold digoxin should be made.
- *Monitor serum potassium.* If the potassium level is low or nearly normal, potassium (IV or PO) should be administered. Potassium displaces digoxin from Na^+, K^+ -ATPase and thereby helps reverse toxicity. However, if potassium levels are high or if AV block is present, no more potassium should be given. Under these conditions, more potassium may cause complete AV block.

- Some patients may require an antidysrhythmic drug. *Phenytoin* and *lidocaine* are most effective. Quinidine, another antidysrhythmic drug, can cause plasma levels of digoxin to rise, and hence should not be used.
- Patients who develop bradycardia or AV block can be treated with atropine. (Atropine blocks the vagal influences that underlie bradycardia and AV block.) Alternatively, electronic pacing may be employed.
- When overdose is especially severe, digoxin levels can be lowered using *Fab antibody fragments* [Digibind]. Following IV administration, these fragments bind digoxin, and thereby prevent it from acting. Treatment is expensive: A full neutralizing dose costs \$2000 to \$3000. *Cholestyramine* and *activated charcoal*, agents that also bind digoxin, can be administered orally to suppress absorption of digoxin from the GI tract.

48.3.1.7 Adverse Effects II: Noncardiac Adverse Effects

The principal noncardiac toxicities of digoxin concern the GI system and the CNS. Since adverse effects on these systems frequently precede development of dysrhythmias, symptoms involving the GI tract and CNS can provide advance warning of more serious toxicity. Accordingly, patients should be taught to recognize these effects and instructed to notify the prescriber if they occur.

Anorexia, *nausea*, and *vomiting* are the most common GI side effects. These responses result primarily from stimulation of the chemoreceptor trigger zone of the medulla. Digoxin rarely causes diarrhea.

Fatigue is the most frequent CNS effect. *Visual disturbances* (eg, blurred vision, yellow tinge to vision, appearance of halos around dark objects) are also relatively common.

48.3.1.8 Adverse Effects III: Measures to Reduce Adverse Effects

Patient education can help reduce the incidence of toxicity. Patients should be warned about digoxin-induced dysrhythmias and instructed to take their medication exactly as prescribed. In addition, they should be informed about symptoms of developing toxicity (altered heart rate or rhythm, visual or GI disturbances) and instructed to notify the prescriber if these develop. If a potassium supplement or potassium-sparing diuretic is part of the regimen, it should be taken exactly as ordered.

48.3.1.9 Drug Interactions

Digoxin is subject to a large number of significant drug interactions. Some are pharmacodynamic and some are pharmacokinetic. Several important interactions are discussed below. A summary of interactions is presented in [Table 47-2](#).

48.3.1.9.1 Diuretics.

Thiazide diuretics and *loop diuretics* promote loss of potassium, and thereby increase the risk of digoxin-induced dysrhythmias. Accordingly, when digoxin and these diuretics are used concurrently, serum potassium levels must be monitored and maintained within a normal range (3.5 to 5 mEq/L). If hypokalemia develops, potassium levels can be restored with potassium supplements, a potassium-sparing diuretic, or both.

48.3.1.9.2 ACE Inhibitors and ARBs.

These drugs can increase potassium levels, and can thereby decrease therapeutic responses to digoxin. Exercise caution if an ACE inhibitor or ARB is combined with potassium supplements or a potassium-sparing diuretic.

TABLE 47-2 Drug Interactions with Digoxin

Drug	Effect
Pharmacodynamic Interactions	
Thiazide diuretics	Promote potassium loss and thereby increase the risk of digoxin-induced dysrhythmias
Loop diuretics	
Beta blockers	Decrease contractility and heart rate
Verapamil	
Diltiazem	
Sympathomimetics	Increase contractility and heart rate
Pharmacokinetic Interactions	
Cholestyramine	Decrease digoxin levels by decreasing digoxin absorption or bioavailability
Kaolin-pectin	
Neomycin	
Sulfasalazine	Increase digoxin levels by increasing digoxin absorption or bioavailability
Aminoglycosides	
Antacids	
Colestipol	
Azithromycin	
Clarithromycin	
Erythromycin	
Omeprazole	
Tetracycline	

Alprazolam	Increase digoxin levels by decreasing excretion of digoxin, altering distribution of digoxin, or both
Amiodarone	
Captopril	
Diltiazem	
Nifedipine	
Nitrendipine	
Propafenone	
Quinidine	
Verapamil	

48.3.1.9.3 Sympathomimetics.

Sympathomimetic drugs (eg, dopamine, dobutamine) act on the heart to increase the rate and force of contraction. The increase in contractile force can add to the positive inotropic effects of digoxin. These complementary actions can be beneficial. In contrast, the ability of sympathomimetics to increase heart rate may be detrimental in that the risk of a tachydysrhythmia is increased.

48.3.1.9.4 Quinidine.

Quinidine is an antidysrhythmic drug that can cause plasma levels of digoxin to rise. Quinidine increases digoxin levels by (1) displacing digoxin from tissue binding sites and (2) reducing the renal excretion of digoxin. By elevating levels of free digoxin, quinidine can promote digoxin toxicity. Accordingly, concurrent use of quinidine and digoxin should be avoided.

48.3.1.9.5 Verapamil.

Verapamil, a calcium channel blocker, can significantly increase plasma levels of digoxin. If the combination is employed, digoxin dosage must be reduced. In addition, verapamil can suppress myocardial contractility, and can thereby counteract the benefits of digoxin.

48.3.1.10 Pharmacokinetics

48.3.1.10.1 Absorption.

Absorption of oral digoxin can be variable. The extent of absorption is lowest and most variable with digoxin *tablets*, ranging between 60% and 80%. Absorption from digoxin capsules [Lanoxicaps]^{*} is more complete and less variable, ranging between 90% and 100%. However, although digoxin capsules permit excellent absorption, they do have one drawback: they are much more expensive than the tablets. Hence, it may be preferable to reserve the capsules for patients in whom stable drug levels cannot be achieved with tablets.

Several factors can decrease digoxin bioavailability. For example, meals high in bran can decrease absorption significantly. Bioavailability can also be decreased by cholestyramine, kaolin-pectin, and certain other drugs (see [Table 47-2](#)). Taking digoxin with meals decreases the rate of absorption but not the extent of absorption.

In the past, there was considerable variability in the absorption of digoxin from tablets prepared by different manufacturers. This variability resulted from differences in the rate and extent of tablet dissolution. Because of this variable bioavailability, it had been recommended that patients not switch between different digoxin brands. Today, bioavailability of digoxin in tablets produced by different companies is fairly uniform, making brands of digoxin more interchangeable than in the past. However, given the narrow therapeutic range of digoxin, some authorities still recommend that patients not switch between brands of digoxin tablets—even when prescriptions are written generically—except with the approval and supervision of the prescriber.

* Digoxin capsules [Lanoxicaps] are available in Canada, but are no longer sold in the United States.

48.3.1.10.2 Distribution.

Digoxin is distributed widely and crosses the placenta. High levels are achieved in cardiac and skeletal muscle, owing largely to binding to Na^+, K^+ -ATPase. About 23% of digoxin in plasma is bound to proteins, mainly albumin.

48.3.1.10.3 Elimination.

Digoxin is eliminated primarily by *renal excretion*. Hepatic metabolism is minimal. Because digoxin is eliminated by the kidneys, renal impairment can lead to toxic accumulation.

Accordingly, dosage must be reduced if kidney function declines. Because digoxin is not metabolized to a significant extent, changes in liver function do not affect digoxin levels.

48.3.1.10.4 Half-Life and Time to Plateau.

The half-life of digoxin is about 1.5 days. Hence, in the absence of a loading dose, about 6 days (four half-lives) are required for plateau levels to be achieved. When use of the drug is discontinued, another 6 days are required for digoxin stores to be eliminated.

48.3.1.10.5 Single-Dose Time Course.

Effects of a single oral dose begin 30 minutes to 2 hours after administration and peak within 4 to 6 hours. Effects of IV digoxin begin rapidly (within 5 to 30 minutes) and peak in 1 to 4 hours.

48.3.1.10.6 A Note on Plasma Digoxin Levels.

Most hospitals are equipped to measure plasma levels of digoxin. The optimal range is 0.5 to 0.8 ng/mL. Levels above 1.0 ng/mL offer no additional benefits, but do increase the risk of toxicity. Knowledge of plasma levels can be useful for

- Establishing dosage
- Monitoring compliance
- Diagnosing toxicity
- Determining the cause of therapeutic failure

Once a stable blood level has been achieved, routine measurement of digoxin levels can be replaced with an annual measurement. Additional measurements may be useful when

- Digoxin dosage is changed
- Symptoms of HF intensify
- Kidney function deteriorates
- Signs of toxicity appear
- Drugs that can affect digoxin levels are added to or deleted from the regimen

Although knowledge of digoxin plasma levels can aid the clinician, it must be understood that the extent of this aid is limited. The correlation between plasma levels of digoxin and clinical

effects—both therapeutic and adverse—is not very tight: Drug levels that are safe and effective for patient A may be subtherapeutic for patient B and toxic for patient C. Because of interpatient variability, knowledge of digoxin levels does not permit precise predictions of therapeutic effects or toxicity. Hence, information regarding drug levels must not be relied on too heavily. Rather, this information should be seen as but one factor among several to be considered when evaluating clinical responses.

48.3.1.11 Preparations, Dosage, and Administration

48.3.1.11.1 Preparations.

Digoxin is available in four formulations:

- Tablets—0.125 and 0.25 mg [Lanoxin]
- Pediatric elixir—0.05 mg/mL [Lanoxin]
- Solution for injection—0.1 and 0.25 mg/mL [Lanoxin]
- Capsules with digoxin in solution—0.05, 0.1, and 0.2 mg [Lanoxicaps]

48.3.1.11.2 Administration.

Digoxin can be administered *orally* and *intravenously*. *Intramuscular* administration should be avoided, owing to a risk of tissue damage and severe pain. Prior to dosing, the rate and regularity of the heartbeat should be determined. If heart rate is less than 60 beats/min or if a change in rhythm is detected, digoxin should be withheld and the prescriber notified. When digoxin is given IV, cardiac status should be monitored continuously for 1 to 2 hours.

48.3.1.11.3 Dosage in Heart Failure.

Most patients can be treated with initial and maintenance dosages of 0.125 mg/day. Doses above 0.25 mg/day are rarely used or needed. The target plasma drug level is 0.5 to 0.8 ng/mL.

48.3.1.11.4 Digitalization.

The term *digitalization* refers to the use of a loading dose to achieve high plasma levels of digoxin quickly. (As noted, 6 days are needed for drug levels to reach plateau if no loading dose is employed.) Although digitalization was common in the past, the practice is now considered both unnecessary and inappropriate.

48.3.2 Digitoxin

Digitoxin, no longer available in the United States, is similar to digoxin in most respects. The drugs have the same mechanism of action (inhibition of Na^+, K^+ -ATPase), the same clinical applications (treatment of HF and dysrhythmias), and the same major toxicities (dysrhythmias). The principal differences between them are pharmacokinetic: Absorption of digitoxin is complete, whereas absorption of digoxin is both incomplete and variable; digitoxin is eliminated by the liver, whereas digoxin is eliminated by the kidneys; and digitoxin has a longer half-life (7 days vs. 1.6 days). Because digitoxin has a prolonged half-life, management of toxicity is much harder than with digoxin. For more information on digitoxin, refer to the fourth edition of this book.

48.4 MANAGEMENT OF HEART FAILURE

Our discussion of HF management is based on recommendations in the *ACC/AHA 2005 Guideline Update for the Evaluation and Management of Chronic Heart Failure in the Adult* and on an update—*Focused Update: ACCF/AHA Guidelines for the Diagnosis and Management of Heart Failure in Adults*—issued in 2009. As noted earlier, these guidelines approach HF as a progressive disease that advances through four stages of increasing severity. Management for each stage is discussed below.

527

These management measures are consistent with those in another guideline—*HFSA 2006 Comprehensive Heart Failure Practice Guideline*—issued by the Heart Failure Society of America. (In addition to discussing heart failure with LV systolic dysfunction [ie, the form of heart failure that we've been discussing], the HFSA guidelines address other issues, including acutely decompensated heart failure, heart failure with preserved LV ejection fraction [diastolic heart failure], and heart failure in special populations.)

528

48.4.1 Stage A

By definition, patients in ACC/AHA Stage A have no symptoms of HF and no structural or functional cardiac abnormalities—but they do have behaviors or conditions strongly associated with developing HF. Important among these are hypertension, coronary artery disease, diabetes, family history of cardiomyopathy, and a personal history of alcohol abuse, rheumatic fever, or treatment with a cardiotoxic drug (eg, doxorubicin, trastuzumab).

Management is directed at reducing risk. Hypertension, hyperlipidemia, and diabetes should be controlled, as should ventricular rate in patients with supraventricular tachycardias. An ACE inhibitor or ARB can be useful for patients with diabetes, atherosclerosis, or hypertension. Patients should cease behaviors that increase HF risk, especially smoking and alcohol abuse. (Excessive, chronic consumption of alcohol is a leading cause of cardiomyopathy. In patients with

HF, acute alcohol consumption can suppress contractility.) There is no evidence that getting regular exercise can prevent development of HF, although exercise does have other health benefits. Routine use of dietary supplements to prevent structural heart disease is not recommended.

48.4.2 Stage B

Like patients in Stage A, those in Stage B have no signs or symptoms of HF, but they do have structural heart disease that is strongly associated with development of HF. Among these structural changes are LV hypertrophy or fibrosis, LV dilation or hypocontractility, valvular heart disease, and previous myocardial infarction.

The goal of management is to prevent development of symptomatic HF. The approach is to implement measures that can prevent further cardiac injury and thereby retard the progression of remodeling and LV dysfunction. Specific measures include all those discussed above for Stage A. In addition, treatment with an ACE inhibitor plus a beta blocker is recommended for all patients with a reduced ejection fraction, history of myocardial infarction, or both. For patients who cannot tolerate ACE inhibitors, an ARB may be used instead. As in Stage A, there is no evidence that using dietary supplements or getting regular exercise can help prevent progression to symptomatic HF.

48.4.3 Stage C

Patients in Stage C have symptoms of HF and also have structural heart disease. As discussed earlier, symptoms include dyspnea, fatigue, peripheral edema, and distention of the jugular veins. Treatment has four major goals: (1) relief of pulmonary and peripheral congestive symptoms, (2) improvement of functional capacity and quality of life, (3) slowing of cardiac remodeling and progression of LV dysfunction, and (4) prolongation of life. Treatment measures include those recommended for Stages A and B, plus those discussed below.

48.4.3.1 Drug Therapy

Drug therapy of HF has changed dramatically over the past 15 years. Formerly, cardiac glycosides—usually digoxin—were the mainstay of treatment. Today, their role is secondary. First-line therapy now consists of three drugs: a diuretic, an ACE inhibitor or ARB, and a beta blocker. As a rule, digoxin is added only when symptoms cannot be managed with the preferred agents.

48.4.3.1.1 Diuretics.

All patients with evidence of fluid retention should restrict salt intake and use a diuretic. Diuretics are the only reliable means of correcting fluid overload. Furthermore, these drugs produce symptomatic improvement faster than any other agents. If renal function is good, a thiazide diuretic will work. However, if renal function is significantly impaired, as it is in most patients, a loop diuretic will be needed. Efficacy of diuresis is best assessed by daily measurement of body weight. Once fluid overload has been corrected, diuretic therapy should continue to prevent recurrence. Diuretics should not be used alone. Rather, for most patients, they should be combined with an ACE inhibitor (or ARB) plus a beta blocker. Since aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) can decrease the effects of diuretics, these agents should be avoided. As noted, although diuretics reduce symptoms, they do not prolong survival.

48.4.3.1.2 ACE Inhibitors and ARBs.

In the absence of specific contraindications (eg, pregnancy), all patients with Stage C HF should receive an ACE inhibitor. If fluid retention is evident, a diuretic should be used as well. Symptomatic improvement may take weeks or even months to develop. However, even in the absence of symptomatic improvement, ACE inhibitors may prolong life. Dosage should be sufficient to reduce mortality (see [Table 47-1](#)).

For patients who cannot tolerate ACE inhibitors (owing to intractable cough or angioedema), ARBs are considered a reasonable alternative. However, it is important to note that clinical experience with ARBs is much less than with ACE inhibitors, and that ACE inhibitors have a more favorable effect on cardiac remodeling.

48.4.3.1.3 Aldosterone Antagonists.

Adding an aldosterone antagonist (spironolactone or eplerenone) to standard therapy (ie, diuretic, ACE inhibitor or ARB, and a beta blocker) is reasonable in patients with moderately severe or severe symptoms of HF following a heart attack. However, aldosterone antagonists must not be used if kidney function is impaired or serum potassium is elevated. Monitoring renal function and potassium levels is imperative.

48.4.3.1.4 Beta Blockers.

In the absence of specific contraindications, all patients with Stage C HF should receive an approved beta blocker (eg, carvedilol). As with ACE inhibitors, symptomatic improvement

may not be evident for months. Nonetheless, life may be prolonged even in the absence of clinical improvement.

48.4.3.1.5 Digoxin.

Digoxin may be used in combination with ACE inhibitors (or ARBs), diuretics, and beta blockers to improve clinical status. However, although digoxin can reduce symptoms, it does not prolong life. The usual dosage is 0.125 mg/day. Adjustments are based on clinical response. Digoxin may be started early to help improve symptoms, or it may be reserved for patients who have not responded adequately to a diuretic, ACE inhibitor or ARB, and beta blocker.

48.4.3.1.6 Isosorbide Dinitrate/Hydralazine.

Adding ISDN/hydralazine is *recommended* to improve outcomes in self-described African Americans who have moderate to severe symptoms despite optimal therapy with ACE inhibitors, beta blockers, and diuretics. For all other patients who continue to have symptoms despite treatment with standard therapy, adding ISDN/hydralazine to the regimen is considered *reasonable*. For patients who cannot tolerate ACE inhibitors or ARBs, *substitution* of ISDN/hydralazine is considered reasonable.

48.4.3.2 Drugs to Avoid

Patients in Stage C should avoid three classes of drugs: antidysrhythmics, calcium channel blockers, and NSAIDs (eg, aspirin). Reasons for not using these drugs are:

- *Antidysrhythmic agents*—These drugs have cardiosuppressant and prodysrhythmic actions that can make HF worse. Only two agents—amiodarone [Cordarone] and dofetilide [Tikosyn]—have been proven not to reduce survival.
- *Calcium channel blockers*—These drugs can make HF worse and may increase the risk of adverse cardiovascular events. Only the vasoselective CCBs have been shown not to reduce survival.
- *NSAIDs*—These drugs promote sodium retention and peripheral vasoconstriction. Both actions can make HF worse. In addition, NSAIDs can reduce the efficacy and intensify the toxicity of diuretics and ACE inhibitors. Hence, even though aspirin has beneficial effects on coagulation, it should still be avoided.

48.4.3.3 Device Therapy

48.4.3.3.1 Implanted Cardioverter-Defibrillators.

Cardiac arrest and fatal ventricular dysrhythmias are relatively common complications of HF. Accordingly, implantable cardioverter-defibrillators are now recommended for primary or secondary prevention to reduce mortality in selected patients.

48.4.3.3.2 Cardiac Resynchronization.

When the left and right ventricles fail to contract at the same time, cardiac output is further compromised. Synchronized contractions can be restored with a biventricular pacemaker. In clinical trials, cardiac resynchronization improved exercise tolerance and quality of life and reduced all-cause mortality.

48.4.3.4 Exercise Training

In the past, bed rest was recommended owing to concern that physical activity might accelerate progression of LV dysfunction. However, we now know that inactivity is actually detrimental: it reduces conditioning, worsens exercise intolerance, and contributes to HF symptoms. Conversely, studies have shown that exercise training can improve clinical status, increase exercise capacity, and improve quality of life. Accordingly, exercise training should be considered for all stable patients.

48.4.3.5 Evaluating Treatment

Evaluation is based on symptoms and physical findings. Reductions in dyspnea on exertion, paroxysmal nocturnal dyspnea, and orthopnea (difficulty breathing, except in the upright position) indicate success. The physical examination should assess for reductions in jugular distention, edema, and rales. Success is also indicated by increased capacity for physical activity. Accordingly, patients should be interviewed to determine improvements in the maximal activity they can perform without symptoms, the type of activity that regularly produces symptoms, and the maximal activity they can tolerate. (Activity is defined as walking, stair climbing, activities of daily living, or any other activity that is appropriate.) Successful treatment should also improve health-related quality of life in general. Hence the interview should look for improvements in sleep, sexual function, outlook on life, cognitive function (alertness, memory, concentration), and ability to participate in usual social, recreational, and work activities.

Routine measurement of ejection fraction or maximal exercise capacity is not recommended. Although the degree of reduction in ejection fraction measured at the beginning of therapy is predictive of outcome, improvement in the ejection fraction does not necessarily indicate the prognosis has changed.

48.4.4 Stage D

Patients in Stage D have advanced structural heart disease and marked symptoms of HF at rest, despite treatment with maximal dosages of medications used in Stage C. Repeated and prolonged hospitalization is common. For eligible candidates, the best long-term solution is a heart transplant. An implantable LV mechanical assist device can be used as a “bridge” in patients awaiting a transplant and to prolong life in those who are not transplant eligible.

Management focuses largely on control of fluid retention, which underlies most signs and symptoms. Intake and output should be monitored closely, and the patient should be weighed daily. Fluid retention can usually be treated with a loop diuretic, perhaps combined with a thiazide diuretic. If volume overload becomes severe, the patient should be hospitalized and given an IV diuretic. If needed, IV dopamine or dobutamine can be added to increase renal blood flow, thereby enhancing diuresis. Patients should not be discharged until a stable and effective oral diuretic regimen has been established.

What about beta blockers and ACE inhibitors? These agents may be tried, but doses should be low and responses monitored with care. Why? Because, in Stage D, beta blockers pose a significant risk of making HF worse, and ACE inhibitors may induce profound hypotension or renal failure.

When severe symptoms persist despite application of all recommended therapies, options for end-of-life care should be discussed with the patient and family.

529

530

48.4.4.1

KEY POINTS

- Heart failure with LV systolic dysfunction, referred to simply as *heart failure* (HF) in this chapter, is characterized by ventricular dysfunction, reduced cardiac output, signs of inadequate tissue perfusion (fatigue, shortness of breath, exercise intolerance), and signs of fluid overload (venous distention, peripheral edema, pulmonary edema).
- The initial phase of HF consists of cardiac remodeling—a process in which the ventricles dilate (grow larger), hypertrophy (increase in wall thickness), and become more spherical—coupled with cardiac fibrosis and myocyte death. As a result of these changes, cardiac output is reduced.

- Reduced cardiac output leads to compensatory responses: (1) activation of the SNS, (2) activation of the RAAS, and (3) retention of water and expansion of blood volume. As a result of volume expansion, cardiac dilation increases.
- If the compensatory responses are not sufficient to maintain adequate production of urine, body water will continue to accumulate, eventually causing death (from complete cardiac failure secondary to excessive cardiac dilation and cardiac edema).
- There are three major groups of drugs for heart failure: diuretics, ACE inhibitors or ARBs, and beta blockers. Cardiac glycosides (eg, digoxin), which had been used widely in the past, may be added as indicated.
- Diuretics are first-line drugs for all patients with fluid overload. By reducing blood volume, these drugs can decrease venous pressure, arterial pressure, pulmonary edema, peripheral edema, and cardiac dilation.
- Although diuretics can reduce symptoms of HF, they do not prolong survival.
- Thiazide diuretics are ineffective when GFR is low, and hence cannot be used if cardiac output is greatly reduced.
- Loop diuretics are effective even when GFR is low, and hence are preferred to thiazides for most patients.
- Thiazide diuretics and loop diuretics can cause hypokalemia, and can thereby increase the risk of digoxin-induced dysrhythmias.
- Potassium-sparing diuretics are used to counteract potassium loss caused by thiazide diuretics and loop diuretics.
- Potassium-sparing diuretics can cause hyperkalemia. By doing so, they can increase the risk of hyperkalemia in patients taking ACE inhibitors or ARBs.
- In patients with HF, ACE inhibitors improve functional status and reduce mortality. In the absence of specific contraindications, all patients should get one.
- ACE inhibitors block formation of angiotensin II, promote accumulation of kinins, and reduce aldosterone release. As a result, these drugs cause dilation of veins and arterioles, promote renal excretion of water, and favorably alter cardiac remodeling.

- By dilating arterioles, ACE inhibitors (1) improve regional blood flow in the kidneys and other tissues and (2) reduce cardiac afterload, which causes stroke volume and cardiac output to rise.
- By dilating veins, ACE inhibitors reduce venous pressure, which in turn reduces pulmonary congestion, peripheral edema, preload, and cardiac dilation.
- By suppressing aldosterone release, ACE inhibitors increase excretion of sodium and water, and decrease excretion of potassium.
- By increasing levels of kinins (and partly by decreasing levels of angiotensin II), ACE inhibitors can favorably alter cardiac remodeling.
- Side effects of ACE inhibitors include hypotension, hyperkalemia, cough, angioedema, and birth defects.
- ARBs share the beneficial hemodynamic effects of ACE inhibitors, but not the beneficial effects on cardiac remodeling.
- In patients with HF, ARBs should be reserved for patients intolerant of ACE inhibitors (usually owing to cough).
- In patients with HF, aldosterone antagonists (eg, spironolactone, eplerenone) reduce symptoms and prolong life. Benefits derive from blocking aldosterone receptors in the heart and blood vessels.
- Isosorbide dinitrate (which dilates veins) plus hydralazine (which dilates arterioles) can be used in place of an ACE inhibitor (or ARB) if an ACE inhibitor (or ARB) cannot be used.
- BiDil, a fixed-dose combination of hydralazine and isosorbide dinitrate, is approved specifically for treating HF in blacks.
- Beta blockers can prolong survival in patients with HF, and hence are considered first-line therapy.
- To avoid excessive cardiosuppression, beta blocker dosage must be very low initially and then gradually increased.
- Cardiac glycosides and other inotropic agents increase the force of myocardial contraction, and thereby increase cardiac output.

- Of the available inotropic agents, digoxin is the only one that is both effective and safe when used *orally*, and hence the only one suitable for long-term use.
- Digoxin increases contractility by inhibiting myocardial Na^+, K^+ -ATPase, thereby (indirectly) increasing intracellular calcium, which in turn facilitates the interaction of actin and myosin.
- Potassium competes with digoxin for binding to Na^+, K^+ -ATPase. Hence, if potassium levels are low, excessive inhibition of Na^+, K^+ -ATPase can occur, resulting in toxicity. Conversely, if potassium levels are high, insufficient inhibition can occur, resulting in loss of therapeutic effects. Accordingly, it is imperative to keep potassium levels in the normal physiologic range: 3.5 to 5 mEq/L.
- By increasing cardiac output, digoxin can reverse all of the overt manifestations of HF: cardiac output improves, heart rate decreases, heart size declines, constriction of arterioles and veins decreases, water retention reverses, blood volume declines, peripheral and pulmonary edema decrease, weight is lost (owing to water loss), and exercise tolerance improves. Unfortunately, although digoxin can improve symptoms, it does not prolong life.
- In patients with HF, benefits of digoxin are not due solely to improved cardiac output: Neurohormonal effects are important too.
- Digoxin causes dysrhythmias by altering the electrical properties of the heart (secondary to inhibition of Na^+, K^+ -ATPase).

530

- The most common reason for digoxin-related dysrhythmias is diuretic-induced hypokalemia.
- If a severe digoxin overdose is responsible for dysrhythmias, digoxin levels can be lowered using Fab antibody fragments [Digibind].
- In addition to dysrhythmias, digoxin can cause GI effects (anorexia, nausea, vomiting) and CNS effects (fatigue, visual disturbances). Gastrointestinal and CNS effects often precede dysrhythmias, and therefore can provide advance warning of serious toxicity.
- Digoxin has a narrow therapeutic range.
- Digoxin is eliminated by renal excretion.

531

- Although routine monitoring of digoxin levels is generally unnecessary, monitoring can be helpful when dosage is changed, symptoms of HF intensify, kidney function declines, signs of toxicity appear, or drugs that affect digoxin levels are added to or deleted from the regimen.
- Maintenance doses of digoxin are based primarily on observation of the patient: Doses should be large enough to minimize symptoms of HF but not so large as to cause adverse effects.
- Maintenance doses of digoxin must be reduced if renal function declines.
- Therapy of Stage C HF has four major goals: (1) relief of pulmonary and peripheral congestion, (2) improvement of functional status and quality of life, (3) retarding progression of cardiac remodeling and LV dysfunction, and (4) prolongation of life.
- For routine therapy, Stage C HF is treated with a diuretic, an ACE inhibitor or ARB, and a beta blocker

48.4.4.2

Summary of Major Nursing Implications^{*}

48.4.4.2.1

DIGOXIN

48.4.4.2...

Preadministration Assessment

48.4.4.2...

Therapeutic Goal

Digoxin is used to treat HF and dysrhythmias. Be sure to confirm which disorder the drug has been ordered for.

48.4.4.2...

Baseline Data

Assess for signs and symptoms of HF, including fatigue, weakness, cough, breathing difficulty (orthopnea, dyspnea on exertion, paroxysmal nocturnal dyspnea), jugular distention, and edema.

Determine baseline values for maximal activity without symptoms, activity that regularly causes symptoms, and maximal tolerated activity.

Laboratory tests should include an ECG, serum electrolytes, measurement of ejection fraction, and evaluation of kidney function.

48.4.4.2...

Identifying High-Risk Patients

Digoxin is *contraindicated* for patients experiencing ventricular fibrillation, ventricular tachycardia, or digoxin toxicity.

Exercise *caution* in the presence of conditions that can predispose the patient to serious adverse responses to digoxin, such as hypokalemia, partial AV block, advanced HF, or renal impairment.

48.4.4.2...

Implementation: Administration

48.4.4.2...

Routes

Oral, slow IV injection.

48.4.4.2...

Administration

48.4.4.2...

Oral.

Determine heart rate and rhythm prior to administration. If heart rate is less than 60 beats/min or if a change in rhythm is detected, withhold digoxin and notify the prescriber.

Warn patients not to “double up” on doses in attempts to compensate for missed doses.

48.4.4.2...

Intravenous.

Monitor cardiac status closely for 1 to 2 hours following IV injection.

48.4.4.2...

Promoting Adherence

Because digoxin has a narrow therapeutic range, rigid adherence to the prescribed dosage is essential. **Inform patients that failure to take digoxin exactly as prescribed may lead to toxicity or therapeutic failure.** If poor adherence is suspected, serum drug levels may help in assessing the extent of nonadherence.

48.4.4.2...

Implementation: Measures to Enhance Therapeutic Effects

Advise patients to limit salt intake to 2 gm/day, and to avoid excessive fluids.

Advise patients who drink alcohol to consume no more than one drink each day.

Advise obese patients to adopt a reduced-calorie diet. Help patients establish an

48.4.4.2...	<p>appropriate program of regular, mild exercise (eg, walking, cycling). Precipitating factors for HF (eg, hypertension, valvular heart disease) should be corrected.</p>	531
48.4.4.2...	<h2>Ongoing Evaluation and Interventions</h2>	
48.4.4.2...	<h3>Evaluating Therapeutic Effects</h3>	
	<p>Evaluation is based on symptoms and physical findings. Assess for reductions in orthopnea, dyspnea on exertion, paroxysmal nocturnal dyspnea, neck vein distention, edema, and rales, and for increased capacity for physical activity. In addition, assess for improvements in sleep, sexual function, outlook on life, cognitive function, and ability to participate in social, recreational, and work activities.</p>	
48.4.4.2...	<p>Measurement of plasma drug levels can help determine the cause of therapeutic failure. The optimal range for digoxin is 0.5 to 0.8 ng/mL.</p>	532
48.4.4.2...	<h3>Minimizing Adverse Effects</h3>	
48.4.4.2...	<h4>Cardiotoxicity.</h4>	
	<p>Dysrhythmias are the most serious adverse effect of digoxin.</p>	
	<p>Monitor hospitalized patients for alterations in heart rate or rhythm, and withhold digoxin if significant changes develop.</p>	
	<p>Inform outpatients about the danger of dysrhythmias. Teach them to monitor their pulses for rate and rhythm, and instruct them to notify the prescriber if significant changes occur. Provide the patient with an ECG rhythm strip; this can be used by providers unfamiliar with the patient (eg, when the patient is traveling) to verify suspected changes in rhythm.</p>	
	<p>Hypokalemia, usually diuretic induced, is the most frequent underlying cause of dysrhythmias. Monitor serum potassium concentrations. If hypokalemia develops, potassium levels can be raised with potassium supplements, a potassium-sparing diuretic, or both. Teach patients to recognize early signs of hypokalemia (eg, muscle weakness), and instruct them to notify the prescriber if these develop. Severe vomiting and diarrhea can increase potassium loss; exercise caution if these events occur.</p>	
	<p>To treat digoxin-induced dysrhythmias: (1) withdraw digoxin and diuretics (make sure that a written order for digoxin withdrawal is made); (2) administer potassium</p>	

(unless potassium levels are above normal or AV block is present); (3) administer an antidysrhythmic drug (phenytoin or lidocaine, but not quinidine) if indicated; (4) manage bradycardia with atropine or electrical pacing; and (5) treat with Fab fragments if toxicity is life threatening.

48.4.4.2...

Noncardiac Effects.

Nausea, vomiting, anorexia, fatigue, and visual disturbances (blurred or yellow vision) frequently foreshadow more serious toxicity (dysrhythmias) and should be reported immediately. **Inform patients about these early indications of toxicity, and instruct them to notify the prescriber if they develop.**

48.4.4.2...

Minimizing Adverse Interactions

48.4.4.2...

Diuretics.

Thiazide diuretics and *loop diuretics* increase the risk of dysrhythmias by promoting potassium loss. Monitor potassium levels. If hypokalemia develops, it should be corrected with potassium supplements, a potassiumsparing diuretic, or both.

48.4.4.2...

ACE Inhibitors and ARBs.

These drugs can elevate potassium levels, and can thereby decrease therapeutic responses to digoxin. Exercise caution if an ACE inhibitor or ARB is combined with potassium supplements or a potassium-sparing diuretic.

48.4.4.2...

Sympathomimetic Agents.

Sympathomimetic drugs (eg, dopamine, dobutamine) stimulate the heart, thereby increasing the risk of tachydysrhythmias and ectopic pacemaker activity. When sympathomimetics are combined with digoxin, monitor closely for dysrhythmias.

48.4.4.2...

Quinidine.

Quinidine can elevate plasma levels of digoxin. If quinidine is employed concurrently with digoxin, digoxin dosage must be reduced. Do not use quinidine to treat digoxin-induced dysrhythmias.

* Patient education information is highlighted as **blue text**.

⁴⁹CHAPTER 48 Antidysrhythmic Drugs

A dysrhythmia is defined as *an abnormality in the rhythm of the heartbeat*. In their mildest forms, dysrhythmias have only modest effects on cardiac output. However, in their most severe forms, dysrhythmias can so disable the heart that no blood is pumped at all. Because of their ability to compromise cardiac function, dysrhythmias are associated with a high degree of morbidity and mortality.

There are two basic types of dysrhythmias: *tachydysrhythmias* (dysrhythmias in which heart rate is increased) and *bradydysrhythmias* (dysrhythmias in which heart rate is slowed). In this chapter, we only consider the tachydysrhythmias. This is by far the largest group of dysrhythmias and the group that responds best to drugs. We do not discuss the bradydysrhythmias because they are few in number and are commonly treated with electronic pacing. When drugs are indicated, atropine (see [Chapter 14](#)) and isoproterenol (see [Chapter 17](#)) are usually the agents of choice.

It is important to appreciate that virtually all of the drugs used to treat dysrhythmias can also *cause* dysrhythmias. These drugs can create new dysrhythmias and worsen existing ones. Because of these prodysrhythmic actions, antidysrhythmic drugs should be employed only when the benefits of treatment clearly outweigh the risks.

For two reasons, use of antidysrhythmic drugs is declining. First, research has shown that some of these agents actually *increase* the risk of death. Second, nonpharmacologic therapies—especially implantable defibrillators and radiofrequency ablation—have begun to replace drugs as the preferred treatment for many dysrhythmia types.

A note on terminology: Dysrhythmias are also known as *arrhythmias*. Since the term *arrhythmia* denotes an *absence* of cardiac rhythm, whereas *dysrhythmia* denotes an *abnormal* rhythm, dysrhythmia would seem the more appropriate term.

^{49.1} INTRODUCTION TO CARDIAC ELECTROPHYSIOLOGY, DYSRHYTHMIAS, AND THE ANTIDYSRHYTHMIC DRUGS

In this section we discuss background information that will help you understand the actions and uses of antidysrhythmic drugs. We begin by reviewing the electrical properties of the heart and the electrocardiogram. Next, we discuss how dysrhythmias are generated. After that, we discuss classification of the antidysrhythmic drugs as well as the ability of these drugs to *cause* dysrhythmias themselves. We conclude by discussing the major dysrhythmias and the basic principles that guide antidysrhythmic therapy.

49.2 ELECTRICAL PROPERTIES OF THE HEART

Dysrhythmias result from alteration of the electrical impulses that regulate cardiac rhythm—and antidysrhythmic drugs control rhythm by correcting or compensating for these alterations.

Accordingly, in order to understand both the generation and treatment of dysrhythmias, we must

first understand the electrical properties of the heart. Therefore, we begin the chapter by reviewing (1) pathways and timing of impulse conduction, (2) cardiac action potentials, and (3) basic elements of the electrocardiogram (ECG).

533

534

49.2.1 Impulse Conduction: Pathways and Timing

For the heart to pump effectively, contraction of the atria and ventricles must be coordinated. Coordination is achieved through precise timing and routing of impulse conduction. In the healthy heart, impulses originate in the sinoatrial (SA) node, spread rapidly through the atria, pass slowly through the atrioventricular (AV) node, and then spread rapidly through the ventricles via the His-Purkinje system ([Fig. 48-1](#)).

49.2.1.1 SA Node.

Under normal circumstances, the SA node serves as the pacemaker for the heart. Pacemaker activity results from spontaneous phase 4 depolarization (see below). Because cells of the sinus node usually discharge faster than other cells that display automaticity, the SA node normally dominates all other potential pacemakers.

After the SA node discharges, impulses spread rapidly through the atria along the *internodal pathways*. This rapid conduction allows the atria to contract in unison.

49.2.1.2 AV Node.

Impulses originating in the atria must travel through the AV node to reach the ventricles. In the healthy heart, impulses arriving at the AV node are delayed before going on to excite the ventricles. This delay provides time for blood to fill the ventricles prior to ventricular contraction.

49.2.1.3 His-Purkinje System.

The fibers of the His-Purkinje system consist of specialized conducting tissue. The function of these fibers is to conduct electrical excitation very rapidly to all parts of the ventricles. Stimulation of the His-Purkinje system is caused by impulses leaving the AV node. These impulses are conducted rapidly down the bundle of His, enter the right and left bundle branches,

and then distribute to the many fine branches of the Purkinje fibers (see [Fig. 48-1](#)). Because impulses travel quickly through this system, all regions of the ventricles are stimulated almost simultaneously, producing synchronized ventricular contraction with resultant forceful ejection of blood.

49.2.2 Cardiac Action Potentials

Cardiac cells can initiate and conduct action potentials, consisting of self-propagating waves of depolarization followed by repolarization. As in neurons, cardiac action potentials are generated by the movement of ions into and out of cells. These ion fluxes take place by way of specific channels in the cell membrane. In the resting cardiac cell, negatively charged ions cover the inner surface of the cell membrane while positively charged ions cover the external surface. Because of this separation of charge, the cell membrane is said to be *polarized*. Under proper conditions, channels in the cell membrane open, allowing positively charged ions to rush in. This influx eliminates the charge difference across the cell membrane, and hence the cell is said to depolarize. Following depolarization, positively charged ions are extruded from the cell, causing the cell to return to its original polarized state.

In the heart, two kinds of action potentials occur: *fast potentials* and *slow potentials*. These potentials differ with respect to the mechanisms by which they are generated, the

Figure 48-1 Cardiac conduction pathways.

kinds of cells in which they occur, and the drugs to which they respond.

Profiles of fast and slow potentials are depicted in [Figure 48-2](#). Please note that action potentials in this figure represent the electrical activity of *single cardiac cells*. Such single-cell recordings, which are made using experimental preparations, should not be confused with the ECG, which is made using surface electrodes, and hence reflects the electrical activity of the entire heart.

49.2.2.1 Fast Potentials

Fast potentials occur in fibers of the *His-Purkinje system* and in *atrial and ventricular muscle*. These responses serve to conduct electrical impulses rapidly throughout the heart.

As indicated in panel A of [Figure 48-2](#), fast potentials have five distinct phases, labeled 0, 1, 2, 3, and 4. As we discuss each phase, we will focus on its ionic basis and its relationship to the actions of antidysrhythmic drugs.

49.2.2.1.1 Phase 0.

In phase 0, the cell undergoes *rapid depolarization* in response to *influx of sodium ions*. Phase 0 is important in that the speed of phase 0 depolarization determines the velocity of impulse conduction. Drugs that decrease the rate of phase 0 depolarization (by blocking sodium channels) slow impulse conduction through the His-Purkinje system and myocardium.

49.2.2.1.2 Phase 1.

During phase 1, rapid (but partial) repolarization takes place. Phase 1 has no relevance to antidysrhythmic drugs.

49.2.2.1.3 Phase 2.

Phase 2 consists of a prolonged plateau in which the membrane potential remains relatively stable. During this phase, *calcium* enters the cell and promotes contraction of atrial and ventricular muscle. Drugs that reduce calcium entry during phase 2 do *not* influence *cardiac rhythm*. However, since calcium influx is required for contraction, these drugs *can* reduce myocardial contractility.

49.2.2.1.4 Phase 3.

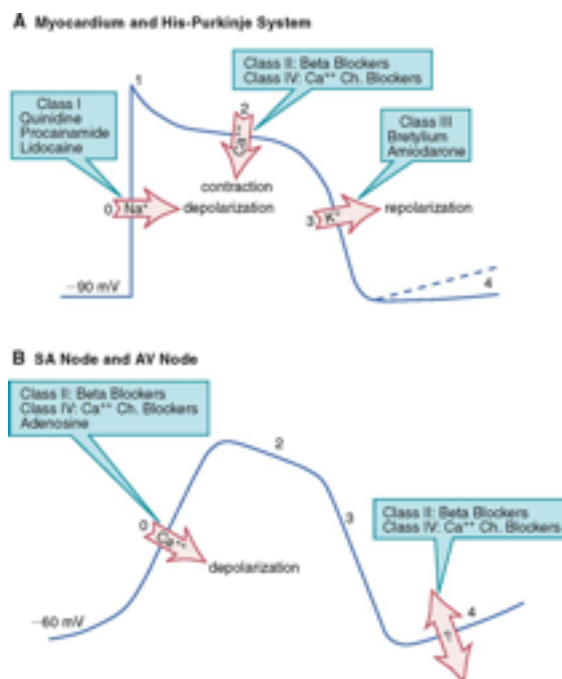

In phase 3, rapid repolarization takes place. This repolarization is caused by *extrusion of potassium* from the cell. Phase 3 is relevant in that delay of repolarization prolongs the action potential duration, and thereby prolongs the effective refractory period (ERP). (The ERP is the time during which a cell is unable to respond to excitation and initiate a new action

potential. Hence, extending the ERP prolongs the minimum interval between two propagating responses.) Phase 3 repolarization can be delayed by drugs that block potassium channels.

534

535

Figure 48-2 Ion fluxes during cardiac action potentials and effects of antidysrhythmic drugs. **A**, Fast potential of the His-Purkinje system and atrial and ventricular myocardium. Blockade of sodium influx by class I drugs slows conduction in the His-Purkinje system. Blockade of calcium influx by beta blockers and calcium channel blockers decreases contractility. Blockade of potassium efflux by class III drugs delays repolarization and thereby prolongs the effective refractory period. **B**, Slow potential of the sinoatrial (SA) node and atrioventricular (AV) node. Blockade of calcium influx by beta blockers, calcium channel blockers, and adenosine slows AV conduction. Beta blockers and calcium channel blockers decrease SA nodal automaticity (phase 4 depolarization); the ionic basis of this effect is not understood.

49.2.2.1.5 Phase 4.

During phase 4, two types of electrical activity are possible: (1) the membrane potential may remain *stable* (solid line in [Fig. 48-2A](#)), or (2) the membrane may undergo *spontaneous depolarization* (dotted line). In cells undergoing spontaneous depolarization, the membrane potential gradually rises until a threshold potential is reached. At this point, rapid phase 0 depolarization takes place, setting off a new action potential. Hence, it is phase 4 depolarization that gives cardiac cells *automaticity* (ie, the ability to initiate an action potential through self-excitation). The capacity for self-excitation makes potential pacemakers of all cells that have it.

Under normal conditions, His-Purkinje cells undergo very slow spontaneous depolarization, and myocardial cells do not undergo any. However, under pathologic conditions, significant phase 4 depolarization may occur in all of these cells, and especially in Purkinje fibers. When this happens, a dysrhythmia can result.

49.2.2.2 Slow Potentials

Slow potentials occur in cells of the *SA node* and *AV node*. The profile of a slow potential is depicted in [Figure 48-2B](#). Like fast potentials, slow potentials are generated by ion fluxes. However, the specific ions involved are not the same for every phase.

From a physiologic and pharmacologic perspective, slow potentials have three features of special significance: (1) phase 0 depolarization is slow and mediated by calcium influx, (2) these potentials conduct slowly, and (3) spontaneous phase 4 depolarization in the SA node normally determines heart rate.

49.2.2.2.1 Phase 0.

Phase 0 (depolarization phase) of slow potentials differs significantly from phase 0 of fast potentials. As we can see from [Figure 48-2](#), whereas phase 0 of fast potentials is caused by a *rapid influx of sodium*, phase 0 of slow potentials is caused by slow *influx of calcium*. Because calcium influx is slow, the rate of depolarization is slow; and

535

Figure 48-3 The electrocardiogram.

because depolarization is slow, these potentials conduct slowly. This explains why impulse conduction through the AV node is delayed. Phase 0 of the slow potential is of therapeutic significance in that drugs that suppress calcium influx during phase 0 can slow (or stop) AV conduction.

49.2.2.2.2 Phases 1, 2, and 3.

Slow potentials lack a phase 1 (see [Fig. 48-2B](#)). Phases 2 and 3 of the slow potential are not significant with respect to the actions of antidysrhythmic drugs.

49.2.2.2.3 Phase 4.

Cells of the SA node and AV node undergo spontaneous phase 4 depolarization. The ionic basis of this phenomenon is complex and incompletely understood.

Under normal conditions, the rate of phase 4 depolarization in cells of the SA node is faster than in all other cells of the heart. As a result, the SA node discharges first and determines heart rate. Hence, the SA node is referred to as the cardiac *pacemaker*.

As indicated in [Figure 48-2B](#), two classes of drugs (beta blockers and calcium channel blockers) can suppress phase 4 depolarization. By doing so, these agents can decrease automaticity in the SA node.

49.2.3 The Electrocardiogram

The ECG provides a graphic representation of cardiac electrical activity. The ECG can be used to identify dysrhythmias and monitor responses to therapy. (*Note:* In referring to the electrocardiogram, two abbreviations may be used: EKG and ECG. Some people prefer EKG over ECG. Why? Because ECG sounds much like EEG [electroencephalogram] when spoken aloud.)

The major components of an ECG are illustrated in [Figure 48-3](#). As we can see, three features are especially prominent: the P wave, the QRS complex, and the T wave. The P wave is caused by *depolarization in the atria*. Hence, the P wave corresponds to atrial contraction. The QRS complex is caused by *depolarization of the ventricles*. Hence, the QRS complex corresponds to ventricular contraction. If conduction through the ventricles is slowed, the QRS complex will widen. The T wave is caused by *repolarization of the ventricles*. Hence, this wave is not associated with overt physical activity of the heart.

In addition to the features just described, the ECG has three other components of interest: the PR interval, the QT interval, and the ST segment. The PR interval is defined as the time between the onset of the P wave and the onset of the QRS complex. Lengthening of this interval indicates a delay in conduction through the AV node. Several drugs increase the PR interval. The QT interval is defined as the time between the onset of the QRS complex and completion of the T wave. This interval is prolonged by drugs that delay ventricular repolarization. The ST segment is the portion of the ECG that lies between the end of the QRS complex and the beginning of the T wave. Digoxin depresses the ST segment.

49.3 GENERATION OF DYSRHYTHMIAS

Dysrhythmias arise from two fundamental causes: *disturbances of impulse formation* (automaticity) and *disturbances of impulse conduction*. One or both of these disturbances underlie all dysrhythmias. Factors that may alter automaticity or conduction include hypoxia, electrolyte imbalance, cardiac surgery, reduced coronary blood flow, myocardial infarction, and antidysrhythmic drugs.

49.3.1 Disturbances of Automaticity

Disturbances of automaticity can occur in any area of the heart. Cells normally capable of automaticity (cells of the SA node, AV node, and His-Purkinje system) can produce dysrhythmias if their normal rate of discharge changes. In addition, dysrhythmias may be produced if tissues that do not normally express automaticity (atrial and ventricular muscle) develop spontaneous phase 4 depolarization.

Altered automaticity in the SA node can produce tachycardia or bradycardia. Excessive discharge of sympathetic neurons that innervate the SA node can augment automaticity to such a degree that sinus tachycardia results. Excessive vagal (parasympathetic) discharge can suppress automaticity to such a degree that sinus bradycardia results.

Increased automaticity of Purkinje fibers is a common cause of dysrhythmias. The increase can be brought on by injury and by excessive stimulation of Purkinje fibers by the sympathetic nervous system. If Purkinje fibers begin to discharge faster than the SA node, they will escape control by the SA node; potentially serious dysrhythmias may result.

Under special conditions, automaticity may develop in cells of atrial and ventricular muscle. Dysrhythmias will result if these cells begin to fire faster than the SA node.

49.3.2 Disturbances of Conduction

49.3.2.1 Atrioventricular Block.

Impaired conduction through the AV node produces varying degrees of AV block. If impulse conduction is delayed (but not prevented entirely), the block is termed *first degree*. If some impulses pass through the node but others do not, the block is termed *second degree*. If all traffic through the AV node stops, the block is termed *third degree*.

49.3.2.2 Reentry (Recirculating Activation).

Reentry, also referred to as recirculating activation, is a generalized mechanism by which dysrhythmias can be produced. Reentry causes dysrhythmias by establishing a localized, self-sustaining circuit capable of repetitive cardiac stimulation. Reentry results from a unique form of conduction disturbance. The mechanism of reentrant activation and the effects of drugs on this process are described below.

536

Figure 48-4 **Reentrant activation: mechanism and drug effects.** **A**, In normal conduction, impulses from the branched Purkinje fiber stimulate the strip of ventricular muscle in two places. Within the muscle, waves of excitation spread from both points of excitation, meet between the Purkinje fibers, and cease further travel. **B**, In the presence of one-way block, the strip of muscle is excited at only one location. Impulses spreading from this area meet no impulses coming from the left and, therefore, can travel far enough to stimulate branch 1 of the Purkinje fiber. This stimulation passes back up the fiber, past the region of one-way block, and then stimulates branch 2, causing reentrant activation. **C**, Elimination of reentry by a drug that improves conduction in the sick branch of the Purkinje fiber. **D**, Elimination of reentry by a drug that further suppresses conduction in the sick branch, thereby converting one-way block into two-way block.

The mechanism for establishing a reentrant circuit is depicted in [Figure 48-4](#), panels A and B. In the figure, the inverted Y-shaped structure represents a branched Purkinje fiber terminating on a strip of ventricular muscle, which appears as a horizontal bar. Normal impulse conduction is shown in [Figure 48-4A](#). As indicated by the arrows, impulses travel down both branches of the Purkinje fiber to cause excitation of the muscle at two locations. Impulses created within the muscle travel in both directions (to the right and left) away from their sites of origin. Those impulses that are moving toward each other meet midway between the two branches of the Purkinje fiber. Since in the wake of both impulses the muscle is in a refractory state, neither impulse can proceed further, and hence both impulses stop.

[Figure 48-4B](#) depicts a reentrant circuit. The shaded area in branch 1 of the Purkinje fiber represents a region of one-way conduction block. This region prevents conduction of impulses downward (toward the muscle) but does not prevent impulses from traveling upward. (Impulses can travel back up the block because impulses in muscle are very strong, and hence are able to pass the block, whereas impulses in the Purkinje fiber are weaker, and hence are unable to pass.) A region of one-way block is essential for reentrant activation.

How does one-way block lead to reentrant activation? As an impulse travels down the Purkinje fiber, it is stopped in branch 1 but continues unimpeded in branch 2. Upon reaching the tip of branch 2, the impulse stimulates the muscle. As described above, the impulse in the muscle travels to the right and to the left away from its site of origin. However, in this new situation, as the impulse travels toward the impaired branch of the Purkinje fiber, it meets no impulse coming from the other direction, and hence continues on, resulting in stimulation of the terminal end of branch 1. This stimulation causes an impulse to travel backward up the Purkinje fiber. Since blockade of conduction is unidirectional, the impulse passes through the region of block and then back down into branch 2, causing reentrant activation of this branch. Under proper conditions, the impulse will continue to cycle indefinitely, resulting in repetitive ectopic beats.

There are two mechanisms by which drugs can abolish a reentrant dysrhythmia. First, drugs can improve conduction in the sick branch of the Purkinje fiber, and can thereby eliminate the one-way block ([Fig. 48-4C](#)). Alternatively, drugs can suppress conduction in the sick branch, thereby converting one-way block into two-way block ([Fig. 48-4D](#)).

^{49.4} CLASSIFICATION OF ANTIDYSRHYTHMIC DRUGS

According to the Vaughan Williams classification scheme, the antidysrhythmic drugs fall into five groups ([Table 48-1](#)). As the table shows, there are four major classes of antidysrhythmic drugs (classes I, II, III, and IV) and a fifth group that includes adenosine and digoxin. Membership in

classes I through IV is determined by effects on ion movements during slow and fast potentials (see [Fig. 48-2](#)).

TABLE 48-1 Vaughan Williams Classification of Antidysrhythmic Drugs

Class I: Sodium Channel Blockers**Class IA**

Quinidine

Procainamide [Procanbid]

Disopyramide [Norpace]

Class IB

Lidocaine [Xylocaine]

Phenytoin [Dilantin]

Mexiletine [Mexitil]

Class IC

Flecainide [Tambocor]

Propafenone [Rythmol]

Other Class I

Moricizine [Ethmozine]

Class II: Beta Blockers

Propranolol [Inderal]

Acebutolol [Sectral]

Esmolol [Brevibloc]

Class III: Potassium Channel Blockers (Drugs That Delay Repolarization)

Amiodarone [Cordarone, Pacerone]

Dofetilide [Tikosyn]

Ibutilide [Corvert]

Bretylium

Sotalol [Betapace]

Class IV: Calcium Channel Blockers

Diltiazem [Cardizem, others]

Verapamil [Isoptin, Calan, Verelan]

Other Antidysrhythmic Drugs

Adenosine [Adenocard]

Digoxin [Lanoxin]

49.4.1 Class I: Sodium Channel Blockers

Class I drugs block cardiac sodium channels (see [Fig. 48-2A](#)). By doing so, these drugs slow impulse conduction in the atria, ventricles, and His-Purkinje system. Class I constitutes the largest group of antidysrhythmic drugs.

49.4.2 Class II: Beta Blockers

Class II consists of beta-adrenergic blocking agents. As suggested by [Figure 48-2](#), these drugs reduce calcium entry (during fast and slow potentials) and they depress phase 4 depolarization (in slow potentials only). Beta blockers have three prominent effects on the heart:

- In the SA node, they reduce automaticity.
- In the AV node, they slow conduction velocity.
- In the atria and ventricles, they reduce contractility.

Cardiac effects of the beta blockers are nearly identical to those of the calcium channel blockers.

49.4.3 Class III: Potassium Channel Blockers (Drugs That Delay Repolarization)

Class III drugs block potassium channels ([Fig. 48-2A](#)), and thereby delay repolarization of fast potentials. By delaying repolarization, these drugs prolong both the action potential duration and the effective refractory period.

49.4.4 Class IV: Calcium Channel Blockers

Only two calcium channel blockers—verapamil and diltiazem—are employed as antidysrhythmics. As indicated in [Figure 48-2](#), calcium channel blockade has the same impact on cardiac action potentials as beta blockade. Accordingly, verapamil, diltiazem, and beta blockers have nearly identical effects on cardiac function—namely, reduction of automaticity in the SA node, delay of conduction through the AV node, and reduction of myocardial contractility. Antidysrhythmic benefits derive from suppressing AV nodal conduction.

49.4.5 Other Antidysrhythmic Drugs

Adenosine and digoxin do not fit into the four major classes of antidysrhythmic drugs. Both drugs suppress dysrhythmias by decreasing conduction through the AV node and reducing automaticity in the SA node.

49.5 PRODYSRHYTHMIC EFFECTS OF ANTIDYSRHYTHMIC DRUGS

Virtually all of the drugs used to treat dysrhythmias have prodysrhythmic (proarrhythmic) effects. That is, *all of these drugs can worsen existing dysrhythmias and generate new ones*. This ability was documented dramatically in the Cardiac Arrhythmia Suppression Trial (CAST), in which use of class IC drugs (encainide and flecainide) to prevent dysrhythmias after myocardial infarction actually *doubled the rate of mortality*. Because of their prodysrhythmic actions, antidysrhythmic drugs should be used only when dysrhythmias are symptomatically significant, and only when the potential benefits clearly outweigh the risks. Applying this guideline, it would be inappropriate to give antidysrhythmic drugs to a patient with nonsustained ventricular tachycardia, since this dysrhythmia does not significantly reduce cardiac output. Conversely, when a patient is facing death from ventricular fibrillation, any therapy that might work must be tried; in this case, the risk of prodysrhythmic effects is clearly outweighed by the potential benefits of stopping the fibrillation. Regardless of the particular circumstances of drug use, all patients must be followed closely.

Of the mechanisms by which drugs can cause dysrhythmias, one deserves special mention: prolongation of the QT interval. As discussed in [Chapter 7](#), drugs that prolong the QT interval increase the risk of *torsades de pointes*, a dysrhythmia that can progress to fatal ventricular fibrillation. All class IA and class III agents cause QT prolongation, and hence must be used with special caution.

49.6 OVERVIEW OF COMMON DYSRHYTHMIAS AND THEIR TREATMENT

The common dysrhythmias can be divided into two major groups: *supraventricular dysrhythmias* and *ventricular dysrhythmias*. In general, ventricular dysrhythmias are more dangerous than supraventricular dysrhythmias. With either type, intervention is required only if the dysrhythmia interferes with effective ventricular pumping. Treatment often proceeds in two phases: (1) *termination* of the dysrhythmia (with electrical countershock, drugs, or both), followed by (2) *long-term suppression* with drugs. Dysrhythmias can also be treated with an implantable cardioverter-defibrillator or by destroying small areas of cardiac tissue using radiofrequency (RF) catheter ablation.

538

539

It is important to appreciate that drug therapy of dysrhythmias is highly empiric (ie, based largely on the response of the patient and not on scientific principles). In practice, this means that, even after a dysrhythmia has been identified, we cannot predict with certainty just which drugs will be effective. Frequently, trials with several drugs are required before control of rhythm is achieved. In the discussion below, only first-choice drugs are considered.

49.6.1 Supraventricular Dysrhythmias

Supraventricular dysrhythmias are dysrhythmias that arise in areas of the heart above the ventricles (atria, SA node, AV node). Supraventricular dysrhythmias per se are not especially harmful. Why? Because dysrhythmic activity within the atria does not significantly reduce cardiac output (except in patients with valvular disorders and heart failure). Supraventricular tachydysrhythmias *can* be dangerous, however, in that atrial impulses are likely to traverse the AV node, resulting in excitation of the ventricles. If the atria drive the ventricles at an excessive rate, diastolic filling will be incomplete and cardiac output will decline. Hence, when treating supraventricular tachydysrhythmias, the objective is frequently one of slowing ventricular rate (by blocking impulse conduction through the AV node) and not elimination of the dysrhythmia itself. Of course, if treatment did abolish the dysrhythmia, this outcome would not be unwelcome. Acute treatment of supraventricular dysrhythmias is accomplished with vagotonic maneuvers, direct-current (DC) cardioversion, and certain drugs: class II agents, class IV agents, adenosine, and digoxin.

49.6.1.1 Atrial Fibrillation.

Atrial fibrillation is the most common sustained dysrhythmia, affecting about 2 million people in the United States. The disorder is caused by multiple atrial ectopic foci firing randomly; each focus stimulates a small area of atrial muscle. This chaotic excitation produces a highly irregular atrial rhythm. Depending upon the extent of impulse transmission through the AV node, ventricular rate may be very rapid or nearly normal.

In addition to compromising cardiac performance, atrial fibrillation carries a high risk of stroke. Why? Because in patients with atrial fibrillation, some blood can become trapped in the atria (rather than flowing straight through to the ventricles), thereby permitting formation of a clot. When normal sinus rhythm is restored, the clot may become dislodged, and then may travel to the brain to cause stroke.

Treatment of atrial fibrillation has two goals: improvement of ventricular pumping and prevention of stroke. Pumping can be improved by either (1) restoring normal sinus rhythm or (2) slowing ventricular rate. The preferred method is to slow ventricular rate. How? By *long-*

term therapy with a beta blocker (atenolol or metoprolol) or cardioselective calcium channel blocker (diltiazem or verapamil)—drugs that impede conduction through the AV node. If episodes of atrial fibrillation are infrequent (eg, less than 12 a year), they can be managed with PRN flecainide or propafenone. This so-called pill-in-the-pocket approach is analogous to treating infrequent attacks of angina with sublingual nitroglycerin. For patients who elect to restore normal rhythm, options are DC cardioversion, short-term treatment with drugs (eg, amiodarone, sotalol), or RF ablation of the dysrhythmia source.

To prevent stroke, most patients should be treated with warfarin. For those taking a drug long term to control ventricular rate, warfarin must be taken long term too. For those undergoing treatment to restore normal sinus rhythm, warfarin should be taken for 3 to 4 weeks prior to the procedure and for several weeks after.

49.6.1.2 Atrial Flutter.

Atrial flutter is caused by an ectopic atrial focus discharging at a rate of 250 to 350 times a minute. Ventricular rate is considerably slower, however, because the AV node is unable to transmit impulses at such a high rate. Typically, one atrial impulse out of two reaches the ventricles. The treatment of choice is DC cardioversion, which almost always converts atrial flutter to normal sinus rhythm. Cardioversion may also be achieved with IV ibutilide. To prevent the dysrhythmia from recurring, patients may need long-term therapy with drugs—either a class IC agent (flecainide or propafenone) or a class III agent (amiodarone, sotalol, dofetilide).

There are two alternatives to cardioversion: (1) RF ablation of the dysrhythmia focus and (2) control of ventricular rate with drugs. As with atrial fibrillation, ventricular rate is controlled with drugs that suppress AV conduction: verapamil, diltiazem, or a beta blocker.

Like atrial fibrillation, atrial flutter poses a risk of stroke, which can be reduced by treatment with warfarin.

49.6.1.3 Sustained Supraventricular Tachycardia (SVT).

Sustained SVT is usually caused by an AV nodal reentrant circuit. Heart rate is increased to 150 to 250 beats/min. SVT often responds to interventions that increase vagal tone, such as carotid sinus massage or the Valsalva maneuver. If these are ineffective, an IV beta blocker or calcium channel blocker can be tried. With these drugs, ventricular rate will be slowed even if the dysrhythmia persists. Once the dysrhythmia has been controlled, beta blockers and/or calcium channel blockers can be taken orally to prevent recurrence. As a last resort, amiodarone can be used for prevention.

49.6.2 Ventricular Dysrhythmias

In contrast to atrial dysrhythmias, which are generally benign, ventricular dysrhythmias can cause significant disruption of cardiac pumping. Accordingly, the usual objective is to abolish the dysrhythmia. Cardioversion is often the treatment of choice. When antidysrhythmic drugs are indicated, agents in class I or class III are usually employed.

49.6.2.1 Sustained Ventricular Tachycardia.

Ventricular tachycardia arises from a single, rapidly firing ventricular ectopic focus, typically located at the border of an old infarction. The focus drives the ventricles at a rate of 150 to 250 beats/min. Since the ventricles cannot pump effectively at these rates, immediate treatment is required. Cardioversion is the treatment of choice. If cardioversion fails to normalize rhythm, IV amiodarone should be administered; lidocaine and procainamide are alternatives. For long-term management, drugs (eg, sotalol, amiodarone) or an implantable cardioverter-defibrillator (ICD) may be employed.

539

49.6.2.2 Ventricular Fibrillation.

Ventricular fibrillation is a life-threatening emergency that requires immediate treatment. This dysrhythmia results from the asynchronous discharge of multiple ventricular ectopic foci. Because many different foci are firing, and because each focus initiates contraction in its immediate vicinity, localized twitching takes place all over the ventricles, making coordinated ventricular contraction impossible. As a result, the pumping action of the heart stops. In the absence of blood flow, the patient becomes unconscious and cyanotic. If heartbeat is not restored rapidly, death soon follows. Electrical countershock (defibrillation) is applied to eliminate fibrillation and restore cardiac function. If necessary, IV lidocaine can be used to enhance the effects of defibrillation. Procainamide and bretylium may also be helpful. Amiodarone can be used for long-term suppression. As an alternative, an ICD may be employed.

540

49.6.2.3 Ventricular Premature Beats (VPBs).

VPBs are beats that occur before they should in the cardiac cycle. These beats are caused by ectopic ventricular foci. VPBs may arise from a single ectopic focus or from several foci. In the absence of additional signs of heart disease, VPBs are benign and not usually treated. However, in the presence of acute myocardial infarction, VPBs may predispose the patient to ventricular fibrillation. In this case, therapy is required. A beta blocker is the agent of choice. Because

VPBs are associated with a premature QRS complex on the ECG, this dysrhythmia is also known as *premature ventricular complexes*.

49.6.2.4 Digoxin-Induced Ventricular Dysrhythmias.

Digoxin toxicity can mimic practically all types of dysrhythmias. Varying degrees of AV block are among the most common. Ventricular flutter and ventricular fibrillation are the most dangerous. Digoxin causes dysrhythmias by increasing automaticity in the atria, ventricles, and His-Purkinje system, and by decreasing conduction through the AV node.

With proper treatment, digoxin-induced dysrhythmias can almost always be controlled. Treatment is discussed at length in [Chapter 47](#). If antidysrhythmic drugs are required, lidocaine and phenytoin are the agents of choice. In patients with digoxin toxicity, DC cardioversion may bring on ventricular fibrillation. Accordingly, this procedure should be used only when absolutely required.

49.6.2.5 Torsades de Pointes.

Torsades de pointes is an atypical, rapid, undulating ventricular tachydysrhythmia that can evolve into potentially fatal ventricular fibrillation. The main factor associated with development of torsades de pointes is prolongation of the QT interval, which can be caused by a variety of drugs (see [Table 7-2](#) in [Chapter 7](#)), including class IA and class III antidysrhythmic agents. Acute management consists of IV magnesium plus cardioversion for sustained ventricular tachycardia.

49.7 PRINCIPLES OF ANTIDYSRHYTHMIC DRUG THERAPY

49.7.1 Balancing Risks and Benefits

Therapy with antidysrhythmic drugs is based on a simple but important concept: Treat only if there is a clear benefit—and then only if the benefit outweighs the risks. As a rule, this means that intervention is needed only when the dysrhythmia interferes with ventricular pumping.

Treatment offers two potential benefits: reduction of symptoms and reduction of mortality. Symptoms that can be reduced include palpitations, angina, dyspnea, and faintness. For most antidysrhythmic drugs, there is little or no evidence of reduced mortality. In fact, mortality may actually increase.

Antidysrhythmic therapy carries considerable risk. Because of their *prodysrhythmic actions*, antidysrhythmic drugs can exacerbate existing dysrhythmias and generate new ones. Examples abound: toxic doses of digoxin can generate a wide variety of dysrhythmias; drugs that prolong

the QT interval can cause torsades de pointes; many drugs can cause ventricular ectopic beats; several drugs (quinidine, encainide, flecainide, propafenone) can cause atrial flutter; and two drugs—encainide and flecainide—can produce incessant ventricular tachycardia. Because of their prodysrhythmic actions, antidysrhythmic drugs can *increase mortality*. Other adverse effects include heart failure and third-degree AV block (caused by calcium channel blockers and beta blockers), as well as many noncardiac effects, including severe diarrhea (quinidine), a lupus-like syndrome (procainamide), and pulmonary toxicity (amiodarone).

49.7.2 Properties of the Dysrhythmia to Be Considered

49.7.2.1 Sustained Versus Nonsustained Dysrhythmias.

As a rule, nonsustained dysrhythmias require intervention only when they are symptomatic; in the absence of symptoms, treatment is usually unnecessary. In contrast, sustained dysrhythmias can be dangerous; hence, the benefits of treatment generally outweigh the risks.

49.7.2.2 Asymptomatic Versus Symptomatic Dysrhythmias.

No study has demonstrated a benefit to treating dysrhythmias that are asymptomatic or minimally symptomatic. In contrast, therapy may be beneficial for dysrhythmias that produce symptoms (palpitations, angina, dyspnea, faintness).

49.7.2.3 Supraventricular Versus Ventricular Dysrhythmias.

Supraventricular dysrhythmias are generally benign. The primary harm comes from driving the ventricles too rapidly to allow adequate filling. The goal of treatment is to either (1) terminate the dysrhythmia or (2) prevent excessive atrial beats from reaching the ventricles (using a beta blocker, calcium channel blocker, or digoxin). In contrast to supraventricular dysrhythmias, ventricular dysrhythmias frequently interfere with pumping. Accordingly, the goal of treatment is to terminate the dysrhythmia and prevent its recurrence.

49.7.3 Phases of Treatment

Treatment has two phases: acute and long term. The goal of acute treatment is to terminate the dysrhythmia. For many dysrhythmias, termination is accomplished with DC cardioversion (electrical countershock) or vagotonic maneuvers (eg, carotid sinus massage), rather than drugs. The goal of long-term therapy is to prevent dysrhythmias from recurring. Quite often, the risks of long-term prophylactic therapy outweigh the benefits.

49.7.4 Long-Term Treatment: Drug Selection and Evaluation

Selecting a drug for long-term therapy is largely empiric. There are many drugs that might be employed, and we usually can't predict which one is going to work. Hence, finding an effective drug is done by trial and error.

Drug selection can be aided with electrophysiologic testing. In these tests, a dysrhythmia is generated artificially by programmed electrical stimulation of the heart. If a candidate drug is able to suppress the electrophysiologically induced dysrhythmia, it may also work against the real thing.

Holter monitoring can be used to evaluate treatment. A Holter monitor is a portable ECG device that is worn by the patient around-the-clock. If Holter monitoring indicates that dysrhythmias are still occurring with the present drug, a different drug should be tried.

49.7.5 Minimizing Risks

Several measures can help minimize risk. These include

- Starting with low doses and increasing them gradually.
- Using a Holter monitor during initial therapy to detect danger signs—especially QT prolongation, which can precede torsades de pointes.
- Monitoring plasma drug levels. Unfortunately, although drug levels can be good predictors of noncardiac toxicity (eg, quinidine-induced nausea), they are less helpful for predicting adverse cardiac effects.

49.8 PHARMACOLOGY OF THE ANTIDYSRHYTHMIC DRUGS

As discussed above, the antidysrhythmic drugs fall into four main groups—classes I, II, III, and IV—plus a fifth group that includes adenosine and digoxin. The pharmacology of these drugs is presented below, and summarized in [Table 48-2](#).

49.9 CLASS I: SODIUM CHANNEL BLOCKERS

Class I antidysrhythmic drugs block cardiac sodium channels. By doing so, they decrease conduction velocity in the atria, ventricles, and His-Purkinje system.

There are three subgroups of class I agents. Drugs in all three groups block sodium channels. In addition, class IA agents delay repolarization, whereas class IB agents accelerate repolarization.

Class IC agents have pronounced proarrhythmic actions.

TABLE 48-2 Properties of Antidysrhythmic Drugs

Drug	Usual Route	Effects on the ECG	Major Antidysrhythmic Applications
Class IA			
Quinidine	PO	Widens QRS, prolongs QT	Broad spectrum: used for long-term suppression of ventricular and supraventricular dysrhythmias
Procainamide	PO	Widens QRS, prolongs QT	Broad spectrum: similar to quinidine, but toxicity makes it less desirable for long-term use
Disopyramide	PO	Widens QRS, prolongs QT	Ventricular dysrhythmias
Class IB			
Lidocaine	IV	No significant change	Ventricular dysrhythmias
Mexiletine	PO	No significant change	Ventricular dysrhythmias
Phenytoin	PO	No significant change	Digoxin-induced ventricular dysrhythmias
Class IC			
Flecainide	PO	Widens QRS, prolongs PR	Maintenance therapy of supraventricular dysrhythmias
Propafenone	PO	Widens QRS, prolongs PR	Maintenance therapy of supraventricular dysrhythmias
Other Class I			
Moricizine	PO	Widens QRS, prolongs PR	Life-threatening ventricular dysrhythmias
Class II			
Propranolol	PO	Prolongs PR, bradycardia	Dysrhythmias caused by excessive sympathetic activity; control of ventricular rate in patients with supraventricular tachydysrhythmias
Acebutolol	PO	Prolongs PR, bradycardia	Premature ventricular beats
Esmolol	IV	Prolongs PR, bradycardia	Control of ventricular rate in patients with supraventricular tachydysrhythmias
Class III			
Amiodarone	PO	Prolongs QT and PR, widens QRS	Life-threatening ventricular dysrhythmias
Bretylum	IV	Prolongs QT	Life-threatening ventricular dysrhythmias
Sotalol	IV	Prolongs QT and PR, bradycardia	Life-threatening ventricular dysrhythmias
Dofetilide	PO	Prolongs QT	Highly symptomatic atrial dysrhythmias
Ibutilide	IV	Prolongs QT	Atrial flutter, atrial fibrillation
Class IV			

Verapamil	PO	Prolongs PR, bradycardia	Control of ventricular rate in patients with supraventricular tachydysrhythmias
Diltiazem	IV	Prolongs PR, bradycardia	Same as verapamil
Others			
Adenosine	IV	Prolongs PR	Termination of paroxysmal supraventricular tachycardia
Digoxin	PO	Prolongs PR, depresses ST	Control of ventricular rate in patients with supraventricular tachydysrhythmias

541

542

The class I drugs are similar in action and structure to the local anesthetics. In fact, one of these drugs—lidocaine—has both local anesthetic and antidysrhythmic applications. Because of their relationship to the local anesthetics, class I agents are sometimes referred to as *local anesthetic antidysrhythmic agents*.

49.9.1 Class IA Agents

49.9.1.1 Quinidine

Quinidine is the oldest and most thoroughly studied of the class IA drugs. Accordingly, quinidine will serve as our prototype for the group. Quinidine is the most frequently used oral antidysrhythmic agent. Like other antidysrhythmic drugs, quinidine has prodysrhythmic actions.

49.9.1.1.1 Chemistry and Source.

Quinidine is similar to quinine in structure and actions. The natural source of both drugs is the bark of the South American cinchona tree. Accordingly, these agents are referred to as *cinchona alkaloids*. Like quinine, quinidine has antimalarial and antipyretic properties.

49.9.1.1.2 Effects on the Heart.

By blocking sodium channels, quinidine *slows impulse conduction* in the atria, ventricles, and His-Purkinje system. In addition, the drug *delays repolarization* at these sites, apparently by blocking potassium channels. Both actions contribute to suppression of dysrhythmias.

Quinidine is strongly *anticholinergic* (atropine-like) and blocks vagal input to the heart. The resultant *increase* in SA nodal automaticity and AV conduction can drive the ventricles at an excessive rate. To prevent excessive ventricular stimulation, patients are usually pretreated with digoxin, verapamil, or a beta blocker, all of which suppress AV conduction.

49.9.1.1.3 Effects on the ECG.

Quinidine has two pronounced effects on the ECG. The drug *widens the QRS complex* (by slowing depolarization of the ventricles) and *prolongs the QT interval* (by delaying ventricular repolarization).

49.9.1.1.4 Therapeutic Uses.

Quinidine is a broad-spectrum agent active against *supraventricular* and *ventricular dysrhythmias*. The drug's principal indication is long-term suppression of dysrhythmias, including SVT, atrial flutter, atrial fibrillation, and sustained ventricular tachycardia. To prevent quinidine from increasing ventricular rate, patients are usually pretreated with an AV nodal blocking agent (digoxin, verapamil, beta blocker). An analysis of older studies indicates that quinidine may actually *increase* mortality in patients with *atrial flutter* and *atrial fibrillation*.

In addition to its antidysrhythmic applications, quinidine is a drug of choice for severe *malaria* (see [Chapter 97](#)).

49.9.1.1.5 Pharmacokinetics.

Quinidine is rapidly absorbed following oral administration. Peak responses to *quinidine sulfate* develop in 30 to 90 minutes; responses to *quinidine gluconate* develop more slowly, peaking after 3 to 4 hours. Elimination is by hepatic metabolism. Accordingly, patients with liver impairment may require a reduction in dosage. Therapeutic plasma levels are 2 to 5 mcg/mL.

49.9.1.1.6 Adverse Effects.

49.9.1.1.6.1 Diarrhea.

Diarrhea and other GI symptoms develop in about 33% of patients. These reactions can be immediate and intense, frequently forcing discontinuation of treatment. Gastric upset can be reduced by administering quinidine with food.

49.9.1.1.6.2 Cinchonism.

Cinchonism is characterized by tinnitus (ringing in the ears), headache, nausea, vertigo, and disturbed vision. These symptoms can develop with just one dose.

49.9.1.1.6.3 Cardiotoxicity.

At high concentrations, quinidine can cause severe cardiotoxicity (sinus arrest, AV block, ventricular tachydysrhythmias, asystole). These reactions occur secondary to increased automaticity of Purkinje fibers and reduced conduction throughout all regions of the heart.

As cardiotoxicity develops, the ECG changes. Important danger signals are *widening of the QRS complex* (by 50% or more) and *excessive prolongation of the QT interval*. The prescriber should be notified immediately if these changes occur.

49.9.1.1.6.4 Arterial Embolism.

Embolism is a potential complication of treating atrial *fibrillation*. During atrial fibrillation, thrombi may form in the atria. When sinus rhythm is restored, these thrombi may be dislodged and cause embolism. To reduce the risk of embolism, warfarin (an anticoagulant) is given for 3 to 4 weeks prior to quinidine, and is maintained for an additional 4 weeks. Signs of embolism (eg, sudden chest pain, dyspnea) should be reported immediately.

49.9.1.1.6.5 Other Adverse Effects.

Quinidine can cause alphaadrenergic blockade, resulting in vasodilation and subsequent *hypotension*. This reaction is much more serious with IV therapy than with oral therapy. Rarely, quinidine has caused *hypersensitivity reactions*, including fever, anaphylactic reactions, and thrombocytopenia.

49.9.1.1.7 Drug Interactions.

Digoxin. Quinidine can double digoxin levels. The increase is caused by displacing digoxin from plasma albumin and by decreasing digoxin elimination. When these drugs are used concurrently, digoxin dosage must be reduced. Also, patients should be monitored closely for digoxin toxicity (dysrhythmias). Because of its interaction with digoxin, quinidine is a last-choice drug for treating digoxin-induced dysrhythmias.

49.9.1.1.7.1 Other Interactions.

Because of its anticholinergic actions, quinidine can intensify the effects of other atropine-like drugs; one possible result is excessive tachycardia. Phenobarbital, phenytoin, and other drugs that induce hepatic drug metabolism can shorten the half-life of quinidine by as much as 50%. Quinidine can intensify the effects of warfarin by a mechanism that is not known.

49.9.1.1.8 Preparations, Dosage, and Administration.

49.9.1.1.8.1 Preparations.

Quinidine is available as two salts: *quinidine sulfate* and *quinidine gluconate*. Because these salts have different molecular weights, equal doses (on a milligram basis) do not provide equal amounts of quinidine. A 200-mg dose of quinidine sulfate is equivalent to 275 mg of quinidine gluconate. Quinidine sulfate is available in immediate-release tablets (200 and 300 mg) and sustained-release tablets (300 mg). Quinidine gluconate is available in sustained-release tablets (324 mg) and in solution (80 mg/mL) for parenteral use.

49.9.1.1.8.2 Dosage.

The usual dosage of quinidine sulfate is 200 to 400 mg every 4 to 6 hours. The usual dosage of quinidine gluconate is 324 to 648 mg every 8 to 12 hours. Dosage is adjusted to produce plasma quinidine levels between 2 and 5 mcg/mL.

49.9.1.1.8.3 Administration.

Quinidine is almost always administered by mouth. If time permits, a small test dose (200 mg PO or IM) should be given prior to the full therapeutic dose to assess for hypersensitivity. Intramuscular administration is painful and produces erratic absorption. Intravenous injection carries a high risk of adverse cardiovascular reactions, and hence continuous cardiovascular monitoring is required.

49.9.1.2 Procainamide

Procainamide [Procanbid] is similar to quinidine in actions and uses. Like quinidine, procainamide is active against a broad spectrum of dysrhythmias. Unfortunately, serious side effects frequently limit its use.

49.9.1.2.1 Effects on the Heart and ECG.

Like quinidine, procainamide blocks cardiac sodium channels, thereby decreasing conduction velocity in the atria, ventricles, and His-Purkinje system. Also, the drug delays repolarization. In contrast to quinidine, procainamide is only weakly anticholinergic, and hence is not likely to increase ventricular rate. Effects on the ECG are the same as with quinidine: widening of the QRS complex and prolongation of the QT interval.

49.9.1.2.2 Therapeutic Uses.

Procainamide is effective against a broad spectrum of atrial and ventricular dysrhythmias. 542

Like quinidine, the drug can be used for long-term suppression. However, since prolonged therapy is often associated with serious adverse effects, procainamide is less desirable than quinidine for long-term use. In contrast to quinidine, procainamide can be used to terminate ventricular tachycardia and ventricular fibrillation. 543

49.9.1.2.3 Pharmacokinetics.

Routes are oral, IV, and IM. Peak plasma levels develop 1 hour after oral dosing. Procainamide has a short half-life and requires more frequent dosing than quinidine.

Elimination is by hepatic metabolism and renal excretion. The major metabolite—*N*-acetylprocainamide (NAPA)—has antidysrhythmic properties of its own. NAPA is excreted by the kidneys and can accumulate to toxic levels in patients with renal impairment.

49.9.1.2.4 Adverse Effects.

Systemic Lupus Erythematosus–like Syndrome. Prolonged treatment with procainamide is associated with severe immunologic reactions. Within a year, about 70% of patients develop antinuclear antibodies (ANAs)—antibodies directed against the patient's own nucleic acids. If procainamide is continued, between 20% and 30% of patients with ANAs go on to develop symptoms resembling those of systemic lupus erythematosus (SLE). These symptoms include pain and inflammation of the joints, pericarditis, fever, and hepatomegaly. When procainamide is withdrawn, symptoms usually slowly subside. If the patient has a life-threatening dysrhythmia for which no alternative drug is available, procainamide can be continued and the symptoms of SLE controlled with a nonsteroidal anti-inflammatory drug (eg, aspirin) or a glucocorticoid. All patients taking procainamide chronically should be tested for ANAs. If the ANA titer rises, discontinuing treatment should be considered.

49.9.1.2.4.1 Blood Dyscrasias.

About 0.5% of patients develop blood dyscrasias, including neutropenia, thrombocytopenia, and agranulocytosis. Fatalities have occurred. These reactions usually develop during the first 12 weeks of treatment. Complete blood counts should be obtained weekly during this time and periodically thereafter. Also, complete blood counts should be obtained promptly at the first sign of infection, bruising, or bleeding. If blood counts indicate bone marrow suppression, procainamide should be withdrawn. Hematologic status usually returns to baseline within 1 month.

49.9.1.2.4.2 Cardiotoxicity.

Procainamide has cardiotoxic actions like those of quinidine. Danger signs are QRS widening (more than 50%) and excessive QT prolongation. If these develop, the drug should be withheld and the prescriber informed.

49.9.1.2.4.3 Other Adverse Effects.

Like quinidine, procainamide can cause *GI symptoms* and *hypotension*. However, these are much less prominent than with quinidine. Procainamide is a derivative of procaine (a local anesthetic), and patients with a history of procaine allergy are at high risk of having an *allergic response* to procainamide. As with quinidine, *arterial embolism* may occur during treatment of atrial fibrillation.

49.9.1.2.5 Preparations, Dosage, and Administration.

49.9.1.2.5.1 Oral.

Procainamide is available in capsules (250, 375, and 500 mg) and sustained-release tablets (250, 500, 750, and 1000 mg). The usual maintenance dosage is 50 mg/kg/day in divided doses. The capsules are administered every 3 to 4 hours and the sustained-release tablets every 6 hours (or every 12 hours for *Procanbid* tablets). Dosage is adjusted to maintain plasma drug levels between 4 and 10 mcg/mL.

49.9.1.2.5.2 Parenteral.

Procainamide solution (500 mg/mL) is available for IM and IV administration. Intramuscular injection is made deep into the gluteal muscle; dosage is 0.5 to 1 gm repeated every 4 to 8 hours.

Intravenous infusion may be performed at an initial rate of 20 mg/min (maximal loading dose is 500 to 600 mg). After the loading period, an infusion rate of 2 to 6 mg/min should be employed. Once the dysrhythmia has been controlled, the patient should be switched to oral procainamide. Three hours should elapse between terminating the infusion and the first oral dose.

49.9.1.3 Disopyramide

Disopyramide [Norpace] is a class I drug with actions like those of quinidine. However, because of prominent side effects, indications for disopyramide are limited.

49.9.1.3.1 Effects on the Heart and ECG.

Cardiac effects are similar to those of quinidine. By blocking sodium channels, disopyramide decreases conduction velocity in the atria, ventricles, and His-Purkinje system. In addition, the drug delays repolarization. Anticholinergic actions are greater than those of quinidine. In contrast to quinidine, disopyramide causes a pronounced reduction in contractility. Like quinidine, disopyramide widens the QRS complex and prolongs the QT interval.

49.9.1.3.2 Adverse Effects.

Anticholinergic responses are most common. These include dry mouth, blurred vision, constipation, and urinary hesitancy or retention. Urinary retention frequently requires discontinuation of treatment.

Because of its negative inotropic effects, disopyramide can cause *severe hypotension* (secondary to reduced cardiac output) and can *exacerbate heart failure* (HF). The drug should not be administered to patients with HF or to patients taking a beta blocker. Whenever disopyramide is used, pressor drugs should be immediately available.

49.9.1.3.3 Therapeutic Uses.

Disopyramide is indicated only for ventricular dysrhythmias (VPBs, ventricular tachycardia, ventricular fibrillation). The drug is reserved for patients who cannot tolerate safer medications (eg, quinidine, procainamide).

49.9.1.3.4 Preparations, Dosage, and Administration.

Disopyramide [Norpace] is available in immediate- and extended-release capsules (100 and 150 mg). An initial loading dose (200 to 300 mg) is followed by maintenance doses (100 to 200 mg) every 6 hours.

49.9.2 Class IB Agents

As a group, class IB agents differ from quinidine and the other class IA agents in two respects: (1) whereas class IA agents *delay* repolarization, class IB agents *accelerate* repolarization; and (2) class IB agents have little or no effect on the ECG.

49.9.2.1 Lidocaine

Lidocaine [Xylocaine], an intravenous agent, is used only for ventricular dysrhythmias. In addition to its antidysrhythmic applications, lidocaine is employed as a local anesthetic (see [Chapter 26](#)).

49.9.2.1.1 Effects on the Heart and ECG.

Lidocaine has three significant effects on the heart: (1) like other class I drugs, lidocaine blocks cardiac sodium channels and thereby *slows conduction* in the atria, ventricles, and His-Purkinje system; (2) the drug *reduces automaticity* in the ventricles and His-Purkinje system by a mechanism that is poorly understood; and (3) lidocaine *accelerates repolarization* (shortens the action potential duration and ERP). In contrast to quinidine and procainamide, lidocaine is devoid of anticholinergic properties. Also, lidocaine has no significant impact on the ECG: A small reduction in the QT interval may occur, but there is no QRS widening.

49.9.2.1.2 Pharmacokinetics.

Lidocaine undergoes rapid hepatic metabolism. If the drug were administered orally, most of each dose would be inactivated on its first pass through the liver. For this reason, administration is by IV infusion.

Because lidocaine is rapidly degraded, plasma drug levels can be easily controlled: If levels climb too high, the infusion can be slowed and the liver will quickly remove excess drug from the circulation. The therapeutic range for lidocaine is 1.5 to 5 mcg/mL.

49.9.2.1.3 Antidysrhythmic Use.

Antidysrhythmic use of lidocaine is limited to short-term therapy of *ventricular dysrhythmias*. Lidocaine is not active against supraventricular dysrhythmias.

49.9.2.1.4 Adverse Effects.

Lidocaine is generally well tolerated. However, adverse central nervous system (CNS) effects can occur. High therapeutic doses can cause *drowsiness*, *confusion*, and *paresthesias*. Toxic doses may produce *convulsions* and *respiratory arrest*. Consequently, whenever lidocaine is used, equipment for resuscitation must be available. Convulsions can be managed with diazepam or phenytoin.

49.9.2.1.5 Preparations, Dosage, and Administration.

Administration is parenteral only. The usual route is IV. Intramuscular injection can be used in emergencies. Blood pressure and the ECG should be monitored for signs of toxicity.

49.9.2.1.5.1 Intravenous.

Lidocaine [Xylocaine] preparations intended for IV administration are clearly labeled as such. They contain no preservatives or catecholamines. (Lidocaine used for local anesthesia frequently contains epinephrine.) *Preparations that contain epinephrine or another catecholamine must never be administered IV, since doing so can cause severe hypertension and life-threatening dysrhythmias.*

543

544

Intravenous therapy is initiated with a loading dose followed by continuous infusion for maintenance. The usual loading dose is 50 to 100 mg (1 mg/kg) administered at a rate of 25 to 50 mg/min. An infusion rate of 1 to 4 mg/min is used for maintenance; the rate is adjusted on the basis of cardiac response. Intravenous lidocaine should be discontinued as soon as possible, usually within 24 hours. Lidocaine for IV administration is supplied in concentrated and dilute formulations. The concentrated formulations must be diluted with 5% dextrose in water.

To avoid toxicity, dosage should be reduced in patients with impaired hepatic function or impaired hepatic blood flow (eg, elderly patients; patients with cirrhosis, shock, or HF).

49.9.2.1.5.2 Intramuscular.

Lidocaine is available in an automatic injection device [LidoPen Auto-Injector] for IM administration. A dose of 300 mg is injected into the deltoid muscle. This dose can be repeated in 60 to 90 minutes if necessary. The patient should be switched to IV lidocaine as soon as possible.

49.9.2.2 Phenytoin

Phenytoin [Dilantin] is an antiseizure drug that is also used to treat digoxin-induced dysrhythmias. The basic pharmacology of phenytoin is presented in [Chapter 24](#) (Drugs for Epilepsy). Discussion here is limited to antidysrhythmic applications.

49.9.2.2.1 Effects on the Heart and ECG.

Like lidocaine, phenytoin reduces automaticity (especially in the ventricles), and has little or no effect on the ECG. In contrast to lidocaine (and practically all other antidysrhythmic agents), phenytoin increases AV nodal conduction.

49.9.2.2.2 Pharmacokinetics.

Phenytoin has two unfortunate kinetics properties. First, metabolism of the drug is subject to wide interpatient variation. Second, doses only slightly greater than therapeutic are likely to cause toxicity. Because of these characteristics, maintenance of therapeutic plasma levels (5 to 20 mcg/mL) is difficult.

49.9.2.2.3 Adverse Effects and Interactions.

The most common adverse reactions are sedation, ataxia, and nystagmus. With too-rapid IV administration, phenytoin can cause hypotension, dysrhythmias, and cardiac arrest. Gingival hyperplasia is a frequent complication of long-term treatment. Phenytoin is subject to multiple undesirable drug interactions (see [Chapter 24](#)).

49.9.2.2.4 Antidysrhythmic Applications.

Phenytoin has been used to treat digoxin-induced dysrhythmias and for acute and chronic suppression of ventricular dysrhythmias. The ability of phenytoin to increase AV nodal conduction can help counteract the reduction in AV conduction caused by digoxin intoxication. Phenytoin should not be used to treat atrial fibrillation or atrial flutter. Why? Because enhanced AV conduction could increase the number of atrial impulses reaching the ventricles, thereby driving the ventricles at an excessive rate.

49.9.2.2.5 Dosage and Administration.

Phenytoin [Dilantin] can be given PO or IV. For PO therapy, a loading dose (14 mg/kg) is followed by daily maintenance doses (200 to 400 mg).

Intravenous administration is reserved for severe, acute dysrhythmias. Blood pressure and the ECG must be monitored continuously. Phenytoin is not soluble in water and must be diluted in the medium supplied by the manufacturer. This medium is highly alkaline (pH 12) and will cause phlebitis if given by continuous infusion. Consequently, administration is by intermittent injections. Intravenous injections must be performed slowly (50 mg/min or less), since rapid injection can cause cardiovascular collapse. Treatment is begun with a series of

loading doses (50 to 100 mg every 5 minutes until the dysrhythmia has been controlled or until toxicity appears). Maintenance dosages range from 200 to 400 mg/day.

49.9.2.3 Mexiletine

Mexiletine [Mexitil] is an oral analog of lidocaine used for symptomatic ventricular dysrhythmias. Principal indications are VPBs and sustained ventricular tachycardia. Like lidocaine, mexiletine does not alter the ECG. The drug is eliminated by hepatic metabolism, and hence effects may be prolonged in patients with liver disease or reduced hepatic blood flow. The most common adverse effects are GI (nausea, vomiting, diarrhea, constipation) and neurologic (tremor, dizziness, sleep disturbances, psychosis, convulsions). About 40% of patients find these intolerable. Like other class I agents, mexiletine has prodysrhythmic properties. The initial dosage is 100 to 200 mg every 8 hours. The maintenance dosage is 100 to 300 mg every 6 to 12 hours. All doses should be taken with food.

Mexiletine is also used to alleviate persistent pain of diabetic neuropathy. Benefits derive from lidocaine-like anesthetic actions. Because mexiletine can *cause* dysrhythmias, it should not be used by diabetic patients with heart disease.

49.9.3 Class IC Agents

Class IC antidysrhythmics block cardiac sodium channels and thereby reduce conduction velocity in the atria, ventricles, and His-Purkinje system. In addition, these drugs delay ventricular repolarization, causing a small increase in the effective refractory period. All class IC agents can exacerbate existing dysrhythmias and create new ones. Currently, only two class IC agents are available: flecainide and propafenone.

49.9.3.1 Flecainide

Flecainide [Tambocor] is active against a variety of ventricular and supraventricular dysrhythmias. However, use is restricted largely to maintenance therapy of supraventricular dysrhythmias. Like other class IC agents, flecainide decreases cardiac conduction and increases the effective refractory period. Prominent effects on the ECG are prolongation of the PR interval and widening of the QRS complex. Excessive QRS widening indicates a need for dosage reduction. Flecainide has prodysrhythmic effects. As a result, the drug can intensify existing dysrhythmias and provoke new ones. In patients with asymptomatic ventricular tachycardia associated with acute myocardial infarction, flecainide has caused a twofold increase in mortality. Flecainide decreases myocardial contractility and can thereby exacerbate or precipitate heart failure. Accordingly, the drug should not be combined with other agents that can decrease contractile force (eg, beta blockers, verapamil, diltiazem). Elimination is by

hepatic metabolism and renal excretion. Dosage is low initially (100 mg every 12 hours) and then gradually increased to a maximum of 400 mg/day. Because of its potential for serious side effects, flecainide should be reserved for severe ventricular dysrhythmias that have not responded to safer drugs. Patients should be monitored closely.

49.9.3.2 Propafenone

Propafenone [Rythmol] is similar to flecainide in actions and uses. By blocking cardiac sodium channels, the drug decreases conduction velocity in the atria, ventricles, and His-Purkinje system. In addition, it causes a small increase in the ventricular ERP. Prominent effects on the ECG are QRS widening and PR prolongation. Like flecainide, propafenone has prodysrhythmic actions that can exacerbate existing dysrhythmias and create new ones. It is not known if propafenone, like flecainide, increases mortality in patients with asymptomatic ventricular dysrhythmias after myocardial infarction. Propafenone has beta-adrenergic blocking properties and can thereby decrease myocardial contractility and promote bronchospasm. Accordingly, the drug should be used with caution in patients with heart failure, AV block, or asthma. Noncardiac adverse effects are generally mild and include dizziness, altered taste, blurred vision, and GI symptoms (abdominal discomfort, anorexia, nausea, vomiting). Because of its prodysrhythmic actions, propafenone should be reserved for patients who have not responded to safer drugs. Propafenone is available in immediate-release tablets (150, 225, and 300 mg) and extended-release capsules (225, 325, and 425 mg). For the immediate-release tablets, the dosage is 150 mg every 8 hours initially, and can be gradually increased to 300 mg every 8 hours.

49.9.4 Other Class I: Moricizine

Moricizine [Ethmozine] is a class I antidysrhythmic drug approved for oral therapy of life-threatening ventricular dysrhythmias. This agent shares properties with other class I drugs but doesn't quite fit any of the existing subclasses (IA, IB, and IC). Like other class I agents, moricizine blocks cardiac sodium channels and thereby decreases conduction velocity in the atria, ventricles, and His-Purkinje system. Prominent effects on the ECG are QRS widening and PR prolongation. The most common adverse effects are dizziness, nausea, and headache. Like other antidysrhythmic drugs, moricizine is prodysrhythmic. In addition, moricizine can cause bradycardia, AV heart block, and heart failure. Interactions with digoxin, diuretics, beta blockers, calcium channel blockers, angiotensin-converting enzyme inhibitors, and warfarin have not been reported. Because of its potential for adverse cardiac effects, moricizine should be reserved for life-threatening ventricular dysrhythmias that have not responded to safer drugs. Moricizine is available in 200-, 250-, and 300-mg tablets. The dosage is 200 mg every 8 hours initially, and may be gradually increased to a maximum of 300 mg every 8 hours.

49... CLASS II: BETA BLOCKERS

Class II consists of beta-adrenergic blocking agents. At this time only four beta blockers—propranolol, acebutolol, esmolol, and sotalol—are approved for treating dysrhythmias. One of these drugs—sotalol—also blocks potassium channels, and hence is discussed under class III. The basic pharmacology of the beta blockers is presented in [Chapter 18](#). Discussion here is limited to their antidysrhythmic use.

544

545

49.10.1 Propranolol

Propranolol [Inderal] is considered a nonselective beta-adrenergic antagonist, in that it blocks both beta₁- and beta₂-adrenergic receptors. As discussed in [Chapter 18](#), beta₁ blockade affects the heart and beta₂ blockade affects the bronchi.

49.10.1.1 Effects on the Heart and ECG.

Blockade of cardiac beta₁ receptors attenuates sympathetic stimulation of the heart. The result is (1) decreased automaticity of the SA node, (2) decreased velocity of conduction through the AV node, and (3) decreased myocardial contractility. The reduction in AV conduction velocity translates to a prolonged PR interval on the ECG.

It is worth noting that cardiac beta₁ receptors are functionally coupled to calcium channels, and that beta₁ blockade causes these channels to close. Hence, the effects of beta blockers on heart rate, AV conduction, and contractility all result from decreased calcium influx. Because beta blockers and calcium channel blockers both decrease calcium entry, the cardiac effects of these drugs are very similar.

49.10.1.2 Therapeutic Use.

Propranolol is especially useful for treating dysrhythmias caused by excessive sympathetic stimulation of the heart. Among these are sinus tachycardia, severe recurrent ventricular tachycardia, exercise-induced tachydysrhythmias, and paroxysmal atrial tachycardia provoked by emotion or exercise. In patients with supraventricular tachydysrhythmias, propranolol has two beneficial effects: (1) suppression of excessive discharge of the SA node, and (2) slowing of ventricular rate by decreasing transmission of atrial impulses through the AV node.

49.10.1.3 Adverse Effects.

Beta blockers are generally well tolerated. Principal adverse effects concern the heart and bronchi. By blocking cardiac β_1 receptors, propranolol can cause *heart failure*, *AV block*, and *sinus arrest*. Hypotension can occur secondary to reduced cardiac output. In patients with asthma, blocking β_2 receptors in the lung can cause *bronchospasm*. Because of its cardiac and pulmonary effects, propranolol is contraindicated for patients with asthma, sinus bradycardia, high-degree heart block, and heart failure.

49.10.1.4 Dosage and Administration.

Propranolol can be administered orally and, in life-threatening emergencies, by IV injection. Dosages with either route show wide individual variation. Oral dosages range from 10 to 80 mg every 6 to 8 hours. The usual IV dose is 1 to 3 mg injected at a rate of 1 mg/min.

49.10.2 Acebutolol

Acebutolol [Sectral] is a cardioselective beta blocker approved for oral therapy of VPBs. Adverse effects are like those of propranolol: bradycardia, heart failure, AV block, and—despite cardioselectivity—bronchospasm. Accordingly, acebutolol is contraindicated for patients with heart failure, severe bradycardia, AV block, and asthma. Acebutolol can also cause adverse immunologic reactions; titers of antinuclear antibodies may rise, resulting in myalgia, arthralgia, and arthritis. For suppression of VPBs, the initial dosage is 200 mg twice daily. Usual maintenance dosages range from 600 to 1200 mg/day.

49.10.3 Esmolol

Esmolol [Brevibloc] is a cardioselective beta blocker with a very short half-life (9 minutes). Administration is by IV infusion. The drug is employed for immediate control of ventricular rate in patients with atrial flutter and atrial fibrillation. Use is short term only (eg, in patients with dysrhythmias associated with surgery). The most common adverse reaction is hypotension. However, like other beta blockers, esmolol can also cause bradycardia, heart block, heart failure, and bronchospasm (at higher doses). In addition, pain can occur at the infusion site. Esmolol is available in two concentrations: 10 mg/mL and 250 mg/mL. *The concentrated formulation must be diluted prior to use.* Treatment is begun with a loading dose of 500 mcg/kg infused over 1 minute. The usual maintenance infusion rate is 100 mcg/kg/min.

^{49...} CLASS III: POTASSIUM CHANNEL BLOCKERS (DRUGS THAT DELAY REPOLARIZATION)

Five class III antidysrhythmics are available: bretylium, amiodarone, dofetilide, ibutilide, and sotalol (which is also a beta blocker). All five delay repolarization of fast potentials. Hence, all five prolong the action potential duration and ERP. By doing so, they prolong the QT interval. In addition, each drug can affect the heart in other ways, and hence they are not interchangeable.

^{49.11.1} Bretylium

Bretylium is used only for short-term therapy of severe ventricular dysrhythmias. The drug's principal adverse effect is profound hypotension.

^{49.11.1.1} Effects on the Heart and ECG.

Therapeutic effects result from blocking potassium channels in Purkinje fibers and ventricular muscle (see [Fig. 48-24](#)). By doing so, bretylium delays repolarization and thereby prolongs both the action potential duration and ERP. Because ventricular repolarization is delayed, the QT interval is prolonged.

When first administered, bretylium is taken up by sympathetic neurons, where it causes a transient increase in catecholamine release, followed by blockade of further release. In the heart, the initial increase in release can briefly exacerbate dysrhythmias. In blood vessels, extended blockade of release produces hypotension.

^{49.11.1.2} Adverse Effects.

Profound and persistent hypotension is the most troubling side effect. This reaction is common, occurring in up to 66% of patients. Blood pressure may fall in patients who are supine as well as in those who are standing. Hypotension results from blockade of norepinephrine release in sympathetic neurons that promote contraction of vascular smooth muscle. Continuous monitoring of blood pressure is required. If hypotension develops, blood pressure may be raised with dopamine or norepinephrine.

^{49.11.1.3} Therapeutic Use.

Bretylium is indicated for short-term therapy of ventricular fibrillation and recurrent ventricular tachycardia in patients who have been refractory to more conventional therapy (cardioversion, amiodarone). For these patients, bretylium may be lifesaving.

49.11.1.4 Preparations, Dosage, and Administration.

Bretylum is supplied in solution (2, 4, and 50 mg/mL). The drug must be diluted for certain applications. In all cases, the ECG and blood pressure should be monitored continuously.

49.11.1.4.1 Intravenous.

For nonemergency treatment, bretylium is administered by slow IV infusion. Rapid injection is reserved for emergencies. To manage ventricular fibrillation, the following protocol may be employed: (1) rapid IV injection of a 5-mg/kg dose, (2) rapid IV injection of additional doses (10 mg/kg) until the dysrhythmia has been controlled, and (3) slow IV infusion of maintenance doses (5 to 10 mg/kg) every 6 hours. (Maintenance doses are infused slowly because rapid administration results in nausea and vomiting. Initial doses are injected rapidly, despite the risk of nausea and vomiting, because of the need for rapid control of rhythm.)

49.11.1.4.2 Intramuscular.

Bretylum is used undiluted for IM injection. The initial dose is 5 to 10 mg/kg. Dosing may be repeated every 6 to 8 hours. The injection site should be rotated.

545

49.11.2 Amiodarone

546

Amiodarone [Cordarone, Pacerone] is a class III antidysrhythmic agent that has complex effects on the heart. The drug is highly effective against both atrial and ventricular dysrhythmias. Unfortunately, serious toxicities (eg, lung damage, visual impairment) are common, and may persist for months after treatment has stopped. Because of toxicity, amiodarone is *approved* only for life-threatening ventricular dysrhythmias that have been refractory to safer agents. Nonetheless, because of its efficacy, amiodarone is one of our most frequently prescribed antidysrhythmic drugs, used for atrial and ventricular dysrhythmias alike.

Amiodarone is available for oral and IV use. Indications, electrophysiologic effects, time course of action, and adverse effects differ for each route. Accordingly, oral and IV therapy are discussed separately.

49.11.2.1 Oral Therapy

49.11.2.1.1 Therapeutic Use.

Although amiodarone is very effective, concerns about toxicity limit its indications. In the United States, oral amiodarone is approved only for long-term therapy of two life-threatening

ventricular dysrhythmias: *recurrent ventricular fibrillation* and *recurrent hemodynamically unstable ventricular tachycardia*. Treatment should be reserved for patients who have not responded to safer drugs.

In addition to its approved uses, oral amiodarone has been used with success to convert *atrial fibrillation* to normal sinus rhythm, and to maintain normal sinus rhythm following conversion.

49.11.2.1.2 Effects on the Heart and ECG.

Amiodarone has complex effects on the heart. Like bretylium, amiodarone delays repolarization, and thereby prolongs the action potential duration and ERP. The underlying cause of these effects may be blockade of potassium channels. Additional cardiac effects include reduced automaticity in the SA node, reduced contractility, and reduced conduction velocity in the AV node, ventricles, and His-Purkinje system. These occur secondary to blockade of sodium channels, calcium channels, and beta receptors. Prominent effects on the ECG are QRS widening and prolongation of the PR and QT intervals. Amiodarone also acts on coronary and peripheral blood vessels to promote dilation.

49.11.2.1.3 Pharmacokinetics.

Amiodarone is highly lipid soluble and accumulates in many tissues, especially the liver and lungs. The drug is metabolized in the liver by CYP3A4 (the 3A4 isozyme of cytochrome P450) followed by excretion in the bile. Amiodarone has an extremely long half-life, ranging from 25 to 110 days. Because of its slow elimination, amiodarone continues to act long after dosing has ceased.

49.11.2.1.4 Adverse Effects.

Amiodarone produces many serious adverse effects. Furthermore, because the drug's half-life is protracted, toxicity can continue for weeks or months after drug withdrawal. To reduce adverse events, the Food and Drug Administration requires that all patients using amiodarone be given a Medication Guide describing potential toxicities.

49.11.2.1.4.1 Pulmonary Toxicity.

Lung damage—hypersensitivity pneumonitis, interstitial/alveolar pneumonitis, pulmonary fibrosis—is the greatest concern. Symptoms (dyspnea, cough, chest pain) resemble those of heart failure and pneumonia. Pulmonary toxicity develops in 2% to 17% of patients and carries a 10% risk of mortality. Patients at highest risk are those receiving long-term, high-

dose therapy. A baseline chest x-ray and pulmonary function test are required. Pulmonary function should be monitored throughout treatment.

49.11.2.1.4.2 Cardiotoxicity.

Amiodarone may cause a paradoxical increase in dysrhythmic activity. In addition, by suppressing the SA and AV nodes, the drug can cause sinus bradycardia and AV block. By reducing contractility, amiodarone can precipitate heart failure.

49.11.2.1.4.3 Toxicity in Pregnancy and Breast-feeding.

Amiodarone crosses the placental barrier and enters breast milk, and can thereby harm the developing fetus and breast-feeding infant. Accordingly, pregnancy and breast-feeding should be avoided while using the drug and for several months after stopping it.

49.11.2.1.4.4 Other Adverse Effects.

Virtually all patients develop *corneal microdeposits*, which may cause photophobia or blurred vision. *Optic neuropathy*, sometimes progressing to *blindness*, may also occur. Between 2% and 5% of patients experience *blue-gray discoloration of the skin*.

Gastrointestinal reactions (anorexia, nausea, vomiting) are common. Possible *CNS reactions* include ataxia, dizziness, tremor, mood alteration, and hallucinations. *Hepatitis and thyroid dysfunction* (hypothyroidism, hyperthyroidism) have occurred, and hence all patients should undergo periodic tests of liver and thyroid function.

49.11.2.1.5 Drug Interactions.

Amiodarone is subject to significant interactions with many drug. The result can be toxicity or reduced therapeutic effects. Accordingly, combined use with these drugs should be avoided. When it cannot, the patient should be monitored closely. Interactions of concern include the following:

- Amiodarone can *increase* levels of several drugs, including quinidine, procainamide, phenytoin, digoxin, diltiazem, warfarin, cyclosporine, and three statins: lovastatin, simvastatin, and atorvastatin. Dosages of these agents often require reduction.
- Amiodarone levels can be *increased* by grapefruit juice and by inhibitors of CYP3A4. Toxicity can result.
- Amiodarone levels can be *reduced* by cholestyramine (which decreases amiodarone absorption) and by agents that induce CYP3A4 (eg, St. John's wort, rifampin).

- The risk of severe dysrhythmias is increased by diuretics (because they can reduce levels of potassium and magnesium) and by drugs that prolong the QT interval, of which there are many (see [Chapter 7](#), [Table 7-2](#)).
- Combining amiodarone with a beta blocker, verapamil, or diltiazem can lead to excessive slowing of heart rate.

49.11.2.1.6 Dosage.

Oral amiodarone [Pacerone, Cordarone] is available in 100-, 200- and 400-mg tablets. Treatment should be initiated in a hospital. The following schedule is used for loading: 800 to 1600 mg daily for 1 to 3 weeks followed by 600 to 800 mg daily for 4 weeks. The daily maintenance dosage is 100 to 400 mg.

49.11.2.2 Intravenous Therapy

49.11.2.2.1 Therapeutic Use.

Intravenous amiodarone is approved only for initial treatment and prophylaxis of recurrent ventricular fibrillation and hemodynamically unstable ventricular tachycardia in patients refractory to safer drugs. For these indications, amiodarone may be more effective than IV bretylium.

In addition to its approved uses, IV amiodarone has been used with success against other dysrhythmias, including atrial fibrillation, AV nodal reentrant tachycardia, and shock-resistant ventricular fibrillation.

546

49.11.2.2.2 Effects on the Heart and ECG.

547

In contrast to oral amiodarone, which affects multiple aspects of cardiac function, IV amiodarone affects primarily the AV node. Specifically, the drug slows AV conduction and prolongs AV refractoriness. Both effects probably result from antiadrenergic actions. The mechanism underlying antidysrhythmic effects is unknown.

49.11.2.2.3 Adverse Effects.

The most common adverse effects are hypotension and bradydysrhythmias. Hypotension develops in 15% to 20% of patients, and may require discontinuation of treatment. Bradycardia or AV block occurs in 5% of patients; discontinuation of treatment or insertion of a pacemaker may be needed. Infused concentrations above 3 mg/mL (in 5% dextrose in water) produce a high incidence of phlebitis, and hence should be administered through a

central venous catheter. Torsades de pointes in association with QT prolongation occurs rarely.

49.11.2.2.4 Dosage.

Dosing is complex. During the first 24 hours, a total dose of 1050 mg is infused. After that, a maintenance infusion (0.5 mg/min) is given around the clock. The usual duration of treatment is 2 to 4 days. However, maintenance infusions may be continued for up to 3 weeks before switching to oral amiodarone.

49.11.3 Sotalol

49.11.3.1 Actions and Uses.

Sotalol [Betapace] is a beta blocker that also delays repolarization. Hence, the drug has combined class II and class III properties. Proarrhythmic properties are pronounced. Sotalol was initially approved only for ventricular dysrhythmias, such as sustained ventricular tachycardia, that are considered life threatening. In 1999, it was also approved for prophylaxis and treatment of atrial flutter and fibrillation, but only if symptoms are severe. The drug is not approved for hypertension or angina pectoris (the primary indications for other beta blockers).

49.11.3.2 Pharmacokinetics.

Sotalol is administered orally and undergoes nearly complete absorption. The drug is excreted unchanged in the urine. Its half-life is 12 hours.

49.11.3.3 Adverse Effects.

The major adverse effect is torsades de pointes, a serious dysrhythmia that develops in about 5% of patients. Risk is increased by hypokalemia and by other drugs that prolong the QT interval.

At therapeutic doses, sotalol produces substantial beta blockade. Hence, it can cause bradycardia, AV block, heart failure, and bronchospasm. Accordingly, the usual contraindications to beta blockers apply.

49.11.3.4 Preparations, Dosage, and Administration.

Sotalol is available in tablets (80, 120, 160, and 240 mg) for oral use. Treatment should start in a hospital. The initial dosage is 80 mg twice daily. The usual maintenance dosage is 160 to 320 mg/day in two or three divided doses. The dosing interval should be increased in patients with renal impairment.

49.11.4 Dofetilide

49.11.4.1 Therapeutic Use.

Dofetilide [Tikosyn] is an oral class III antidysrhythmic indicated for restoring and maintaining normal sinus rhythm in patients with atrial flutter or atrial fibrillation. The drug causes dose-related QT prolongation and thereby poses a serious risk of torsades de pointes. Accordingly, it should be reserved for patients with highly symptomatic atrial dysrhythmias. Initial treatment requires continuous ECG monitoring in a hospital. Dosage must be carefully titrated on the basis of renal function tests. Dofetilide is available only through authorized hospitals and prescribers.

49.11.4.2 Effects on the Heart and ECG.

Like other class III agents, dofetilide blocks cardiac potassium channels, and thereby delays repolarization, and hence prolongs the QT interval on the ECG. Dofetilide does not affect the PR interval or widen the QRS complex, and has no effect on cardiac beta receptors or sodium channels.

49.11.4.3 Pharmacokinetics.

Dofetilide is well absorbed (90%) both in the presence and absence of food. Very little is metabolized. About 80% of each dose is excreted in the urine, primarily unchanged. Renal excretion results largely from active tubular secretion, mediated by *cationic pumps* (ie, pumps specific for molecules that are cations). In patients with normal renal function, the drug's half-life is about 10 hours. However, in patients with renal impairment, the half-life is increased. In patients with moderate impairment, dosage must be reduced; in patients with severe impairment, dofetilide must not be used.

49.11.4.4 Adverse Effects.

By increasing the QT interval, dofetilide predisposes to *torsades de pointes*, which can progress to fatal ventricular fibrillation. The risk is directly related to dofetilide blood levels, and is increased by hypokalemia and by other drugs that cause QT prolongation. To assess risk, an ECG should be obtained at baseline, and ECG monitoring should be continuous during the initial phase of treatment. Dofetilide is contraindicated for patients with a baseline QT interval greater than 440 milliseconds (or greater than 500 milliseconds in patients with ventricular conduction abnormalities). Other side effects include headache (11%), chest pain (10%), and dizziness (8%).

49.11.4.5 Drug Interactions.

Drugs that are excreted by renal cation pumps can interfere with the excretion of dofetilide, thereby causing its levels to rise. Accordingly, concurrent use of these drugs (eg, cimetidine, trimethoprim, ketoconazole, prochlorperazine, megestrol) is contraindicated.

Drugs that prolong the QT interval may increase the risk of dysrhythmias, and hence should be avoided. Among these are class I and class III antidysrhythmics, phenothiazines, tricyclic antidepressants, and some macrolide antibiotics.

Combining verapamil with dofetilide increases the risk of torsades de pointes, and should be avoided.

49.11.4.6 Preparations, Dosage, and Administration.

Dofetilide [Tikosyn] is available in capsules (125, 250, and 500 mg) for oral administration. Because of the risk of dysrhythmias, treatment must be initiated in a hospital with *continuous ECG monitoring for at least 3 days*. Because dysrhythmia risk is directly related to plasma drug levels, which in turn are directly related to creatinine clearance (a measure of renal function), *creatinine clearance must be monitored*. Dosage should be reduced with decreasing creatinine clearance as follows: For patients with normal renal function (creatinine clearance greater than 60 mL/min), give 500 mg twice a day; for creatinine clearance 40 to 60 mL/min, give 250 mg twice a day; for creatinine clearance 20 to 39.9 mL/min, give 125 mg twice a day; and for creatinine clearance below 20 mL/min, withhold dofetilide. If the QT interval becomes excessively prolonged (greater than 500 milliseconds, or greater than 550 milliseconds in patients with ventricular conduction abnormalities), dosage should be reduced.

49.11.5 Ibutilide

Ibutilide [Corvert] is an IV agent used to terminate atrial flutter and atrial fibrillation of recent onset (ie, that has been present no longer than 90 days). Conversion to sinus rhythm occurs during the infusion or within 90 minutes of its termination. Ibutilide is more effective against atrial flutter (48% to 70% success) than atrial fibrillation (22% to 43% success). Like other class III agents, ibutilide blocks potassium channels and thereby prolongs the action potential duration and QT interval. Up to 8% of patients develop torsades de pointes, frequently in association with QT prolongation. Oral doses are teratogenic and embryocidal in rats. For patients who weigh over 60 kg, the dosage is 1 mg infused over 10 minutes. If the dysrhythmia does not convert within 10 minutes of terminating the infusion, a second 1-mg infusion may be tried.

^{49...} CLASS IV: CALCIUM CHANNEL BLOCKERS

Only two calcium channel blockers—verapamil [Calan, Isoptin, Verelan] and diltiazem [Cardizem, others]—are able to block calcium channels in the heart. Accordingly, they are the only calcium channel blockers used to treat dysrhythmias. Their basic pharmacology is discussed in [Chapter 44](#). Consideration here is limited to use against dysrhythmias.

^{49.12.1} Effects on the Heart and ECG.

Blockade of cardiac calcium channels has three effects:

- Slowing of SA nodal automaticity
- Delay of AV nodal conduction
- Reduction of myocardial contractility

Note that these are identical to the effects of beta blockers, which makes sense in that beta blockers promote calcium channel closure in the heart. The principal effect on the ECG is prolongation of the PR interval, reflecting delayed AV conduction.

^{49.12.2} Therapeutic Uses.

Verapamil and diltiazem have two antidysrhythmic uses. First, they can slow ventricular rate in patients with atrial fibrillation or atrial flutter. Second, they can terminate SVT caused by an AV nodal reentrant circuit. In both cases, benefits derive from suppressing AV nodal conduction. With IV administration, effects can be seen in 2 to 3 minutes. Verapamil and diltiazem are not active against ventricular dysrhythmias.

547

548

^{49.12.3} Adverse Effects.

Although generally safe, these drugs *can* cause undesired effects. Blockade of cardiac calcium channels can cause *bradycardia*, *AV block*, and *heart failure*. Blockade of calcium channels in vascular smooth muscle can cause vasodilation, resulting in *hypotension* and *peripheral edema*. Blockade of calcium channels in intestinal smooth muscle can produce *constipation*.

^{49.12.4} Drug Interactions.

Both verapamil and diltiazem can elevate levels of *digoxin*, thereby increasing the risk of digoxin toxicity. Also, since digoxin shares with verapamil and diltiazem the ability to decrease AV conduction, combining digoxin with either drug increases the risk of AV block.

Because verapamil, diltiazem, and *beta blockers* have nearly identical suppressant effects on the heart, combining verapamil or diltiazem with a beta blocker increases the risk of bradycardia, AV block, and heart failure.

49.12.5 Preparations, Dosage, and Administration.

49.12.5.1 Verapamil.

Dosing may be IV or oral. Intravenous therapy is preferred for initial treatment. Oral therapy is used for maintenance.

Verapamil for intravenous use is supplied in solution (5 mg/2 mL). The initial dose is 5 to 10 mg injected slowly (over 2 to 3 minutes). If the dysrhythmia persists, an additional 10 mg may be administered in 30 minutes. An IV infusion (0.375 mg/min) can be used for maintenance. Intravenous verapamil can cause serious cardiovascular effects. Accordingly, blood pressure and the ECG should be monitored, and equipment for resuscitation should be immediately available.

Verapamil for oral use is available in immediate- and sustained-release tablets. The maintenance dosage is 40 to 120 mg 3 or 4 times a day.

49.12.5.2 Diltiazem.

Like verapamil, diltiazem may be given IV or PO. Intravenous therapy is preferred for initial treatment, and oral therapy is used for maintenance.

Intravenous therapy is initiated with an IV bolus (0.25 mg/kg). If the response is inadequate, a second bolus (0.35 mg/kg) may be administered in 15 minutes. If appropriate, initial therapy may be followed with a continuous IV infusion (up to 24 hours' duration) at a rate of 5 to 15 mg/hr.

49... OTHER ANTIDYSRHYTHMIC DRUGS

49.13.1 Adenosine

Adenosine [Adenocard], a naturally occurring nucleotide, is a drug of choice for terminating paroxysmal SVT. The drug has an extremely short half-life, and hence must be administered IV. Adverse effects are minimal because adenosine is rapidly cleared from the blood.

49.13.1.1 Effects on the Heart and ECG.

Adenosine decreases automaticity in the SA node and greatly slows conduction through the AV node. The most prominent ECG change is prolongation of the PR interval, brought on by delayed AV conduction. Adenosine works in part by inhibiting cyclic AMP–induced calcium influx, thereby suppressing calcium-dependent action potentials in the SA and AV nodes.

49.13.1.2 Therapeutic Use.

Adenosine is approved only for termination of paroxysmal SVT, including Wolff-Parkinson-White syndrome. The drug is not active against atrial fibrillation, atrial flutter, or ventricular dysrhythmias.

49.13.1.3 Pharmacokinetics.

Adenosine has an extremely short plasma half-life (estimated at 1.5 to 10 seconds) owing primarily to rapid uptake by cells, and partly to deactivation by circulating adenosine deaminase. Because of its rapid clearance from the blood, adenosine must be administered by IV bolus, as close to the heart as possible.

49.13.1.4 Adverse Effects.

Adverse effects are short lived, lasting less than 1 minute. The most common are sinus bradycardia, dyspnea (from bronchoconstriction), hypotension and facial flushing (from vasodilation), and chest discomfort (perhaps from stimulation of pain receptors in the heart).

49.13.1.5 Drug Interactions.

Methylxanthines (aminophylline, theophylline, caffeine) block receptors for adenosine. Hence, asthma patients taking aminophylline or theophylline need larger doses of adenosine, and even then adenosine may not work.

Dipyridamole, an antiplatelet drug, blocks cellular uptake of adenosine, and can thereby intensify its effects.

49.13.1.6 Preparations, Dosage, and Administration.

Adenosine [Adenocard] is supplied in solution (3 mg/mL) for bolus IV administration. The injection should be made as close to the heart as possible, and should be followed by a saline flush. The initial dose is 6 mg. If there is no response in 1 or 2 minutes, 12 mg may be tried and

repeated once. If a response is going to occur, it should happen as soon as the drug reaches the AV node.

49.13.2 Digoxin

Although its primary indication is heart failure, digoxin [Lanoxin] is also used to treat supraventricular dysrhythmias. The basic pharmacology of digoxin is discussed in [Chapter 47](#). Consideration here is limited to treatment of dysrhythmias.

49.13.2.1 Effects on the Heart.

Digoxin suppresses dysrhythmias by decreasing conduction through the AV node and by decreasing automaticity in the SA node. The drug decreases AV conduction by (1) a direct depressant effect on the AV node and by (2) acting in the CNS to increase vagal (parasympathetic) impulses to the AV node. Digoxin decreases automaticity of the SA node by increasing vagal traffic to the node and by decreasing sympathetic traffic. It should be noted that, although digoxin decreases automaticity in the SA node, it can *increase* automaticity in *Purkinje fibers*. The latter effect contributes to dysrhythmias *caused* by digoxin.

49.13.2.2 Effects on the ECG.

By slowing AV conduction, digoxin prolongs the PR interval. The QT interval may be shortened, reflecting accelerated repolarization of the ventricles. Depression of the ST segment is common. The T wave may be depressed or even inverted. There is little or no change in the QRS complex.

49.13.2.3 Adverse Effects and Interactions.

The major adverse effect is *cardiotoxicity* (dysrhythmias). Risk is increased by hypokalemia, which can result from concurrent therapy with diuretics (thiazides and high-ceiling agents). Accordingly, it is essential that potassium levels be kept within the normal range (3.5 to 5 mEq/L). The most common adverse effects are GI disturbances (anorexia, nausea, vomiting, abdominal discomfort). CNS responses (fatigue, visual disturbances) are also relatively common.

49.13.2.4 Antidysrhythmic Uses.

Digoxin is used only for supraventricular dysrhythmias. The drug is inactive against ventricular dysrhythmias.

49.13.2.4.1 Atrial Fibrillation and Atrial Flutter.

Digoxin can be used to slow ventricular rate in patients with atrial fibrillation and atrial flutter. Ventricular rate is decreased by reducing the number of atrial impulses that pass through the AV node.

49.13.2.4.2 Supraventricular Tachycardia.

Digoxin may be employed acutely and chronically to treat SVT. Acute therapy is used to abolish the dysrhythmia. Chronic therapy is used to prevent its return. Digoxin suppresses SVT by increasing cardiac vagal tone and by decreasing sympathetic tone.

49.13.2.5 Dosage and Administration.

Oral therapy is generally preferred. The initial dosage is 1 to 1.5 mg administered in three or four doses over 24 hours. The maintenance dosage is 0.125 to 0.5 mg/day.

49... NONDRUG TREATMENT OF DYSRHYTHMIAS

49.14.1 Implantable Cardioverter-Defibrillators

ICDs are surgically implanted devices that monitor and analyze cardiac rhythm and, by delivering electrical shocks to the heart, terminate any dysrhythmias that develop. Termination is accomplished with either (1) a series of pacing stimuli, which are usually imperceptible; or (2) a defibrillating shock, which can be painful. It is important to note that ICDs do not prevent dysrhythmias. Rather, they neutralize the ones that occur. ICDs are indicated for patients with recurrent ventricular fibrillation or sustained ventricular tachycardia. For these patients, ICDs significantly reduce the risk of sudden death. The major complication associated with ICDs is mortality during surgical implantation. The mortality rate had been as high as 8%, but is declining due to use of newer techniques. ICDs cost about \$20,000 to \$25,000. The cost for implantation, including hospitalization, adds another \$30,000 to \$50,000.

548

549

49.14.2 Radiofrequency Catheter Ablation

Radiofrequency (RF) catheter ablation is a technique in which cardiac tissue responsible for causing a dysrhythmia is identified and destroyed. The result is often permanent cure. In preparation for RF ablation, the patient undergoes electrophysiologic cardiac testing to identify the small region of the heart that is generating the dysrhythmia. Next, an RF catheter is placed at the site. Activation of the catheter generates RF energy, which heats (and thereby destroys) all tissue within 5 to 8 mm of the catheter tip. Destruction of the offending tissue eliminates the

dysrhythmia. Success rates depend on the dysrhythmia being treated. In patients with atrial tachycardia, AV nodal reentrant tachycardia, or dysrhythmias associated with Wolff-Parkinson-White syndrome, the rate of permanent cure is between 90% and 100%. In patients with atrial flutter, initial responses are generally good, but recurrence is common. Complications develop in less than 5% of procedures. The most common complications are AV block and myocardial perforation. Complications that require intervention or that result in long-term injury occur in only 1% of patients. For treatment of atrial dysrhythmias, catheter ablation costs about \$25,000 to \$30,000.

49.14.2.1

KEY POINTS

- Dysrhythmias result from alteration of the electrical impulses that regulate cardiac rhythm. Antidysrhythmic drugs control rhythm by correcting or compensating for these alterations.
- In the healthy heart, the SA node is the pacemaker.
- Impulses originating in the SA node must travel through the AV node to reach the ventricles. Impulses arriving at the AV node are delayed before going on to excite the ventricles.
- The His-Purkinje system conducts impulses rapidly throughout the ventricles, thereby causing all parts of the ventricles to contract in near synchrony.
- The heart employs two kinds of action potentials: fast potentials and slow potentials.
- Fast potentials occur in the His-Purkinje system, atrial muscle, and ventricular muscle.
- Slow potentials occur in the SA node and AV node.
- Phase 0 of fast potentials (depolarization) is generated by rapid influx of sodium. Because depolarization is fast, these potentials conduct rapidly.
- During phase 2 of fast potentials, calcium enters myocardial cells, thereby promoting contraction.
- Phase 3 of fast potentials (repolarization) is generated by rapid extrusion of potassium.
- Phase 0 of slow potentials (depolarization) is caused by slow influx of calcium. Because depolarization is slow, these potentials conduct slowly.

- Spontaneous phase 4 depolarization—of fast or slow potentials—confers automaticity upon cells. Spontaneous phase 4 depolarization of cells in the SA node normally determines heart rate.
- The P wave of an ECG is caused by depolarization of the atria.
- The QRS complex is caused by depolarization of the ventricles. Widening of the QRS complex indicates slowed conduction through the ventricles.
- The T wave is caused by repolarization of the ventricles.
- The PR interval represents the time between onset of the P wave and onset of the QRS complex. PR prolongation indicates delayed AV conduction.
- The QT interval represents the time between onset of the QRS complex and completion of the T wave. QT prolongation indicates delayed ventricular repolarization.
- Dysrhythmias arise from disturbances of impulse formation (automaticity) or impulse conduction.
- Reentrant dysrhythmias result from a localized, self-sustaining circuit capable of repetitive cardiac stimulation.
- Tachydysrhythmias can be divided into two major groups: supraventricular dysrhythmias and ventricular dysrhythmias. In general, ventricular dysrhythmias disrupt cardiac pumping more than do supraventricular dysrhythmias.
- Treatment of supraventricular tachydysrhythmias is often directed at blocking impulse conduction through the AV node, rather than at eliminating the dysrhythmia.
- Treatment of ventricular dysrhythmias is usually directed at eliminating the dysrhythmia.
- All antidysrhythmic drugs are also prodysrhythmic (proarrhythmic). That is, they all can worsen existing dysrhythmias and generate new ones.
- Class I antidysrhythmic drugs block cardiac sodium channels, and thereby slow impulse conduction through the atria, ventricles, and His-Purkinje system.
- Slowing ventricular conduction widens the QRS complex.
- Quinidine (a class IA drug) blocks sodium channels and delays ventricular repolarization. Delaying ventricular repolarization prolongs the QT interval.

- Quinidine causes diarrhea and other GI symptoms in 33% of patients. These effects frequently force drug withdrawal.
- Quinidine can cause dysrhythmias. Widening of the QRS complex (by 50% or more) and excessive prolongation of the QT interval are warning signs.
- Quinidine elevates digoxin levels. If the drugs are used together, digoxin dosage must be reduced.
- Class IB agents differ from class IA agents in two ways: they accelerate repolarization and have little or no effect on the ECG.

549

- Lidocaine (a class IB agent) is used only for ventricular dysrhythmias. The drug is not active against supraventricular dysrhythmias.
- Lidocaine undergoes rapid inactivation by the liver. As a result, the drug must be administered by continuous IV infusion.
- Propranolol and other class II drugs block cardiac β_1 receptors.
- By blocking cardiac β_1 receptors, propranolol attenuates sympathetic stimulation of the heart, and thereby decreases SA nodal automaticity, AV conduction velocity, and myocardial contractility.
- By decreasing AV conduction velocity, propranolol prolongs the PR interval.
- The effects of propranolol on the heart result (ultimately) from suppressing calcium entry. Hence, the effects of propranolol and the effects of calcium channel blockers are nearly identical.
- Propranolol is especially useful for treating dysrhythmias caused by excessive sympathetic stimulation of the heart.
- In patients with supraventricular tachydysrhythmias, propranolol helps by (1) slowing discharge of the SA node and (2) decreasing conduction through the AV node, which prevents the atria from driving the ventricles at an excessive rate.
- Class III antidysrhythmics block potassium channels, and thereby delay repolarization of fast potentials. As a result, they prolong the action potential duration and the effective refractory period. By delaying ventricular repolarization, they prolong the QT interval.

550

- Bretylium (a class III agent) is used only for short-term therapy of severe ventricular dysrhythmias that have been refractory to safer treatments.
- Bretylium blocks release of norepinephrine from sympathetic nerves, and thereby causes profound and persistent hypotension in up to 66% of patients.
- Amiodarone (a class III agent) is highly effective against atrial and ventricular dysrhythmias, but can cause multiple serious adverse effects, including damage to the lungs, eyes, liver, and thyroid.
- Verapamil and diltiazem (class IV antidysrhythmics) block cardiac calcium channels, and thereby reduce automaticity of the SA node, slow conduction through the AV node, and decrease myocardial contractility. These effects are identical to those of the beta blockers.
- By suppressing AV conduction, verapamil and diltiazem prolong the PR interval.
- Verapamil and diltiazem are used to slow ventricular rate in patients with atrial fibrillation or atrial flutter and to terminate SVT caused by an AV nodal reentrant circuit. In both cases, benefits derive from suppressing AV nodal conduction.
- Adenosine is a drug of choice for terminating paroxysmal SVT.
- Adenosine has a very short half-life (less than 10 seconds), and hence must be given by IV bolus.

49.14.2.2

Summary of Major Nursing Implications*

Summaries are limited to the major antidysrhythmic drugs. Summaries for beta blockers (propranolol, acebutolol, and esmolol), phenytoin, calcium channel blockers (verapamil and diltiazem), and digoxin appear in [Chapters 18](#), [24](#), [44](#), and [47](#), respectively.

49.14.2....

QUINIDINE

49.14.2....

Preadministration Assessment

49.14.2....

Therapeutic Goal

The usual goal is long-term suppression of atrial and ventricular dysrhythmias.

49.14.2....

Baseline Data

Obtain a baseline ECG and laboratory evaluation of liver function. Determine blood pressure.

49.14.2....

Identifying High-Risk Patients

Quinidine is *contraindicated* for patients with a history of hypersensitivity to quinidine or other cinchona alkaloids and for patients with complete heart block, digoxin intoxication, or conduction disturbances associated with marked QRS widening and QT prolongation.

Exercise *caution* in patients with partial AV block, heart failure, hypotensive states, and hepatic dysfunction.

49.14.2....

Implementation: Administration

49.14.2....

Routes

49.14.2....

Usual Route.

Oral.

49.14.2....

Rare Routes.

IM and IV.

49.14.2....

Administration

Before giving full therapeutic doses, assess for hypersensitivity by giving a small test dose (200 mg PO or IM).

Advise patients to take quinidine with meals. Warn them not to crush or chew sustained-release formulations.

Dosing must account for the particular quinidine salt being used: 200 mg of quinidine sulfate is equivalent to 275 mg of quinidine gluconate.

49.14.2....	Ongoing Evaluation and Interventions	
49.14.2....	Evaluating Therapeutic Effects Monitor for beneficial changes in the ECG. Plasma drug levels should be kept between 2 and 5 mcg/mL.	
49.14.2....	Minimizing Adverse Effects	
49.14.2....	Diarrhea. Diarrhea and other GI disturbances occur in one third of patients and frequently force drug withdrawal. To reduce these effects, administer quinidine with meals.	550
49.14.2....	Cinchonism. Inform patients about symptoms of cinchonism (tinnitus, headache, nausea, vertigo, disturbed vision), and instruct them to notify the prescriber if these develop.	551
49.14.2....	Cardiotoxicity. Monitor the ECG for signs of cardiotoxicity, especially widening of the QRS complex (by 50% or more) and excessive prolongation of the QT interval. Monitor pulses for significant changes in rate or regularity. If signs of cardiotoxicity develop, withhold quinidine and notify the prescriber.	
49.14.2....	Arterial Embolism. Embolism may occur during therapy of atrial fibrillation. The risk can be reduced with warfarin (an anticoagulant). Observe for signs of thromboembolism (eg, sudden chest pain, dyspnea) and report these immediately.	
49.14.2....	Minimizing Adverse Interactions	
49.14.2....	Digoxin. Quinidine can double digoxin levels. When these drugs are combined, digoxin dosage should be reduced. Monitor patients for digoxin toxicity (dysrhythmias).	

PROCAINAMIDE

Preadministration Assessment

Therapeutic Goal

Procainamide is indicated for acute and long-term management of ventricular and supraventricular dysrhythmias. Because procainamide can be toxic with long-term use, quinidine is preferred to procainamide for chronic suppression.

Baseline Data

Obtain a baseline ECG, complete blood count, and laboratory evaluations of liver and kidney function. Determine blood pressure.

Identifying High-Risk Patients

Procainamide is *contraindicated* for patients with systemic lupus erythematosus (SLE), complete AV block, and second-degree or third-degree AV block in the absence of an electronic pacemaker.

Exercise *caution* in patients with hepatic or renal dysfunction or a history of procaine allergy.

Implementation: Administration

Routes

Oral, IM, IV.

Administration

Instruct patients to administer procainamide at evenly spaced intervals around the clock. Warn patients not to crush or chew sustained-release formulations.

When switching from IV procainamide to oral procainamide, allow 3 hours to elapse between stopping the infusion and giving the first oral dose.

Give IM injections deep into the gluteal muscle.

49.14.2....

Ongoing Evaluation and Interventions

49.14.2....

Evaluating Therapeutic Effects

Monitor the ECG for beneficial changes. Plasma drug levels should be kept between 3 and 10 mcg/mL.

49.14.2....

Minimizing Adverse Effects

49.14.2....

SLE-like Syndrome.

Prolonged therapy can produce a syndrome resembling SLE. **Inform patients about manifestations of SLE (joint pain and inflammation; hepatomegaly; unexplained fever; soreness of the mouth, throat, or gums), and instruct them to notify the prescriber if these develop.** If SLE is diagnosed, procainamide should be discontinued. If discontinuation is impossible, signs and symptoms can be controlled with a nonsteroidal anti-inflammatory drug (eg, aspirin) or a glucocorticoid. The ANA titer should be measured periodically and, if it rises, procainamide withdrawal should be considered.

49.14.2....

Blood Dyscrasias.

Procainamide can cause agranulocytosis, thrombocytopenia, and neutropenia. Deaths have occurred. Obtain complete blood counts weekly during the first 3 months of treatment and periodically thereafter. **Instruct patients to inform the prescriber at the first sign of infection (fever, chills, sore throat), bruising, or bleeding.** If subsequent blood counts indicate hematologic disturbance, discontinue procainamide immediately.

49.14.2....

Cardiotoxicity.

Procainamide can cause dysrhythmias. Monitor pulses for changes in rate or regularity. Monitor the ECG for excessive QRS widening (greater than 50%) and for PR prolongation. If these occur, withhold procainamide and notify the prescriber.

49.14.2....

Arterial Embolism.

Embolism may occur during therapy of atrial fibrillation. The risk can be reduced with warfarin. Observe for signs of thromboembolism (eg, sudden chest pain, dyspnea) and report these immediately.

49.14.2....	LIDOCAINE	
49.14.2....	Preadministration Assessment	
49.14.2....	Therapeutic Goal Acute management of ventricular dysrhythmias.	
49.14.2....	Baseline Data Obtain a baseline ECG and determine blood pressure.	
49.14.2....	Identifying High-Risk Patients Lidocaine is <i>contraindicated</i> for patients with StokesAdams syndrome, Wolff-Parkinson-White syndrome, and severe degrees of SA, AV, or intraventricular block in the absence of electronic pacing. Exercise <i>caution</i> in patients with hepatic dysfunction or impaired hepatic blood flow.	
49.14.2....	Implementation: Administration

49.14.2....	IM.	551
49.14.2....	Administration	552
49.14.2....	Intravenous. Make certain the lidocaine preparation is labeled for IV use (ie, is devoid of preservatives and catecholamines). Dilute concentrated preparations with 5% dextrose in water.	

The initial dose is 50 to 100 mg (1 mg/kg) infused at a rate of 25 to 50 mg/min. For maintenance, monitor the ECG and adjust the infusion rate on the basis of cardiac response. The usual rate is 1 to 4 mg/min.

49.14.2....

Intramuscular.

Reserve for emergencies. The usual dose is 300 mg injected into the deltoid muscle. Switch to IV lidocaine as soon as possible.

49.14.2....

Ongoing Evaluation and Interventions

49.14.2....

Evaluating Therapeutic Effects

Continuous ECG monitoring is required. Plasma drug levels should be kept between 1.5 and 5 mcg/mL.

49.14.2....

Minimizing Adverse Effects

Excessive doses can cause convulsions and respiratory arrest. Equipment for resuscitation should be available. Convulsions can be managed with diazepam or phenytoin.

* Patient education information is highlighted as **blue text**.

⁵⁰CHAPTER 49 Prophylaxis of Coronary Heart Disease: Drugs That Help Normalize Cholesterol and Triglyceride Levels

Marshal Shlafer

Our main topic for the chapter is drugs used to lower cholesterol. Drugs used to lower triglycerides are considered as well. Why focus on cholesterol? Because of its impact on *coronary artery atherosclerosis* (thickening of the coronary arteries), also known as coronary heart disease (CHD). Moderate CHD manifests as anginal pain. Severe CHD sets the stage for myocardial infarction (MI; heart attack). In the United States, CHD is the leading killer of men and women, causing over 450,000 deaths in 2004 alone. According to the American Heart Association, about 16 million Americans alive today have a history of coronary events (angina, MI, or both). More than half of these people are women. Additional sobering statistics are presented in [Table 49-1](#).

Until recently, atherosclerosis was largely a disease of older people. Not so any more. Why? Because lifestyles have changed. A generation ago, diets included generally healthy made-from-scratch “balanced” meals, and on nice days the children were shooed out of the house to play. Nowadays, we're so busy that fast-food restaurants and heat-and-eat meals are the new tradition, even though (or because?) they may be loaded with all sorts of heart-unhealthy fats, along with the heart's other big enemy: salt. And while many youngsters are shuttled off to school, then to soccer, then to baseball, track, or swimming, too many others seem to be in competition for Couch-Potato-of-the-Year. So now, rather than developing CHD in their fourth or fifth decade, people are getting the disease sooner, as can be attested to by attending clinicians and the pathologists doing the autopsies. Of course, this disturbing trend couldn't possibly apply to the young students reading this book.

How does atherosclerosis develop? It begins as a fatty streak in the arterial wall. This is followed by deposition of fibrous plaque. As atherosclerotic plaque grows, it impedes coronary blood flow, causing anginal pain. Worse yet, coronary atherosclerosis encourages formation of thrombi, which can block flow entirely, thereby causing MI.

It is important to appreciate that atherosclerosis is not limited to arteries of the heart: Atherosclerotic plaque can develop in any artery, and can thereby compromise circulation to any tissue. Furthermore, adverse effects can occur at sites distant from the original lesion: A ruptured lesion can produce a thrombus, which can travel downstream to block a new vessel. Blockage in the lungs and brain is of particular concern.

The risk of developing CHD is directly related to increased levels of blood cholesterol, in the form of low-density lipoproteins (LDLs). By reducing levels of LDL cholesterol, we can slow progression of atherosclerosis, reduce the risk of serious CHD, and prolong life. The preferred method for lowering LDL cholesterol is modification of diet combined with exercise. Drugs are employed only when diet modification and exercise are insufficient.

We approach our primary topic—cholesterol and its impact on CHD—in three stages. First, we discuss cholesterol itself, plasma lipoproteins (structures that transport cholesterol in blood), and the process of atherogenesis. Second, we discuss guidelines for cholesterol screening and management of high cholesterol. Third, we discuss the pharmacology of the cholesterol-lowering drugs, as well as drugs used to lower triglycerides.

553

554

TABLE 49-1 Morbidity and Mortality from Cardiovascular Disease in General, and Coronary Heart Disease in Particular, United States

Cardiovascular Disease of All Types

- Cardiovascular disease took nearly 870,000 lives in 2004 (the latest year for which good data are available)—accounting for 36% of all deaths that year, regardless of cause. In 2004, the number of deaths from cardiovascular disease was about
 - 1.6 times the number of deaths from all cancers
 - 8 times the number of deaths caused by accidents
 - 55 times the number of deaths from HIV/AIDS

Coronary Heart Disease

- Coronary heart disease (CHD), characterized by buildup of atherosclerotic plaque in coronary arteries, is the major cause of angina pectoris, heart attacks, and death.
- In 2004, CHD caused 451,326 deaths, and it is the single leading cause of death in the United States today.
- Each year, about 310,000 people die of heart attacks, either in an emergency department or without being hospitalized. Most of these are sudden deaths caused by cardiac arrest, usually resulting from ventricular fibrillation (a cardiac dysrhythmia that is fatal within seconds of onset).
- 16 million people alive today have a history of heart attack, angina pectoris, or both—roughly 8.7 million males and 7.3 million females.
- Each year, about 1.2 million Americans will have a new or recurrent heart attack.

Modified from data published by the American Heart Association (www.americanheart.org/presenter.jhtml?identifier=4478).

50.1 CHOLESTEROL

Cholesterol has many physiologic roles. Of greatest importance, cholesterol is a component of all cell membranes and membranes of intracellular organelles. In addition, cholesterol is required for synthesis of certain hormones (estrogen, progesterone, testosterone, adrenal corticosteroids) and for synthesis of bile salts, which are needed to absorb and digest dietary fats. Also, cholesterol is deposited in the stratum corneum of the skin, where it reduces evaporation of water and blocks transdermal absorption of water-soluble compounds.

Some of our cholesterol comes from dietary sources (exogenous cholesterol) and some is manufactured by cells (endogenous cholesterol), primarily in the liver. More cholesterol comes from endogenous production than from the diet. A critical step in hepatic cholesterol synthesis is catalyzed by an enzyme named hydroxymethylglutaryl coenzyme A reductase, or simply HMG-CoA reductase. As discussed below, drugs that inhibit this enzyme—the statins—are our most widely used cholesterol-lowering agents.

An increase in dietary cholesterol produces only a small increase in cholesterol in the blood, primarily because increased ingestion of cholesterol inhibits endogenous cholesterol synthesis. Interestingly, an increase in dietary saturated fats produces a substantial (15% to 25%) increase in circulating cholesterol. Why? Because the liver uses saturated fats to make cholesterol. Accordingly, when we want to reduce cholesterol levels, it is more important to reduce intake of saturated fats than to reduce intake of cholesterol itself, although cholesterol intake should definitely be lowered.

50.2 PLASMA LIPOPROTEINS

50.2.1 Structure and Function of Lipoproteins

50.2.1.1 Function.

Lipoproteins serve as carriers for transporting lipids—cholesterol and triglycerides—in blood. Like all other nutrients and metabolites, lipids use the bloodstream to move throughout the body. However, since cholesterol and triglycerides are not water soluble, these substances cannot dissolve directly in plasma. Lipoproteins represent a means of solubilizing these lipids, thereby permitting transport.

50.2.1.2 Basic Structure.

The basic structure of lipoproteins is depicted in [Figure 49-1](#). As indicated, lipoproteins are tiny, spherical structures that consist of a *hydrophobic core*, composed of cholesterol and triglycerides, surrounded by a *hydrophilic shell*, composed primarily of phospholipids. Because the hydrophilic (water-soluble) shell completely covers the lipid core, the entire structure is soluble in plasma.

50.2.1.3 Apolipoproteins.

All lipoproteins have one or more *apolipoprotein* molecules embedded in their shell (see [Fig. 49-1](#)). Apolipoproteins, which constitute the protein component of lipoproteins, have three functions:

- They serve as recognition sites for cell-surface receptors, and thereby allow cells to bind with and ingest lipoproteins.
- They activate enzymes that metabolize lipoproteins.
- They increase the structural stability of lipoproteins.

The apolipoproteins of greatest clinical interest are labeled A-I, A-II, and B-100. All lipoproteins that deliver cholesterol and triglycerides to nonhepatic tissues contain *apolipoprotein B-100*. Conversely, all lipoproteins that transport lipids from nonhepatic tissues back to the liver (ie, that remove lipids from tissues) contain *apolipoprotein A-I*.

50.2.2 Classes of Lipoproteins

There are six major classes of plasma lipoproteins. Distinctions among classes are based on size, density, apolipoprotein content, transport function, and primary core lipids (cholesterol or triglyceride). From a pharmacologic perspective, the features of greatest interest are *lipid content*, *apolipoprotein content*, and *transport function*.

The topic of lipoprotein density deserves comment for two reasons. First, naming of lipoprotein types is based on their density. Second, differences in density provide the basis for the physical isolation and subsequent measurement of plasma lipoproteins, as is done in research and clinical laboratories. The various classes of lipoproteins differ in density because they differ in their percent composition of lipid and protein. Because protein is more dense than lipid, lipoproteins that have a high percentage of protein (and a low percentage of lipid) have a relatively high density. Conversely, lipoproteins with a lower percentage of protein have a lower density.

554

555

Of the six major classes of lipoproteins, three are especially important in coronary atherosclerosis. These classes are named (1) very-low-density lipoproteins (VLDLs), (2) low-density lipoproteins (LDLs), and (3) high-density lipoproteins (HDLs). Properties of these classes are summarized in [Table 49-2](#).

50.2.2.1 Very-Low-Density Lipoproteins

VLDLs contain *triglycerides* (and some cholesterol) as their core lipids, and account for nearly all of the triglycerides in blood. The main physiologic role of VLDLs is to *deliver triglycerides* from the liver to adipose tissue and muscle. Each VLDL particle contains one molecule of *apolipoprotein B-100*, which allows VLDLs to bind with cell-surface receptors and thereby transfer their lipid content to cells.

The role of VLDLs in atherosclerosis is unclear. Although several studies suggest a link between elevated levels of VLDLs and development of atherosclerosis, this link has not been firmly established. However, we do know that elevation of triglyceride levels (above 500 mg/dL) increases the risk of *pancreatitis*.

50.2.2.2 Low-Density Lipoproteins

LDLs contain *cholesterol* as their primary core lipid, and they account for the majority (60% to 70%) of all cholesterol in blood. The physiologic role of LDLs is *delivery of cholesterol to nonhepatic tissues*. Each LDL particle contains one molecule of *apolipoprotein B-100*, which is needed for binding of

Figure 49-1 Basic structure of plasma lipoproteins.

LDL particles to LDL receptors on cells. LDLs can be viewed as by-products of VLDL metabolism, in that the lipids and apolipoproteins that compose LDLs are remnants of VLDL degradation.

Cells that require cholesterol meet their needs through endocytosis (engulfment) of LDLs from the blood. The process begins with binding of LDL particles to LDL receptors on the surface of the cells. When cellular demand for cholesterol increases, cells synthesize more LDL receptors and thereby increase their capacity for LDL uptake. Cells that are unable to make more LDL receptors cannot increase cholesterol absorption. Increasing the number of LDL receptors on cells is an important mechanism by which certain drugs increase LDL uptake, and thereby reduce LDL levels in blood.

Of all lipoproteins, LDLs make the greatest contribution to coronary atherosclerosis. The probability of developing CHD is directly related to the level of LDLs in blood. Conversely, by reducing LDL levels, we decrease the risk of CHD. Accordingly, *when cholesterol-lowering drugs are used, the primary goal is to reduce elevated LDL levels.* Multiple studies have shown that, by reducing LDL levels, we can arrest or perhaps even reverse atherosclerosis, and can thereby reduce mortality from CHD. In fact, for each 1% reduction in the LDL level, there is a 1% reduction in the risk of a major cardiovascular (CV) event.

There is growing evidence that a genetic variant of LDL, known as *lipoprotein(a)* [Lp(a)], may be the form of LDL that is most responsible for increasing cardiovascular risk, especially in certain ethnic groups. However, since this evidence is limited, and since we lack drugs that specifically target Lp(a), we don't routinely measure Lp(a) levels in our patients.

50.2.2.3 High-Density Lipoproteins

Like LDLs, HDLs contain *cholesterol* as their primary core lipid, and account for 20% to 30% of all cholesterol in blood. In contrast to LDLs, whose function is delivery of cholesterol to peripheral tissues, HDLs carry cholesterol from peripheral tissues back to the liver. That is, *HDLs promote cholesterol removal.*

The influence of HDLs on CHD is dramatically different from that of LDLs. Whereas elevation of LDLs *increases* the risk of CHD, elevation of HDLs *reduces* the risk of CHD. That is, high HDL levels actively protect against CHD.

Not all HDL particles are the same. Some contain only apolipoprotein A-I, whereas others contain apolipoproteins A-I *and* A-II. Available data suggest that cardioprotection is conferred by the HDLs that contain only *apolipoprotein A-I*.

TABLE 49-2 Properties of the Plasma Lipoproteins That Affect Atherosclerosis

Lipoprotein Class*	Major Core Lipids	Apolipoproteins	Transport Function	Influence on Atherosclerosis
VLDL	Triglycerides	B-100, E, others	Delivery of triglycerides to nonhepatic tissues	<i>Probably contribute to atherosclerosis</i>
LDL	Cholesterol	B-100	Delivery of cholesterol to nonhepatic tissues	<i>Definitely contribute to atherosclerosis</i>
HDL	Cholesterol	A-I, A-II, A-IV	Transport of cholesterol from nonhepatic tissues back to the liver	<i>Protect against atherosclerosis</i>

* VLDL = very-low-density lipoproteins, LDL = low-density lipoproteins, HDL = high-density lipoproteins.

555

50.2.3 LDL Cholesterol Versus HDL Cholesterol

556

From the foregoing, it is clear that not all cholesterol in plasma has the same impact on CHD. As discussed, a rise in cholesterol associated with LDLs increases the risk of CHD. In contrast, a rise in cholesterol associated with HDLs lowers the risk of CHD. Consequently, when speaking of plasma cholesterol levels, we need to distinguish between cholesterol that is associated with HDLs and cholesterol that is associated with LDLs. To make this distinction, we use the terms *HDL cholesterol* and *LDL cholesterol*. Because it promotes atherosclerosis, LDL cholesterol has been dubbed *bad cholesterol*. Conversely, because it protects against atherosclerosis, HDL cholesterol is often called *good cholesterol* or *healthy cholesterol*.

50.3 ROLE OF LDL CHOLESTEROL IN ATHEROSCLEROSIS

LDLs initiate and fuel development of atherosclerosis. The process begins with transport of LDLs from the arterial lumen into endothelial cells, and from there into the space that underlies the arterial

epithelium. Once in the subendothelial space, components of LDLs undergo *oxidation*. This step is critical in that oxidized LDLs

- Attract monocytes from the circulation into the subendothelial space, after which the monocytes are converted to macrophages
- Inhibit macrophage mobility, thereby keeping macrophages at the site of atherogenesis
- Undergo uptake by macrophages (macrophages do not take up LDLs that have not been oxidized)
- Are cytotoxic, and hence can damage the vascular endothelium directly

As macrophages engulf more and more cholesterol, they become large and vacuolated. When macrophages assume this form, they are referred to as *foam cells*. Accumulation of foam cells beneath the arterial epithelium produces a fatty streak, which makes the surface of the arterial wall lumpy. Continued accumulation of foam cells can eventually cause rupture of the endothelium, thereby exposing the underlying tissue to the blood. This results in platelet adhesion and formation of microthrombi. As the process continues, smooth muscle cells migrate to the site, synthesis of collagen increases, and there can be repeated rupturing and healing of the endothelium. The end result is a mature atherosclerotic lesion, characterized by a large lipid core and a tough fibrous cap. In less mature lesions, the fibrous cap is not strong, and hence the lesions are unstable. As a result, arterial pressure and shear forces from moving blood can cause the cap to rupture; accumulation of platelets at the site of rupture can rapidly cause thrombosis, and can thereby cause infarction. Infarction is less likely at sites of mature atherosclerotic lesions. The atherosclerotic process is depicted in [Figure 49-2](#).

It is important to appreciate that atherogenesis involves more than just deposition of lipids. In fact, atherogenesis is now considered primarily a chronic *inflammatory process*. When LDLs penetrate the arterial wall, they cause mild injury. The injury, in turn, triggers an inflammatory response, causing infiltration of macrophages, T lymphocytes, and other mediators of inflammation (eg, C-reactive protein [CRP]). In the late stage of the disease process, inflammation can weaken atherosclerotic plaque, leading to rupture of the plaque and subsequent thrombosis. The roles of inflammation and CRP in atherothrombosis are discussed further in [Box 49-1](#) later in the chapter.

50.4 DETECTION, EVALUATION, AND TREATMENT OF HIGH CHOLESTEROL: RECOMMENDATIONS FROM ATP III

It is well established that high cholesterol levels cause substantial morbidity and mortality, and that aggressive treatment can save lives. Accordingly, periodic cholesterol screening and risk assessment are recommended. If the assessment indicates CHD risk, lifestyle changes—especially diet and exercise—should be implemented. If CHD risk is especially high, LDL-lowering drugs should be added to the regimen.

In 1988, the National Cholesterol Education Program (NCEP) began issuing guidelines on cholesterol detection and management. The most recent update was issued in 2001 and amended in 2004. A summary of the 2001 guidelines—*Executive Summary of the Third Report of the National Cholesterol Education Program Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults* (also known as Adult Treatment Panel III or simply ATP III)—was published in *JAMA* (Vol. 285, No. 19, 2486–2497, 2001) and is available online at www.nhlbi.nih.gov/guidelines/cholesterol/atp3xsum.pdf. The 2004 changes to the 2001 guidelines were published in *Circulation* (Vol. 110, 227–239, 2004) and are available online at www.nhlbi.nih.gov/guidelines/cholesterol/atp3upd04.pdf. Previous NCEP guidelines were issued in 1988 (ATP I) and 1993 (ATP II). The discussion below reflects recommendations in ATP III, including the 2004 updates. The next update of these guidelines—ATP IV—is scheduled for release in 2010.

Like earlier NCEP guidelines, ATP III focuses on the role of high cholesterol in CHD and stresses the importance of treatment. However, owing to revised risk assessment criteria, ATP III recommends drug therapy for many more Americans: about 50 million, compared with only 13 million under ATP II. In addition, ATP III addresses two new concerns: *elevated triglycerides* and *metabolic syndrome* (formerly known as syndrome X or insulin resistance syndrome).

50.4.1 Cholesterol Screening

50.4.1.1 Adults

Management of high LDL cholesterol begins with screening, generally done every 5 years for adults over the age of 20. Under ATP II, only LDL and total cholesterol were usually measured. In contrast, ATP III recommends a more thorough screen, consisting of total cholesterol, LDL cholesterol, HDL cholesterol, and triglycerides (TGs). Blood for these tests should be drawn

after fasting. Classification of total cholesterol and LDL cholesterol in ATP III ([Table 49-3](#)) is nearly identical to the classification in ATP II. The only change is that optimal LDL cholesterol is now defined as less than 100 mg/dL, compared with less than 130 mg/dL under ATP II. In addition, the cutoff for *low* HDL cholesterol is now less than 40 mg/dL, up from less than 35 mg/dL under ATP II. (Recall

557

TABLE 49-3 Health Classification of Blood Cholesterol and Triglyceride Levels*

Cholesterol Type	Level (mg/dL)	Classification
LDL cholesterol	<100	Optimal
	100–129	Near optimal/above optimal
	130–159	Borderline high
	160–189	High
	≥190	Very high
Total cholesterol	<200	Desirable
	200–239	Borderline high
	≥240	High
HDL cholesterol	<40	Low
	≥60	High
Triglycerides	<150	Normal
	150–199	Borderline-high
	200–499	High
	≥500	Very high

* Cholesterol values are from the Executive Summary of the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). JAMA 285:2486–2497, 2001. Triglyceride values are from the National Heart, Lung, and Blood Institute of the National Institutes of Health (nhlbisupport.com/chd1/tri.htm).

50.4.1.2 Children and Adolescents

Elevated cholesterol in pediatric patients is a growing concern, and is not addressed in ATP III. Accordingly, in order to identify risk early in life and begin timely intervention, the American Academy of Pediatrics developed guidelines for lipid screening and treatment in at-risk children and adolescents. This document—*Lipid Screening and Cardiovascular Health in Childhood*—was published in the July 2008 issue of *Pediatrics* and is available online at

pediatrics.aappublications.org/cgi/reprint/122/1/198. Cholesterol classification for children and adolescents is presented in [Table 49-4](#).

Who should be tested? The guideline recommends screening for all children and adolescents with a family history of high cholesterol or heart disease. It also recommends screening children whose family history is unknown, as well as children who have other risk factors for heart disease, including obesity, high blood pressure, and diabetes.

When should screening begin? Long before it usually does. The Academy recommends screening for high-risk children when they reach age 2 years, and no later than age 10. If a child has values within the normal range, testing should be repeated in 3 to 5 years. The best method for testing is a fasting lipid profile.

If LDL cholesterol is high, what should be done? For children who are more than 8 years old, a cholesterol-reducing drug (ie, statin) should be considered. Younger patients should focus on weight reduction and increased activity. All patients should receive nutritional counseling. The statement also recommends switching to reduced-fat dairy products, such as 2% milk, for children as young as 1 year of age for whom overweight or obesity is a concern.

TABLE 49-4 NCEP Classification of Cholesterol Levels in Children 2 to 9 Years Old Who Have Premature Cardiovascular Disease or a Familial History of Hypercholesterolemia*

Category	Total Cholesterol (mg/dL)	LDL Cholesterol (mg/dL)
Acceptable	<170	<110
Borderline	170–199	110–129
Elevated	≥200	≥130
Data from National Cholesterol Education Program: Report of the Expert Panel on Blood Cholesterol Levels in Children and Adolescents. <i>Pediatrics</i> 89(3 Pt 2):525–584, 1992.		

* HDL levels should be greater than or equal to 35 mg/dL and triglycerides should be less than or equal to 150 mg/dL.

TABLE 49-5 Major Risk Factors (Other Than High LDL Cholesterol) That Modify LDL Treatment Goals

Positive Risk Factors <ul style="list-style-type: none">• Age:<ul style="list-style-type: none">• Men 45 yr or older• Women 55 yr or older• Family history of premature CHD in a first-degree relative:<ul style="list-style-type: none">• Male first-degree relative less than 55 yr old <i>or</i>• Female first-degree relative less than 65 yr old• Hypertension:<ul style="list-style-type: none">• Blood pressure 140/90 mm Hg or higher <i>or</i>• Taking antihypertensive medication• Current cigarette smoking (smoked at least 1 in the last month)• Low HDL cholesterol (below 40 mg/dL)
Negative Risk Factor <ul style="list-style-type: none">• High HDL cholesterol (60 mg/dL or higher)*
From the Executive Summary of the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). JAMA 285:2486–2497, 2001.
* High HDL cholesterol (60 mg/dL or higher) is protective, and hence counts as a “negative” risk factor; its presence removes one risk factor from the total count.

50.4.2 CHD Risk Assessment

Under ATP III, CHD risk assessment is directed at determining the patient's *absolute risk of developing clinical coronary disease over the next 10 years*. The LDL goal and the mode of intervention are determined by the individual's degree of risk.

50.4.2.1 Factors in Risk Assessment

In order to assess the CHD risk for an individual, we need three kinds of information. Specifically, we need to (1) identify CHD risk factors, (2) calculate 10-year CHD risk, and (3) identify CHD risk equivalents.

50.4.2.1.1 Identifying CHD Risk Factors.

Major risk factors that modify LDL treatment goals are summarized in [Table 49-5](#). The table lists five positive risk factors (advancing age, family history of premature CHD, hypertension, cigarette smoking, and low HDL cholesterol) and one negative risk factor (high HDL cholesterol). (LDL itself is not listed because the reason for counting these risk factors is to modify treatment of high LDL.) For the purpose of CHD risk assessment, each positive factor counts as 1 point; if the patient has high HDL cholesterol (a negative risk factor), 1 point is subtracted. For example, if the subject were a 62-year-old female hypertensive smoker with an HDL level of 62 mg/dL, her point total score would be 2 (3 points for the three positive risk factors minus 1 point for the one negative risk factor).

50.4.2.1.1.1 BOX 49-1 Special Interest Topic

50.4.2.1.1.1.1 INFLAMMATION, C-REACTIVE PROTEIN, AND CARDIOVASCULAR RISK

Although we know about some risk factors for CHD—advancing age, obesity, hypertension, diabetes, smoking, high LDL cholesterol, and sedentary lifestyle—it is clear that other risk factors must exist. Why? Because many young, lean, active, normotensive, nondiabetic, nonsmokers with low cholesterol still manage to die from MI. Obviously, additional risk factors must be involved. The leading suspect is inflammation.

There is good evidence that inflammation plays a central role in atherosclerosis. Although inflammation normally protects tissues, it can also do harm. For example, inflammation in the lungs leads to bronchospasm in asthma, and inflammation of joints underlies tissue injury in arthritis. In arteries, inflammation appears to set the stage for atherogenesis. In addition, inflammation may weaken the surface of atherosclerotic

plaques, thereby increasing the risk of plaque rupture. Factors that might evoke an inflammatory response include smoking, diabetes, and infection.

The strongest evidence implicating inflammation in CHD comes from measuring plasma levels of *C-reactive protein* (CRP), a compound that is produced when inflammation occurs. Large amounts are produced during major inflammatory disorders (eg, arthritis, infection), causing blood levels of CRP to climb very high. In contrast, relatively small amounts are produced by inflammation in arteries. Nonetheless, these amounts are still big enough to cause a measurable increase in blood levels, albeit much smaller than the increase seen in conditions like arthritis or infection. Please note that CRP itself is harmless: The compound is simply a *biomarker* for ongoing inflammatory processes; it does not cause injury by itself.

In clinical studies, elevation of CRP has been associated with increased CV risk. For example, in the *Physicians' Health Study*, high levels of CRP predicted danger 6 to 8 years *in advance*: Among people with no prior CV events, high levels of CRP were associated with a threefold increased risk of heart attacks and a twofold increased risk of stroke. In the *Women's Health Study*, similar results were obtained: Over an 8-year period, women with the highest levels of CRP experienced 4.5 times as many heart attacks or strokes as did women with the lowest levels. Furthermore, not only did elevated CRP predict CV risk, it did so for women whose LDL cholesterol was *normal*—not just those whose LDL cholesterol was high. This is important. Why? Because it means that elevated CRP is an *independent* risk factor for CV events; it's not simply a surrogate for LDL cholesterol. Hence, measuring CRP *and* LDL cholesterol might identify different risk groups.

Cardiovascular protection conferred by aspirin and statins may result in part from anti-inflammatory actions. It is well known that aspirin suppresses platelet aggregation, and thereby helps protect against MI. However, there is evidence that aspirin is most beneficial in patients with high levels of CRP, suggesting that aspirin's anti-inflammatory actions may also contribute to CV benefits. Likewise, it is well known that statins reduce LDL cholesterol levels, and thereby protect against CHD. However, in patients with *normal* cholesterol levels and high levels of CRP, pravastatin still offers protection. Specifically, the drug can lower CRP levels by 17% and reduce the risk of recurrent MI—again suggesting that anti-inflammatory actions may partly explain clinical benefits.

Given that elevated CRP may predict CV events, should we screen people to see if their CRP is high? Yes, we should, according to a 2003 statement issued by an expert panel convened jointly by the American Heart Association (AHA) and the Centers for Disease Control and Prevention (CDC). However, the AHA/CDC panel does not recommend screening for everyone. Rather, screening should be limited to patients deemed at *intermediate* CV risk (ie, having a 10% to 20% risk of developing CHD in the next 10 years) as indicated by their age, LDL cholesterol level, and other traditional risk criteria. The panel does not recommend screening for patients considered at high or low risk. Why? Because the test results are unlikely to reveal information that would alter treatment decisions: With people at high risk, we already have sufficient information to guide treatment; with people at low risk, CRP tests are unlikely to reveal a previously unknown risk that would indicate a need for treatment.

How should CRP be tested? The AHA/CDC panel recommends using a *high-sensitivity CRP* (hsCRP) test, rather than a conventional CRP test, even though both tests measure the same molecule (CRP). Why use the high-sensitivity test? Because it can accurately measure *low levels* of CRP (1 to 10 mg/L)—levels in the range affected by arterial inflammation. The conventional test cannot accurately measure levels this low. Because levels of hsCRP can vary over time, two tests should be done, about 2 weeks apart. The degree of CV risk associated with specific hsCRP levels is as follows:

- Less than 1 mg/L = low risk
- 1 to 3 mg/L = average risk
- More than 3 mg/L = high risk

People in the high-risk group have a twofold greater risk of an adverse CV event compared with people in the low-risk group.

If the hsCRP level indicates high risk, what should be done? Recall that hsCRP testing is recommended only for patients already classified as having intermediate risk, as determined by traditional risk criteria. For these people, a high level of hsCRP would signal a need for more intensive intervention.

It is important to note that hsCRP should not be tested in the presence of trauma, infection, or systemic inflammatory disorders. Why? Because these conditions can raise

hsCRP levels substantially, up to 50 mg/L or even higher. Hence, if hsCRP test results were high, we couldn't tell if these conditions or vascular inflammation were the cause.

Does lowering CRP reduce CV risk? Yes! This was shown for the first time in two sister studies: the *Pravastatin or Atorvastatin Evaluation and Infection Therapy* (PROVE-IT) trial and the *Reversing Atherosclerosis with Aggressive Lipid Lowering* (REVERSAL) trial. In both studies, patients with existing CHD were randomized to receive either standard doses of pravastatin [Pravachol] or high doses of atorvastatin [Lipitor]. The results? In PROVE-IT, patients on the high-dose regimen experienced greater reductions in LDL and CRP levels than did patients on the standard regimen, and they also experienced fewer CV events. Furthermore, whether LDL levels were low or high, reducing CRP levels improved outcomes. The REVERSAL trial, which monitored progression of coronary atherosclerosis, produced parallel results. That is, reductions in LDL and CRP were independently associated with slowed progression of atheroma volume. In fact, among patients with the greatest reductions in LDL and CRP, atheroma volume actually declined.

The results of PROVE-IT and REVERSAL were reinforced and extended by a major new trial—*Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin* (JUPITER)—designed to see if statins can reduce CV events in people with elevated CRP, but with *healthy* levels of LDL cholesterol. The study enrolled nearly 18,000 healthy men and women with LDL cholesterol levels below 130 mg/dL, and with CRP levels of 2 mg/L or higher (ie, levels associated with increased cardiovascular risk). Half the participants received rosuvastatin (20 mg/day) and the other half received a daily placebo. JUPITER was supposed to last 4 years, but was stopped after just 1.9 years. Why? Because early results showed “unequivocal evidence” that rosuvastatin reduced cardiovascular morbidity and mortality: Compared with controls, the rosuvastatin group had a 55% relative reduction in nonfatal MI, a 48% reduction in nonfatal stroke, and a 47% reduction in “hard cardiac events,” defined as the combination of MI (fatal or not), stroke (fatal or not), the need for coronary vessel revascularization (eg, by angioplasty and placement of a stent), and overall death from cardiovascular causes. What was the effect on LDL cholesterol and CRP? Rosuvastatin reduced LDL cholesterol by 50% and CRP by 37%. By comparison, LDL cholesterol and CRP were largely unchanged in the control group. Some experts reviewing these results were underawed. Why? Because, although treatment produced a notable reduction in the *relative* risk, the reduction in *absolute* risk was less impressive.

As one authority calculated, we would have to treat 120 patients for nearly 2 years to prevent just one death from cardiovascular causes. Nonetheless, when we consider that millions of patients are at risk, this treatment could easily save tens of thousands of lives.

Taken together, the PROVE-IT, REVERSAL, and JUPITER studies indicate that reducing CRP levels with statins provides protection against CV events independent of the protection ascribable to reducing LDL.

Since we know that reducing CRP is beneficial, how can we do it? Interestingly, the same measures that reduce LDL cholesterol—healthy diet, exercise, weight loss, smoking cessation, and statin therapy—also reduce levels of CRP. Drugs designed specifically to reduce CRP are in development.

It should be noted that diabetes carries more weight in risk assessment in ATP III than in ATP II. Why? Because we now know that diabetes is a very strong predictor of developing CHD. Accordingly, we no longer consider diabetes to be a risk *factor* (as it was in ATP II). Instead, for the purpose of risk assessment, diabetes is now considered a CHD risk *equivalent*. That is, having diabetes is considered equivalent to having CHD as a predictor of a major coronary event.

[Box 49-1](#) discusses one additional factor—*C-reactive protein* (CRP)—that could aid with CHD risk prediction.

50.4.2.1.2

Calculating 10-Year CHD Risk.

ATP III defines three 10-year risk categories: more than 20%, 10% to 20%, and less than 10%. Some people are automatically in the highest risk group—specifically, those with existing CHD (or other forms of atherosclerotic disease) and those with diabetes. For all other people, 10-year risk must be calculated. The instrument employed is the Framingham Risk Prediction Score, which takes five factors into account: age, total cholesterol, HDL cholesterol, smoking status, and systolic blood pressure. Framingham scores can be determined using either (1) the tables for men and women shown in [Figure 49-3](#) or (2) a web-based risk calculator, such as the one provided by the NCEP at <http://2010.nhlbi.nih.net/atpiii/calculator.asp>.

50.4.2.1.3 Identifying CHD Risk Equivalents.

A CHD risk equivalent is a condition that poses the same risk of a major coronary event as does established CHD (ie, more than 20% risk of a major event within 10 years). There are three basic CHD risk equivalents:

- Diabetes
- Atherosclerotic disease other than CHD (peripheral arterial disease, abdominal aortic aneurysm, and symptomatic carotid artery disease)
- The presence of multiple risk factors that confer a Framingham Risk Prediction Score greater than 20%

50.4.2.2 Identifying an Individual's CHD Risk Category

Under ATP III, there are four categories of CHD risk, labeled I, II, III, and IV ([Table 49-6](#)). People in category I are at highest risk: Their risk of a major coronary event within 10 years is over 20%. In comparison, the 10-year risk for people in category IV is low—less than 10%.

Category assignment is based on (1) the presence or absence of CHD (or a CHD risk equivalent, such as diabetes), (2) the number of risk factors the individual has (other than high LDL cholesterol), and (3) the individual's 10-year Framingham Risk Prediction Score. Although this assessment sounds complicated, it's not. Let's consider the hypothetical case of Ralph J.—and follow along by looking at [Figure 49-3](#). Mr. J. is 62 years old, hypertensive, and smokes—but, remarkably, his HDL cholesterol is high (above 60 mg/dL). He has no family history of premature CHD, does not have CHD himself, and does not have diabetes. His 10-year Framingham Risk Prediction Score is 10.2%.

560

Figure 49-3 **Tables for calculating Framingham Risk Prediction Scores.** To determine an individual's 10-year risk of developing clinical coronary disease, simply circle the appropriate points for each of the five risk factors considered (age, total cholesterol, smoking status, HDL cholesterol, and systolic blood pressure) and then add up the points. The point total indicates the 10-year risk. For example, a total of 13 points indicates a 10-year risk of 12% for men.

Estimate of 10-year risk for MEN						Estimate of 10-year risk for WOMEN					
Age						Age					
Points						Points

17						17					

(Framingham scores can also be determined using a web-based calculator, such as the one provided by the NCEP at <http://2010.nhlbihin.net/atpiii/calculator.asp>.)

tionScore is 11%. What CHD risk category does he belong in? Well, his age, blood pressure, and smoking status represent three major risk factors, but his high (healthy) HDL cholesterol allows subtraction of one risk factor, leaving a net of two major risk factors. The presence of two major risk factors plus the 11% Framingham score place Mr. J. in CHD risk category II (the next to highest risk group). Pretty easy, huh? And even easier if you use an online computational tool, such as the ones available at www.framinghamheartstudy.org/risk/index.html.

TABLE 49-6 LDL Cholesterol Goals and Therapeutic Interventions for People in Specific CHD Risk Categories

CHD Risk Category	LDL Goal	LDL Level at Which to Initiate TLCs*	LDL Level at Which to Consider Drug Therapy
I <i>High Risk</i> : Has CHD or a CHD risk equivalent† (10-year risk is >20%)	<100 mg/dL (with an optional goal of <70 mg/dL)‡	Any level	≥100 mg/dL (at <100 mg/dL, LDL-lowering drugs are optional)§
II <i>Moderately High Risk</i> : Has 2 or more risk factors, but not CHD, and 10-year risk is 10–20%	<130 mg/dL (with an optional goal of <100 mg/dL)	Any level	≥130 mg/dL (between 100 and 129 mg/dL, LDL-lowering drugs are optional)§
III <i>Moderate Risk</i> : Has 2 or more risk factors, but not CHD, and 10-year risk is <10%	<130 mg/dL	≥130 mg/dL	≥160 mg/dL
IV <i>Low to Moderate Risk</i> : Has 0–1 risk factor, but not CHD (10-year risk is probably <10%)¶	<160 mg/dL	≥160 mg/dL	≥190 mg/dL (between 160 and 189 mg/dL, LDL-lowering drugs are optional)
Modified from the Executive Summary of the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). JAMA 285:2486–2497, 2001; as updated in Implications of Recent Clinical Trials for the National Cholesterol Education Program Adult Treatment Panel III Guidelines. Circulation 110:227–239, 2004.			

* TLCs = therapeutic lifestyle changes.

† CHD risk equivalents include diabetes, forms of atherosclerosis other than CHD (eg, peripheral arterial disease, symptomatic coronary artery disease), and any combination of risk factors that creates a 10-year Framingham Risk Prediction Score of greater than 20%.

- ‡ For patients at very high risk (eg, those with a recent heart attack or those with CV disease combined with diabetes), the LDL goal may be set at less than 70 mg/dL, rather than 100 mg/dL.
- § When LDL-lowering drugs are used in patients at high risk or moderately high risk, treatment should be sufficient to decrease the LDL level by 30% to 40%.
- ¶ Almost all people with 0 to 1 risk factor and no CHD have a 10-year risk below 10%, and hence formal evaluation of 10-year risk is not needed.

Risk category IV deserves comment. People assigned to this group have either no CHD risk factors or just one, and do not have CHD. As a rule, their 10-year CHD risk is not calculated. Why? Because there's no need: With so few risk factors, their 10-year risk is almost always below 10%.

50.4.2.3 Final Note: Each Type of Dyslipidemia a Patient Has Contributes Independently to CHD Risk

Patients are likely to have more than one type of dyslipidemia—for example, high LDL cholesterol combined with low HDL cholesterol and high triglycerides—and each of these disorders contributes *independently* to cardiovascular risk. This means that fixing one just one of these problems will not eliminate the risk posed by the others. Accordingly, to get maximal risk reduction, we must correct all lipid abnormalities that are present.

50.4.3 Treatment of High LDL Cholesterol

Treatment of high LDL cholesterol is based on the individual's CHD risk category: The greater the 10-year risk, the more aggressive the treatment. As CHD risk increases, the target LDL goal gets lower, as does the LDL level at which treatment should commence. For example, among individuals in risk category I, the LDL goal is quite low (below 100 mg/dL—or below 70 in people at highest risk), compared with the higher goal (below 160 mg/dL) for people in category IV. Similarly, for individuals in category I, drugs are recommended if the LDL level is 100 mg/dL or above, compared with a much higher value (190 mg/dL or above) for those in category IV. [Table 49-6](#) summarizes the LDL goal and the LDL levels at which to initiate treatment for people in all four CHD risk categories.

To reduce LDL levels, ATP III recommends two forms of intervention: (1) therapeutic lifestyle changes (TLCs) and (2) drug therapy. For some people, cholesterol can be reduced adequately

with TLCs alone. Others require TLCs *plus* cholesterol-lowering drugs. Please note: Drugs should be used only as an *adjunct* to TLCs—not as a *substitute*.

50.4.3.1 Therapeutic Lifestyle Changes

Therapeutic lifestyle changes are nondrug measures used to lower LDL cholesterol. TLCs focus on three main issues: diet, weight control, and exercise. The measures are first-line treatment for LDL reduction, and should be implemented before trying drugs. Unfortunately, TLCs can be a challenge. Furthermore, arthritis and other physical conditions can limit attempts at exercise.

50.4.3.1.1 The TLC Diet.

This diet has two objectives: (1) reducing LDL cholesterol and (2) establishing and maintaining a healthy weight. The central feature of the diet is reduced intake of cholesterol and saturated fats: Individuals should limit intake of cholesterol to 200 mg/day or less and intake of saturated fat to 7% or less of total calories. Intake of *trans fats*—found primarily in crackers, commercial baked goods, and French fries—should be minimized. ATP III recommendations for cholesterol, fats, and other nutrients are summarized in [Table 49-7](#). A list of specific foods to choose or avoid appears in [Table 49-8](#).

If the basic TLC diet fails to lower LDL cholesterol adequately, ATP III recommends two additional measures: increased intake of soluble fiber (10 to 25 gm/day) and increased intake of plant stanols and sterols (2 gm/day). Oatmeal is a good source of soluble fiber. Plant stanols and sterols are available in the form of cholesterol-lowering margarines, commonly advertised as “buttery spreads” (see below under *Plant Stanol and Sterol Esters*).

50.4.3.1.2 Weight Control.

Being overweight or obese is a major risk factor for CHD. Conversely, weight loss can reduce both LDL cholesterol and CHD risk. Weight loss is especially important for people with metabolic syndrome (see below). In ATP III, achieving a healthy weight is encouraged for all people.

50.4.3.1.3 Exercise.

A sedentary lifestyle carries an increased risk of CHD. Conversely, performing regular exercise lowers CHD risk. Running and swimming, for example, can decrease LDL cholesterol and elevate HDL cholesterol, thereby reducing risk. In addition, exercise can

reduce blood pressure, decrease insulin resistance, and improve overall CV performance. Accordingly, ATP III encourages regular physical activity (defined as 30 to 60 minutes of activity on most days). Improvements in the plasma lipid profile depend more on the total time spent exercising than on the intensity of exercise or improvements in fitness.

50.4.3.1.4 Smoking Cessation.

Smoking cigarettes raises LDL cholesterol and lowers HDL cholesterol, thereby increasing the risk of CHD. Smokers should be strongly encouraged to quit—and nonsmokers should be urged not to start.

50.4.3.2 Drug Therapy

Drugs are not the first-line therapy for lowering LDL cholesterol. Rather, drugs should be employed only if TLCs fail to reduce LDL cholesterol to an acceptable level—and then only if the combination of elevated LDL cholesterol and the patient's CHD risk category justify drug use (see [Table 49-6](#)). When drugs are employed, it is essential that dietary modification continues. Why? Because the beneficial effects of diet and drugs are additive; drugs alone may be unable to achieve the LDL goal.

[Table 49-9](#) summarizes properties of the drug families used to lower LDL cholesterol. The most effective agents are the *HMG-CoA reductase inhibitors* (eg, atorvastatin [Lipitor]), usually referred to simply as *statins*. Lesser used alternatives are *bile-acid sequestrants* (eg, cholestyramine) and *nicotinic acid* (niacin). Although fibrates are listed in [Table 49-9](#), these drugs are used primarily to reduce levels of TGs—not LDLs. Treatment is initiated with a single drug, almost always a statin. If the statin is ineffective, a bile-acid sequestrant or nicotinic acid can be added to the regimen. Because LDL cholesterol levels will return to pretreatment values if drugs are withdrawn, *treatment must continue lifelong*. Patients should be made aware of this requirement. It is important to note that the principal benefit of drug therapy is *primary prevention*: Drugs are much better at preventing or retarding CHD than at promoting regression of established coronary atherosclerosis.

In addition to lowering LDL cholesterol, drugs may be used to raise HDL cholesterol. The most effective agents are nicotinic acid and the fibrates. However, as indicated in [Table 49-9](#), virtually all of the drugs that we use to lower LDL cholesterol have the added benefit of increasing HDL cholesterol, at least to some degree.

TABLE 49-7 Nutrient Composition of the TLC Diet Described in ATP III

Nutrient	Recommended Intake
Cholesterol	Less than 200 mg/day
Saturated fat [*]	Less than 7% of total calories
Polyunsaturated fat	Up to 10% of total calories
Monounsaturated fat	Up to 20% of total calories
Total fat	25–35% of total calories
Carbohydrates [†]	50–60% of total calories
Protein	About 15% of total calories
Fiber	20–30 gm/day
Total calories [‡]	Balance energy intake and expenditure to maintain a desirable body weight or prevent weight gain
From the Executive Summary of the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). JAMA 285:2486–2497, 2001.	
TLC = therapeutic lifestyle changes.	

* *Trans*-fatty acids should be kept to a minimum.

† Carbohydrates should be derived mainly from foods rich in complex carbohydrates, such as fruits, vegetables, and grains (especially whole grains).

‡ Daily energy expenditure should include at least moderate physical activity (contributing about 200 kcal/day).

50.4.4 Secondary Treatment Targets

50.4.4.1 Metabolic Syndrome

The term *metabolic syndrome* refers to a group of metabolic abnormalities associated with an increased risk of CHD and type 2 diabetes. The metabolic abnormalities involved are high blood glucose, high triglycerides, high apolipoprotein B, low HDL, small LDL particles, a prothrombotic state, and a proinflammatory state. Hypertension is both common and important. Metabolic syndrome is also known as *syndrome X*.

How is metabolic syndrome diagnosed? The ATP III panel proposed a simple set of diagnostic criteria, which was modified slightly in 2005 by a joint panel of the American Heart Association and the National Heart, Lung, and Blood Institute. According to the modified criteria, metabolic syndrome is diagnosed when three or more of the following are present:

- *Abdominal obesity*—waist circumference 40 inches or more for most men or 35 inches or more for most women (lower limits appear appropriate for Asian Americans)
- *High TG levels*—150 mg/dL or higher (or undergoing drug therapy for high TGs)
- *Low HDL cholesterol*—below 40 mg/dL for men or below 50 mg/dL for women (or undergoing drug therapy for reduced HDL)
- *Hyperglycemia*—fasting blood glucose 110 mg/dL or higher (or undergoing drug therapy for hyperglycemia)
- *High blood pressure*—130/85 mm Hg or higher (or undergoing drug therapy for hypertension)

563

TABLE 49-8 Recommended Dietary Modifications to Lower Serum Cholesterol

Food Type	Recommendation	
	Choose	Decrease
Fish, chicken, turkey, and lean meats	Fish; poultry without skin; lean cuts of beef, lamb, pork, or veal; shellfish	Fatty cuts of beef, lamb, or pork; spareribs; organ meats; regular cold cuts; sausage; hot dogs
Milk, cheese, yogurt, and dairy products	Skim and 1% fat milk (liquid, powdered, evaporated), buttermilk	4% fat milk (regular, evaporated, condensed), 2% fat milk, cream, half-and-half, imitation milk products, most nondairy creamers, whipped toppings
	Nonfat (%) or low-fat yogurt	Whole-milk yogurt
	Low-fat cottage cheese (1% or 2% fat)	Whole-milk cottage cheese (4%)
	Low-fat cheeses, farmer or pot cheeses (all of these cheeses should have no more than 2–6 gm of fat per ounce)	All-natural cheeses (eg, blue, Roquefort, Camembert, cheddar, Swiss)
		Cream cheese (including low-fat and “light” types), sour cream (including low-fat and “light” types)
	Sherbet, sorbet	Ice cream
Eggs	Egg whites (2 whites = 1 whole egg in recipes), cholesterol-free egg substitutes	Egg yolks*
Fruits and vegetables	Fresh, frozen, canned, and dried fruits and vegetables	Vegetables prepared in butter, cream, and other sauces
Breads and cereals	Homemade baked goods using unsaturated oils sparingly, angel food cake, low-fat crackers, low-fat cookies	Commercial baked goods: pies, cakes, muffins, doughnuts, croissants, biscuits, high-fat crackers, high-fat cookies
	Rice, pasta	Egg noodles
	Whole-grain breads and cereals (oatmeal, whole wheat, rye, bran, multigrain, etc.)	Breads in which eggs are a major ingredient

Fats and oils	Unsaturated vegetable oils: corn, olive, canola (rapeseed), safflower, sesame, soybean, sunflower oils	Butter, the so-called tropical oils (coconut oil, palm oil, palm kernel oil), lard, bacon fat
	Margarine (regular or diet), [†] shortening made from one of the unsaturated oils listed above	
	Mayonnaise, salad dressings made with one of the unsaturated oils listed above; low-fat or (preferred) fat-free dressings	Dressings made with egg yolk
	Seeds and nuts (especially walnuts)	Coconut
	Baking cocoa	Chocolate
From the National Cholesterol Education Program Adult Treatment Panel report. Arch Intern Med 148:36, 1988.		

* *Author's note:* Consuming up to 1 egg/day is not associated with an increased risk of fatal or nonfatal MI or ischemic or hemorrhagic stroke, except possibly in people with diabetes.

† *Author's note:* Since the publication of this table in 1988, new evidence indicates that *stick* margarine (but probably not newer low-fat spreads), which contains 17% trans fat, raises LDL cholesterol and lowers HDL cholesterol, and hence should not be recommended.

Treatment has two primary goals: reducing the risk of atherosclerotic disease and reducing the risk of type 2 diabetes. According to ATP III, basic therapy consists of weight reduction and increased physical activity, which, together, can reduce all symptoms of the metabolic syndrome. In addition, specific treatment should be directed at lowering blood pressure and TG levels. Patients should take low-dose aspirin to reduce the risk of thrombosis, unless they are at high risk of intracranial bleeds (hemorrhagic stroke).

Although the term *metabolic syndrome* is widely used, there is debate about its clinical relevance. In the cardiovascular community, most clinicians believe the term has great utility. By contrast, in the diabetes community, many clinicians feel the term is misleading, in that it implies the existence of a specific disease entity, even though it is defined only by a cluster of risk factors that may or may not have a common underlying cause. Furthermore, they point out that the risk associated with a diagnosis of metabolic syndrome is no greater than the sum of the risks of its components. Accordingly, until there is more proof that the metabolic syndrome actually exists, they believe the term serves no clinical purpose and hence should be avoided.

This position was voiced in a joint statement from the American Diabetes Association and the European Association for the Study of Diabetes. The American Heart Association and the National Heart, Lung, and Blood Institute countered with a joint statement of their own, reasserting their belief that the metabolic syndrome is an important clinical entity. Although the two camps disagree about whether the metabolic syndrome is an actual disease, both sides strongly agree that the risk factors that define the syndrome should be identified and treated.

564

565

TABLE 49-9 Drugs Used to Alter Plasma Levels of LDL, HDL, and Triglycerides

Drug Class	Effect on LDL, HDL, and TGs	Common or Serious Adverse Effects	Contraindications	Clinical Trial Results
HMG-CoA reductase inhibitors (statins)	LDL ↓ 21–63% HDL ↑ 5–22% TG ↓ 6–43%	• Myopathy • Hepatotoxicity	<i>Absolute:</i> • Active or chronic liver disease • Pregnancy <i>Relative:</i> • Concurrent use of certain drugs*	Reduced major coronary events, stroke, CHD deaths, need for coronary procedures, and total mortality
Bile-acid sequestrants	LDL ↓ 15–30% HDL ↑ 3–5% TG ↓/no change	• GI distress • Constipation • Reduced drug absorption	<i>Absolute:</i> • Dysbetalipoproteinemia • TG above 400 mg/dL <i>Relative:</i> • TG above 200 mg/dL	Reduced major coronary events and CHD deaths
Nicotinic acid (niacin)	LDL ↓ 5–25% HDL ↑ 15–35% TG ↓ 20–50%	• Flushing • Hyperglycemia • Hyperuricemia • Upper GI distress • Hepatotoxicity	<i>Absolute:</i> • Chronic liver disease • Gout <i>Relative:</i> • Diabetes • Hyperuricemia • Peptic ulcer disease	Reduced major coronary events and, possibly, reduced mortality

Fibrates	LDL ↓ 5–20%, but may increase if TGs are high HDL ↑ 10–20% TG ↓ 20–50%	<ul style="list-style-type: none"> • Dyspepsia • Gallstones • Myopathy 	<i>Absolute:</i> <ul style="list-style-type: none"> • Severe renal disease • Severe liver disease 	Reduced major coronary events
Ezetimibe	LDL ↓ 19% HDL ↑ 1–4% TG ↓ 5–10%	<ul style="list-style-type: none"> • Headache • Myalgia, arthralgia, possible myopathy • Abdominal pain, diarrhea 	<i>Absolute:</i> <ul style="list-style-type: none"> • Moderate to severe liver injury, especially in patients taking a statin 	Impact on coronary events and mortality has not been established
Modified from the Executive Summary of the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). JAMA 285:2486–2497, 2001. Data on ezetimibe are from other sources.				

* Use caution in patients taking nicotinic acid, fibrates, and agents that inhibit cytochrome P450 isozyme 3A4, including cyclosporine, macrolide antibiotics (eg, erythromycin), azole antifungal drugs (eg, ketoconazole), and HIV protease inhibitors (eg, ritonavir).

50.4.4.2 High Triglycerides

High TG levels (above 200 mg/dL) are an independent risk factor for CHD. In clinical practice, high TGs are seen most often in patients with metabolic syndrome. However, high levels may also be associated with obesity, sedentary lifestyle, cigarette smoking, excessive alcohol intake, type 2 diabetes, certain genetic disorders, and high carbohydrate intake (when carbohydrates account for more than 60% of total caloric intake). In patients with high TG levels, the principal treatment goal is to achieve the original LDL goal. Dietary modification is always recommended. Statins being taken to lower cholesterol can help lower TGs as well, perhaps to a satisfactory level. However, if triglyceride levels remain unacceptably high, medications specific to TGs—nicotinic acid and fibrates—may be needed. Unfortunately, when these drugs are combined with cholesterol-lowering drugs (as they often are), the adverse effects of cholesterol-lowering agents may be intensified.

50.5 DRUGS AND OTHER PRODUCTS USED TO ALTER PLASMA LIPID LEVELS

As discussed above, the lipid abnormality that contributes most to cardiovascular disease is high LDL cholesterol. Accordingly, we will focus primarily on drugs for this disorder. Nonetheless, we also need to consider other lipid abnormalities, especially (1) high total cholesterol,^{*} (2) low HDL cholesterol, and (3) high TGs.

Some drugs for dyslipidemias are more selective than others. That is, whereas some drugs may improve just one dyslipidemia (eg, high TGs), others may improve two or more dyslipidemias. The highly selective agents can be useful as add-ons, to “target” a particular lipid abnormality when other medications prove inadequate.

Drugs that lower *LDL cholesterol* levels include HMG-CoA reductase inhibitors, bile-acid sequestrants, nicotinic acid, and ezetimibe. All are effective to varying degrees. The HMG-CoA reductase inhibitors are more effective than the others, cause fewer adverse effects, are better tolerated, and are more likely to improve clinical outcomes.

565

566

As we consider the drugs for lipid disorders, you should be aware of the following: Although all of these drugs can improve lipid profiles, not all of them improve clinical outcomes (reduced morbidity and mortality). This leads us to question whether some of the lipid abnormalities are a true cause of pathophysiology and ultimate death, or whether they are simply “associated markers” of some other pathophysiology that we don't yet understand.

50.5.1 HMG-CoA Reductase Inhibitors (Statins)

HMG-CoA reductase inhibitors, commonly called *statins* (because their generic names end in *statin*), are the most effective drugs for lowering LDL and total cholesterol. In addition, they can raise HDL cholesterol and lower TGs. Most importantly, these drugs have been shown to improve clinical outcomes, including lowering the risk of heart failure and sudden death. Because of these benefits, statins are among our most widely prescribed drugs, and have earned tens of billions for their makers. For example, in 2007 atorvastatin [Lipitor] was the best selling drug in the United States, generating \$12.7 billion in sales.

50.5.1.1 Beneficial Actions

The statins have several actions that can benefit patients with (or at risk of) atherosclerosis. The most obvious is reduction of LDL cholesterol.

50.5.1.1.1 Reduction of LDL Cholesterol.

Statins have a profound effect on LDL cholesterol. Low doses decrease LDL cholesterol by about 25%, and larger doses decrease levels by as much as 63% ([Table 49-10](#)). Reductions are significant within 2 weeks and maximal within 4 to 6 weeks. Because cholesterol synthesis normally increases during the night, statins are most effective when given in the evening. If statin therapy is stopped, serum cholesterol will return to pretreatment levels within weeks to months. Hence, treatment should continue lifelong, unless serious adverse effects or specific contraindications (especially pregnancy or skeletal muscle damage) arise. The mechanism by which statins reduce cholesterol levels is discussed below.

* Note that total cholesterol is slightly different from the simple sum of LDL cholesterol (LDL-C) plus HDL cholesterol (HDL-C); triglycerides (TG) also contribute to the value, as in the following equation: $\text{total cholesterol} = \text{HDL-C} + \text{LDL-C} + (\text{TG}/5)$ (provided TG levels are below 400 mg/dL).

50.5.1.1.2 Elevation of HDL Cholesterol.

Statins can increase levels of HDL cholesterol. Recall that low levels of HDL cholesterol (below 40 mg/dL) are an independent risk factor for CHD. Hence, by raising HDL cholesterol, statins can help reduce the risk of CV events. The objective is to raise levels to 50 mg/dL or more.

50.5.1.1.3 Reduction of Triglyceride Levels.

Although statins mainly affect cholesterol synthesis, and thereby lower cholesterol levels, these drugs may also raise HDL cholesterol and lower TGs. Just why these “anti-cholesterol” drugs lower TGs is unknown, but the response has been amply documented. Please note that, although statins may reduce TG levels, they are not actually prescribed for this action. Hence TG reduction is usually a side benefit in patients taking statins to lower their cholesterol. Of note, the fall of TG levels seems to be short lived, and hence a drug designed to lower TGs (eg, niacin) may eventually be needed.

50.5.1.1.4 Nonlipid Beneficial Cardiovascular Actions.

There is increasing evidence that statins do more than just alter lipid levels. Specifically, they can promote plaque stability (by decreasing plaque cholesterol content), reduce inflammation at the plaque site, slow progression of coronary artery calcification, improve abnormal

endothelial function, enhance the ability of blood vessels to dilate, reduce the risk of atrial fibrillation, and reduce the risk of thrombosis by (1) inhibiting platelet deposition and aggregation and (2) suppressing production of thrombin, a key enzyme in clot formation. All of these actions help reduce the risk of CV events.

50.5.1.1.5 Increased Bone Formation.

There is evidence that statins can promote bone formation, and may thereby reduce the risk of osteoporosis and related fractures. In animal studies, statins have increased bone formation, apparently by enhancing the activity of osteoblasts (the cells that lay down new bone). Several case-control studies in humans have shown an association between statin use and reduced risk of osteoporotic fractures. However, other case-control studies have failed to demonstrate a protective effect. The reason for this discrepancy could lie with the inherent weaknesses of case-control studies. Hence, the issue is likely to remain unresolved until data from randomized controlled trials are available. In the meantime, osteoporosis should be managed with bisphosphonates and/or other drugs with proven efficacy (see [Chapter 74](#), Drugs Affecting Calcium Levels and Bone Mineralization).

50.5.1.2 Mechanism of Cholesterol Reduction

The mechanism by which statins decrease LDL cholesterol levels is complex, and depends ultimately on *increasing the number of LDL receptors on hepatocytes* (liver cells). The process begins with inhibition of hepatic HMG-CoA reductase, the rate-limiting enzyme in cholesterol biosynthesis. In response to decreased cholesterol production, hepatocytes synthesize more HMG-CoA reductase. As a result, cholesterol synthesis is largely restored to pretreatment levels. However—and for reasons that are not fully understood—inhibition of cholesterol synthesis causes hepatocytes to synthesize more LDL receptors. As a result, hepatocytes are able to remove more LDLs from the blood. In patients who are genetically unable to synthesize LDL receptors, statins fail to reduce LDL levels, indicating that (1) inhibition of cholesterol synthesis, by itself, is not sufficient to explain cholesterol-lowering effects; and (2) in order for statins to be effective, synthesis of LDL receptors must increase.

In addition to inhibiting HMG-CoA reductase, statins decrease production of apolipoprotein B-100. As a result, hepatocytes decrease production of VLDLs. This lowers VLDL levels along with LDL levels. Statins also raise HDL levels by 5% to 22%.

50.5.1.3 Clinical Trials

Statins slow progression of CHD and decrease the risk of stroke, hospitalization, cardiac events, peripheral vascular disease, and death. Benefits are seen in men and women, and in apparently healthy people as well as those with a history of CV events. Hence, the statins are useful for both primary and secondary prevention. Furthermore, these drugs can even help people with *normal* LDL levels, in addition to those whose LDL is high. Statins can also protect people with diabetes.

50.5.1.3.1 Secondary Prevention Studies.

In patients with evidence of existing CHD (angina pectoris or previous MI), statins reduce the risk of death from cardiac causes. This was first demonstrated conclusively in the landmark *Scandinavian Simvastatin Survival Study* (4S). After 4.9 to 6.3 years of follow-up, the death rate was 12% among patients taking placebo and 8% among those taking simvastatin—a 30% decrease in overall mortality. Benefits were due to a decrease in cardiac-related mortality; deaths from noncardiac causes were the same in both groups.

566

TABLE 49-10 HMG-CoA Reductase Inhibitors: Selected Aspects of Clinical Pharmacology

Drug	% Change in Serum Lipids*			Liver Function Test (LFT) Monitoring†	Effect of CYP3A4 (Metabolism) Inhibitors on Statin Levels‡	Effect of Renal or Hepatic Impairment on Statin Levels
	LDL-C	HDL-C	TGs			
Atorvastatin [Lipitor]	↓ 27–60	↑ 6–14	↓ 17–53	At 12 wk and then every 6 mo	Moderate ↑	No change with renal disease; significant ↑ with hepatic impairment
Fluvastatin [Lescol]	↓ 22–38	↑ 2–11	↓ 12–25	At 12 wk and then every 6 mo	None	No change with renal disease; possible ↑ with hepatic impairment
Lovastatin [Mevacor]	↓ 21–42	↑ 5–10	↓ 6–27	At 6 and 12 wk and then every 6 mo	Significant ↑	↑ with significant renal dysfunction; no change with hepatic impairment
Pravastatin [Pravachol]	↓ 22–41	↑ 1–14	↓ 10–24	At 12 wk and then every 6 mo	None	Potential ↑ with either renal or hepatic dysfunction
Rosuvastatin [Crestor]	↓ 28–63	↑ 3–22	↓ 10–43	At 12 wk and then every 6 mo	None	↑ levels with severe renal impairment or hepatic dysfunction
Simvastatin [Zocor]	↓ 26–51	↑ 7–16	↓ 8–41	At 6 and 12 mo (and also at 3 mo if 80 mg/day is used)	Significant ↑	Potential ↑ with severe renal or hepatic dysfunction
↑ = increase; ↓ = decrease.						

* LDL-C = low-density lipoprotein cholesterol, HDL-C = high-density lipoprotein cholesterol, TGs = triglycerides. Note that each of these drugs is available and

administered in a range of doses; the changes in lipid levels reported above were obtained from a variety of studies and a variety of indications, and do not reflect the dose dependency of the drugs' effects.

† LFTs should always be performed before starting statin therapy (baseline) and at the indicated times after the first dose and after any change in dosage.

‡ CYP3A4 is an enzyme in the cytochrome P450 family. Inhibitors of CYP3A4 include itraconazole, ketoconazole, erythromycin, clarithromycin, HIV protease inhibitors, cyclosporine, nefazodone, and certain substances found in grapefruit juice.

The *Cholesterol and Recurrent Events* (CARE) trial demonstrated the ability of statins to reduce the risk of stroke in addition to coronary events. In this study, 4159 people with a history of MI were given pravastatin (40 mg daily) or placebo. After 5 years, the incidence of MI (fatal or nonfatal) was 13.2% in those taking placebo and 10.2% in those taking the drug. Pravastatin also produced a 26% decrease in the risk of stroke.

The *Pravastatin or Atorvastatin Evaluation and Infection Therapy* (PROVE-IT) trial was the first to show that *intensive* reductions in LDL with statin therapy provide more CV protection than moderate reductions. In PROVE-IT, 4162 patients with acute coronary syndromes were randomized to either a moderate statin regimen (pravastatin, 40 mg daily) or an intensive statin regimen (atorvastatin, 80 mg daily). The result? LDL levels in the moderate group dropped to 95 mg/dL, compared with 62 mg/dL in the intensive group. Furthermore, not only did intensive therapy produce a greater decrease in LDL cholesterol, it produced a greater reduction in adverse outcomes: After 24 months, the incidence of CV events (death, MI, unstable angina, or revascularization) was only 22.4% in the intensive group compared with 26.3% in the moderate group. These results led the ATP III panel to recommend lower target LDL levels in patients at very high CV risk.

50.5.1.3.2

Primary Prevention Studies.

Two studies have demonstrated the ability of statins to reduce mortality in people with no previous history of coronary events. In the first trial—the *West of Scotland Coronary Prevention Study* (WOSCOPS)—6595 men with high cholesterol were given either pravastatin (40 mg/day) or placebo. During an average follow-up of 4.9 years, 4.1% of those taking placebo died, compared with only 3.2% of those taking the drug. The second trial—the *Air Force/Texas Coronary Atherosclerosis Prevention Study* (AFCAPS/TexCAPS)—enrolled

6605 low-risk patients: men and women with average cholesterol levels (221 mg/dL) and no history of CV events. The subjects were randomly assigned to receive lovastatin (20 to 40 mg/day) or placebo. After an average follow-up of 5.5 years, the incidence of first major coronary events was 5.5% for those taking placebo and 3.5% for those taking the drug—representing a 36% decrease in risk.

50.5.1.3.3 Prevention in Patients with Normal Cholesterol Levels.

The landmark *Heart Protection Study*, published in 2002, was the first major trial to demonstrate that statins can reduce the risk of major coronary events in people who have normal levels of cholesterol. This double-blind, placebo-controlled trial enrolled 20,536 high-risk British patients: men and women with diabetes, prior MI, stroke, or angioplasty. Some had high levels of LDL and total cholesterol; others had normal levels. Subjects were randomly assigned to receive either simvastatin (40 mg/day) or placebo. After 5 years, the incidence of death was 12.9% in the treatment group, compared with 14.7% in the placebo group. Death from CHD was reduced by 18%. In addition, simvastatin reduced the risk of nonfatal MI by 38% and of stroke by 25%, and reduced the need for coronary revascularization (eg, angioplasty) by 30%. Most strikingly, benefits were seen in patients whose LDL cholesterol was *normal* or *low*, as well as in those whose levels were high. These data suggest a radical shift in practice. Specifically, they suggest *we should treat people at high CHD risk—not simply those with high cholesterol levels*. Obviously, doing so would greatly expand the number of patients receiving statin therapy.

50.5.1.3.4 Prevention in Patients with Diabetes.

Results of the *Collaborative Atorvastatin Diabetes Study* (CARDS) indicate that statin therapy can reduce the risk of CV events in diabetes patients, even if LDL levels are normal. This randomized trial, conducted in Britain and Ireland, enrolled 2838 patients with type 2 diabetes who had no history of CV disease. Half received 10 mg of atorvastatin [Lipitor] daily and half received a placebo. After a mean of 4 years, the combined incidence of acute coronary events, coronary revascularization, and stroke was only 5.8% in the atorvastatin group, compared with 9% in the placebo group, representing a 36% reduction in risk. These results suggest that statin therapy could benefit most patients with diabetes, regardless of their LDL level.

50.5.1.4 Therapeutic Uses

Indications for the statins keep expanding. When these drugs were introduced, they were approved only for hypercholesterolemia in adults. As understanding of their benefits has grown, so has the list of indications. Today the statins have nine FDA-approved indications, and can be prescribed for young patients as well as adults. Indications for individual statins are summarized in [Table 49-11](#). Major indications are discussed below.

50.5.1.4.1 Hypercholesterolemia.

Statins are the most effective drugs we have for lowering cholesterol. In sufficient dosage, statins can decrease LDL cholesterol by more than 60%. For many patients, the treatment goal is to drop LDL cholesterol to below 100 mg/dL. For patients at very high CV risk, a target of 70 mg/dL may be appropriate.

TABLE 49-11 HMG-CoA Reductase Inhibitors: FDA-Approved Indications

Indication	Atorvastatin [Lipitor]	Fluvastatin [Lescol]	Lovastatin		Rosuvastatin [Crestor]	Simvastatin [Zocor]
			[Altoprev, Mevacor]	Pravastatin [Pravachol]		
Primary hypercholesterolemia	✓	✓	✓	✓	✓	✓
Homozygous familial hyperlipidemia	✓				✓	✓
Heterozygous familial hypercholesterolemia in adolescents	✓		✓	✓		✓
Mixed dyslipidemia	✓	✓	✓	✓	✓	✓
Primary dysbetalipoproteinemia	✓			✓		✓
Hypertriglyceridemia*	✓			✓	✓	✓
Primary prevention of coronary events	✓		✓	✓		✓
Secondary prevention of cardiovascular events		✓	✓	✓		✓
Increasing HDL cholesterol in primary hypercholesterolemia	✓	✓	✓	✓	✓	✓
Prevention of MI and stroke in type 2 diabetes	✓					

* Statins are not indicated in patients who have hypertriglyceridemia but also have low or normal LDL cholesterol, even if total cholesterol levels are elevated.

50.5.1.4.2 Primary and Secondary Prevention of CV Events.

As discussed, statins can reduce the risk of CV events (eg, MI, angina, stroke) in patients who have never had one (primary prevention) and they can reduce the risk of a subsequent event after one has occurred (secondary prevention). Risk reduction is related to the reduction in LDL: the greater the LDL reduction, the greater the reduction in risk.

50.5.1.4.3 Post-MI Therapy.

Patients who have survived an MI, and who were not on statin therapy at the time of the event, are routinely started on a statin, the rationale being “better late than never.” How soon should statin therapy start? Some clinicians would start “sometime” before hospital discharge. However, the current trend is to begin statins as soon as the patient is stabilized and able to take oral drugs. Other drugs for MI are discussed in [Chapter 52](#).

50.5.1.4.4 Diabetes.

Cardiovascular disease is the primary cause of death in people with diabetes. Hence, to reduce mortality, controlling CV risk factors—especially hypertension and high cholesterol—is as important as controlling high blood glucose. The American Diabetes Association recommends a statin for all patients over the age of 40 whose *total* cholesterol is 135 mg/dL or higher—regardless of LDL cholesterol level. The American College of Physicians recommends a statin for (1) all patients with type 2 diabetes plus diagnosed CHD—*even if they don't have high cholesterol*; and (2) all adults with type 2 diabetes plus one additional risk factor (eg, hypertension, smoking, age over 55)—*even if they don't have high cholesterol*. Taken together, these guidelines suggest that most patients with diabetes should receive a statin.

50.5.1.4.5 Potential Uses.

Potential uses of statins extend well beyond diabetes and cardiovascular disorders. Judging from preliminary evidence, these drugs may eventually be used to prevent and/or treat a variety of conditions, including Parkinson's disease, Alzheimer's disease, kidney disease, multiple sclerosis, macular degeneration, glaucoma, rheumatoid arthritis, weak bones, and even cancer.

50.5.1.5 Pharmacokinetics

Statin are administered orally. The amount absorbed ranges between 30% and 90%, depending on the drug. Regardless of how much is absorbed, most of an absorbed dose is extracted from the blood on its first pass through the liver, the principal site at which statins act. Only a small fraction of each dose reaches the general circulation. Statins undergo rapid hepatic metabolism followed by excretion primarily in the bile. Only three agents—*lovastatin*, *pravastatin*, and *simvastatin*—undergo clinically significant (10% to 20%) excretion in the urine.

Three statins—*atorvastatin*, *lovastatin*, and *simvastatin*—are metabolized by the 3A4 isozyme of cytochrome P450 (CYP3A4). As a result, levels of these drugs can be lowered by agents that induce CYP3A4 synthesis. More importantly, their levels can be increased—sometimes dramatically—by agents that inhibit CYP3A4 (see below).

One agent—*rosuvastatin*—reaches abnormally high levels in people of Asian heritage. At usual therapeutic doses, rosuvastatin levels in these people are about twice those in whites. Accordingly, if rosuvastatin is used by Asians, dosage should be reduced.

50.5.1.6 Adverse Effects

Statins are generally well tolerated. Side effects are uncommon. Some patients develop headache, rash, or GI disturbances (dyspepsia, cramps, flatulence, constipation, abdominal pain). However, these effects are usually mild and transient. Serious adverse effects—
hepatotoxicity and myopathy—are relatively rare. With one agent—rosuvastatin—serious effects may occur more often than with other statins.

568

569

50.5.1.6.1 Myopathy/Rhabdomyolysis.

Statins can injure muscle tissue. *Mild injury* occurs in 1% to 5% of patients. Characteristic symptoms are muscles aches, tenderness, and weakness that may be localized or diffuse. Rarely, mild injury progresses to *myositis*, defined as muscle inflammation associated with moderate elevation of creatine kinase (CK), an enzyme released from injured muscle. Release of potassium from muscle may cause blood potassium to rise. Rarely, myositis progresses to potentially fatal *rhabdomyolysis*, defined as muscle disintegration or dissolution, associated with marked elevation of CK (greater than 10 times the upper limit of normal [ULN]) and possibly with renal failure. Fortunately, fatal rhabdomyolysis is extremely rare: the overall incidence is less than 0.15 case per 1 million prescriptions. Patients should be informed about the risk of myopathy and instructed to notify the prescriber if unexplained muscle pain or tenderness occurs. How statins cause myopathy is unknown.

Several factors increase the risk of myopathy. Among these are advanced age, small body frame, frailty, multisystem disease (eg, chronic renal insufficiency, especially associated with diabetes), use of statins in high doses, concurrent use of fibrates (which can cause myopathy too), and use of drugs that can raise statin levels (see below). In addition, hypothyroidism increases risk. Accordingly, if muscle pain develops, thyroid function should be assessed.

Measurement of CK levels can facilitate diagnosis. The level should be determined at baseline, and again if symptoms of myopathy appear. If the CK level is more than 10 times the ULN, the statin should be discontinued. If the level is less than 10 times the ULN, the statin can be continued, provided myopathy symptoms and the CK level are followed weekly. Routine monitoring of CK in asymptomatic patients is unnecessary.

What is the risk with individual statins? Of the six statins in current use, *rosuvastatin* [Crestor] poses the highest risk of rhabdomyolysis. But even with this drug, the absolute number of cases is extremely low. With the other five statins, the risk is even lower. A seventh agent—*cerivastatin* [Baycol]—was withdrawn in 2001 because the risk was 16 to 80 times higher than with other statins.

Should concerns about myopathy discourage statin use? Definitely not! Remember that risk of serious myopathy is extremely low, whereas the risk of untreated high cholesterol is very high. Accordingly, when statins are used to lower cholesterol, the benefits of therapy (reduction of cardiovascular events) far outweigh the small risk of myopathy.

50.5.1.6.2

Hepatotoxicity.

Liver injury, as evidenced by elevations in serum transaminase levels, develops in 0.5% to 2% of patients treated 1 year or longer. However, jaundice and other clinical signs are rare. Progression to outright liver failure occurs very rarely, if at all. Because of the risk of liver injury, product labeling recommends that liver function tests (LFTs) be done before treatment and every 6 to 12 months thereafter (see [Table 49-10](#)). However, there is evidence that routine monitoring may not really be needed. If serum transaminase levels rise to 3 times the ULN and remain there, statins should be discontinued. Transaminase levels decline to pretreatment levels following drug withdrawal.

Should statins be used by patients with active liver disease? The answer depends on the disease. In patients with viral or alcoholic hepatitis, statins should be avoided. However, in patients with the most common cause of hepatitis—nonalcoholic fatty liver disease—statins are acceptable therapy. In fact, in these patients, not only can statins reduce cholesterol levels, they may also decrease liver inflammation, improve LFTs, and reduce steatosis (fatty infiltration in the liver). Should LFTs be monitored? Yes—at baseline and every 3 months thereafter. If LFTs climb to 3 times the ULN, statin use should stop.

50.5.1.6.3 Peripheral Neuropathy.

Very rarely, peripheral neuropathy develops in statin users. Symptoms include weakness, difficulty walking, and tingling and pain in the hands and feet. The underlying mechanism could be disruption of neuronal integrity secondary to inhibition of cholesterol synthesis. Statin-related neuropathy is often reversible, but may take 3 to 12 months to resolve. At this time, solid proof that statins cause neuropathy is lacking—although the available data are strongly suggestive. Hence, if symptoms of neuropathy develop, the statin should be suspected.

50.5.1.6.4 Parkinson's Disease.

Recent evidence indicates a possible link between reduced LDL cholesterol levels and development of Parkinson's disease, and suggests that the statins employed to lower LDL levels might be the cause. There is no proof, however, that statins increase the risk for Parkinson's disease. Indeed, statins are being studied for their *protective* effects against this common neurologic condition. Here again, the well-established benefits of statin therapy would seem to clearly outweigh this potential risk.

50.5.1.7 Drug Interactions

50.5.1.7.1 With Other Lipid-Lowering Drugs.

Combining a statin with most other lipid-lowering drugs (except probably the bile-acid sequestrants) can increase the incidence and severity of the most serious statin-related adverse events: muscle injury, liver injury, and kidney damage. Increased risk occurs primarily with fibrates (gemfibrozil, fenofibrate), which are commonly combined with statins. The bottom line: When statins are combined with other lipid-lowering agents, use extra caution and monitor for adverse effects more frequently.

50.5.1.7.2 With Drugs That Inhibit CYP3A4.

Agents that inhibit CYP3A4 can raise levels of *lovastatin* and *simvastatin* substantially, and can raise levels of *atorvastatin* moderately. How? By slowing inactivation of these statins. Important inhibitors of CYP3A4 include macrolide antibiotics (eg, erythromycin), azole antifungal drugs (eg, ketoconazole, itraconazole), HIV protease inhibitors (eg, ritonavir), amiodarone (an antidysrhythmic drug), and cyclosporine (an immunosuppressant). If these

drugs are combined with a statin, increased caution is advised. Some authorities recommend an automatic reduction in statin dosage if these inhibitors are used.

In addition to drugs, certain chemicals in grapefruit juice (and perhaps limes, tangelos, and Seville oranges) can inhibit CYP3A4—and the inhibition may persist for 3 days or more. How much grapefruit juice is needed for clinically significant inhibition? Older studies suggest that 1 quart (32 ounces) is required. In contrast, more recent studies suggest that as little as 8 ounces would do the job. Given this uncertainty, prudence dictates that, until more is known, statin users should avoid grapefruit juice entirely.

50.5.1.8 Use in Pregnancy

Statins are classified in Food and Drug Administration Pregnancy Risk Category X: the risks to the fetus outweigh any potential benefits of treatment. Some statins have been shown to produce fetal malformations in animal models—but only at doses far higher than are used in humans. Teratogenic effects in humans have not been reported. However, because statins inhibit synthesis of cholesterol, and since cholesterol is required for synthesis of cell membranes as well as several fetal hormones, concern regarding human fetal injury remains. Moreover, there is no compelling reason to continue lipid-lowering drugs during pregnancy. Women of child-bearing age should be informed about the potential for fetal harm and warned against becoming pregnant. If pregnancy occurs, statins should be discontinued.

569

570

TABLE 49-12 HMG-CoA Reductase Inhibitors: Preparations, Dosage, and Administration

Drug	Dosage	Administration with Regard to Meals	Dosage Changes in Special Populations	Preparations
Atorvastatin [Lipitor]	<i>Initial:</i> 10 mg at bedtime <i>Maximum:</i> 80 mg at bedtime	Take without regard to meals	No changes needed	<i>Lipitor:</i> 10-, 20-, 40-, 80-mg tablets
Fluvastatin [Lescol, Lescol XL]	<i>Initial:</i> 20 mg at bedtime <i>Maximum:</i> 40 mg twice a day (Lescol); 80 mg at bedtime (Lescol XL)	Take without regard to meals	No changes needed	<i>Lescol:</i> 20-, 40-mg capsules <i>Lescol XL:</i> 80-mg extended-release tablets
Lovastatin [Altoprev, Mevacor, and generics]	<i>Initial:</i> 20 mg with the evening meal <i>Maximum:</i> 40 mg twice daily or 80 mg at bedtime	Take with evening meal to increase absorption	Reduce dosage for severe renal impairment	<i>Altoprev:</i> 10-, 20-, 40-, 60-mg extended-release tablets <i>Mevacor and generics:</i> 10-, 20-, 40-mg tablets
Pravastatin [Pravachol and generics]	<i>Initial:</i> 20 mg at bedtime <i>Maximum:</i> 40 mg at bedtime	Take without regard to meals	Reduce dosage for moderate to severe renal or hepatic impairment	<i>Pravachol and generics:</i> 10-, 20-, 40-, 80-mg tablets
Rosuvastatin [Crestor]	<i>Initial:</i> 20 mg at bedtime <i>Maximum:</i> 80 mg at bedtime	Take without regard to meals	Reduce dosage for severe renal impairment Reduce dosage in Asian patients	<i>Crestor:</i> 5-, 10-, 20-, 40-mg tablets

Simvastatin [Zocor and generics]	<i>Initial:</i> 20 mg at bedtime <i>Maximum:</i> 40 mg twice daily or 80 mg at bedtime <i>Note:</i> Rapidly disintegrating tablets are placed on the tongue; drug will then be swallowed in the saliva	Take without regard to meals	Reduce dosage for severe renal impairment	<i>Zocor and generics:</i> 5-, 10-, 20-, 40-, 80- mg tablets <i>Generic oral, rapidly disintegrating:</i> 10-, 20-, 40-, 80-mg tablets
--	--	---------------------------------	---	---

50.5.1.9 Preparations, Dosage, and Administration

Six statins are available for use alone: atorvastatin, fluvastatin, lovastatin, pravastatin, rosuvastatin, and simvastatin. Information on preparations, dosage, and administration is summarized in [Table 49-12](#). Fixed-dose combination products are discussed separately below.

Dosing is done once daily in the *evening*, either with the evening meal or at bedtime. Why take these drugs late in the day? Because endogenous cholesterol synthesis increases during the night. As a result, statins have the greatest impact when given in the evening.

50.5.1.10 Drug Selection

Several factors bear on statin selection, including the LDL goal, drug interactions, kidney function, safety in Asians, and price.

50.5.1.10.1 LDL Goal.

If a 30% to 40% reduction in LDL is deemed sufficient, any statin will do. However, if LDL must be lowered by more than 40%, then atorvastatin or simvastatin may be preferred. Although rosuvastatin is also highly effective, experience with this drug is relatively limited, and hence we can't be as comfortable regarding its safety or ability to reduce CV events.

50.5.1.10.2 Drug Interactions.

Drugs that inhibit CYP3A4 can raise levels of atorvastatin, lovastatin, and simvastatin, thereby increasing the risk of toxicity, especially myopathy and liver injury. Accordingly, in patients taking a CYP3A4 inhibitor, other statins are preferred.

50.5.1.10.3 Kidney Function.

For patients with normal renal function, any statin is acceptable. However, for patients with significant renal impairment, atorvastatin or fluvastatin is preferred (because no dosage adjustment is needed).

50.5.1.10.4 Safety in Asians.

The same dose of *rosuvastatin*, when given to Asian and Caucasian subjects, may produce twofold higher blood levels in the Asians. Accordingly, when rosuvastatin is used in Asians, start with the lowest available dosage and monitor diligently.

50.5.1.10.5 Price.

One agent—lovastatin—is available as a generic product, and hence is cheaper than all other statins. For patients who need a modest reduction in LDL and are not taking a CYP3A4 inhibitor, lovastatin would be the best choice.

50.5.2 Nicotinic Acid (Niacin)

Nicotinic acid [Niacor, Niaspan] reduces LDL and TG levels. In addition, it increases HDL levels better than any other drug. In patients with high LDL levels, nicotinic acid reduces the risk of major coronary events and may also reduce total mortality. Unfortunately, although nicotinic acid is effective, flushing and other side effects can be unpleasant, and may lead to nonadherence.

570

Niacin is available in three formulations, which differ with respect to onset, duration, and the incidence and severity of side effects.

571

50.5.2.1 Mechanism of Action.

The primary effect of nicotinic acid is to decrease production of VLDLs. Since LDLs are by-products of VLDL degradation, the fall in VLDL levels causes LDL levels to fall as well. There appear to be several mechanisms by which nicotinic acid decreases VLDL production. Notable among these is inhibition of lipolysis in adipose tissue.

50.5.2.2 Effect on Plasma Lipoproteins.

Nicotinic acid reduces LDL cholesterol by 5% to 25% and TGs by 20% to 50%. In addition, it raises HDL cholesterol by 15% to 35%. Triglyceride levels begin to fall within the first 4 days

of therapy. LDL levels decline more slowly, taking 3 to 5 weeks for maximum reductions. Combining nicotinic acid with lovastatin can reduce LDL cholesterol by 45% and can raise HDL cholesterol by 41%. Triple therapy (nicotinic acid plus a statin plus a bile-acid sequestrant) can decrease LDL cholesterol by 70% or more.

50.5.2.3 Therapeutic Use.

Nicotinic acid is a drug of choice for lowering TG levels in patients at risk of pancreatitis. Additional uses include mixed elevation of LDLs and TGs, and elevation of TGs in combination with low levels of HDLs. One formulation—sold as Niaspan—is approved for elevating HDL cholesterol.

Nicotinic acid (niacin) also has a role as a vitamin. The doses employed to correct niacin deficiency are much smaller than those employed to reduce lipoprotein levels. The role of nicotinic acid as a vitamin is discussed in [Chapter 80](#).

50.5.2.4 Adverse Effects.

The most frequent adverse reactions involve the skin (flushing, itching) and GI tract (gastric upset, nausea, vomiting, diarrhea). *Intense flushing* of the face, neck, and ears occurs in practically all patients receiving nicotinic acid in pharmacologic doses. This reaction diminishes in several weeks, and can be attenuated by taking 325 mg of aspirin 30 minutes before each dose. (Aspirin reduces flushing by preventing synthesis of prostaglandins, which mediate the flushing response.) Flushing can also be reduced by using extended-release niacin (eg, Niaspan) rather than immediate-release niacin (eg, Niacor).

Nicotinic acid is *hepatotoxic*. Severe liver damage has occurred. Liver injury is most likely with Slo-Niacin (a *long-acting* formulation), especially in high doses (above 2 gm/day). Liver injury is less likely with Niaspan, the extended-release formulation noted above. Because of the risk of hepatotoxicity, liver function should be assessed before treatment and periodically thereafter.

Additional adverse effects are *hyperglycemia* and *gouty arthritis*.

50.5.2.5 Preparations, Dosage, and Administration.

Nicotinic acid (niacin) is marketed generically and under several trade names. The drug is available in tablets (immediate-release [IR], timed-release, controlled-release, sustained-release) or capsules (timed-release, extended-release, sustained-release).

With IR formulations (prescription Niacor and over-the-counter products), blood levels of niacin climb rapidly. As a result, these products are associated with the highest incidence and severity of facial and upper body flushing, at least for the first few weeks. Thereafter, the intensity of these responses tends to fade. To manage flushing, patients using IR niacin often take prophylactic aspirin. (The need for aspirin is much lower with the long-acting products.) With IR niacin, blood levels of niacin can fall relatively soon. Therefore, to maintain steady blood levels, the total daily dose should be given as two or three divided doses (1 to 3 gm each), rather than as one large dose.

The most popular niacin formulation is Niaspan, a so-called slow-release formulation. Following oral dosing, the tablet slowly dissolves, causing blood levels to rise slowly and remain relatively steady. As a result, flushing is minimized, and once-daily dosing (usually 1 to 3 gm) is adequate. The major drawback to Niaspan is that it costs more than other niacin products.

Long-acting niacin [Slo-Niacin] has a longer half-life than other formulations. While this may seem like a therapeutic advantage (longer lasting high levels of drug), there is an increased risk of hepatotoxicity, and hence this product should be avoided.

(*Note:* When nicotinic acid is taken as a vitamin, the dosage is only about 25 mg/day—much lower than the dosages employed to lower plasma lipoproteins.)

50.5.3 Bile-Acid Sequestrants

Bile-acid sequestrants reduce LDL cholesterol levels. In the past, these drugs were a mainstay of lipid-lowering therapy. Today, they are used primarily as adjuncts to statins. Three agents are available: colestevlam, cholestyramine, and colestipol. Colestevlam is newer than the other two, and better tolerated.

50.5.3.1 Colestevlam

Colestevlam [Welchol], approved for hyperlipidemia in 2000, is the drug of choice when a bile-acid sequestrant is indicated. Like the older sequestrants, colestevlam is a nonabsorbable resin that binds (sequesters) bile acids and other substances in the GI tract, and thereby prevents their absorption and promotes their excretion. Colestevlam is preferred to the older sequestrants for three reasons: (1) the drug is better tolerated (less constipation, flatulence, bloating, and cramping); (2) it does not reduce absorption of fat-soluble vitamins (A, D, E, and K); and (3) it

does not significantly reduce the absorption of statins, digoxin, warfarin, and most other drugs studied.

In addition to its beneficial effects on plasma lipids, colestevlam can help control hyperglycemia in patients with type 2 diabetes. The drug was approved for adjunctive therapy of this disorder in 2008. Diabetes and its management are the subject of [Chapter 56](#).

50.5.3.1.1 Effect on Plasma Lipoproteins.

The main response to bile-acid sequestrants is a reduction in LDL cholesterol. LDL decline begins during the first week of therapy, and becomes maximal (about a 20% drop) within about a month. When these drugs are discontinued, LDL cholesterol returns to pretreatment levels in 3 to 4 weeks.

Bile-acid sequestrants may increase VLDL levels in some patients. In most cases, the elevation is transient and mild. However, if VLDL levels are elevated prior to treatment, the increase induced by the bile-acid sequestrants may be sustained and substantial. Accordingly, bile-acid sequestrants are not drugs of choice for lowering LDL cholesterol in patients with high VLDL levels.

50.5.3.1.2 Pharmacokinetics.

Bile-acid sequestrants are biologically inert. Also, they are insoluble in water, cannot be absorbed from the GI tract, and are not attacked by digestive enzymes. Following oral administration, they simply pass through the intestine and become excreted in the feces.

50.5.3.1.3 Mechanism of Action.

The bile-acid sequestrants lower LDL cholesterol through a mechanism that ultimately depends on increasing LDL receptors on hepatocytes. As background, you need to know that bile acids secreted into the intestine are normally reabsorbed and reused. Bile-acid sequestrants prevent this reabsorption. Here's what happens. Following oral administration, these drugs form an insoluble complex with bile acids in the intestine; this complex prevents the reabsorption of bile acids, and thereby accelerates their excretion. Because bile acids are normally reabsorbed, the increase in excretion creates a demand for increased synthesis, which takes place in the liver. Since bile acids are made from cholesterol, liver cells must have an increased cholesterol supply in order to increase bile acid production. The required cholesterol is provided by LDL. To avail themselves of more LDL cholesterol, liver cells

571

572

increase their number of LDL receptors, thereby increasing their capacity for LDL uptake. The result is an increase in LDL uptake from plasma, which decreases circulating LDL levels. Individuals who are genetically incapable of increasing LDL receptor synthesis are unable to benefit from these drugs.

50.5.3.1.4 Therapeutic Use.

Colesevelam is indicated as adjunctive therapy to diet and exercise for reducing LDL cholesterol in patients with primary hypercholesterolemia. The drug may be used alone, but usually is combined with a statin. On average, colesevelam alone can lower LDL cholesterol by about 20% (the typical range is between 15% and 30%). In contrast, combined therapy with a statin can reduce LDL cholesterol by up to 50%. Similar results can be obtained by combining a sequestrant with nicotinic acid.

50.5.3.1.5 Adverse Effects.

The bile-acid sequestrants are not absorbed from the GI tract, and hence are devoid of systemic effects. Accordingly, they are safer than all other lipid-lowering drugs.

Adverse effects are limited to the GI tract. *Constipation* is the main complaint. This can be minimized by increasing dietary fiber and fluids. If necessary, a mild laxative may be used. Other GI effects include *bloating*, *indigestion*, and *nausea*. The older agents—cholestyramine and colestipol—can decrease fat absorption, and may thereby *decrease uptake of fat-soluble vitamins*. However, this does not seem to be a problem with colesevelam.

50.5.3.1.6 Drug Interactions.

The bile-acid sequestrants can form insoluble complexes with other drugs. Medications that undergo binding cannot be absorbed, and hence are not available for systemic effects. Drugs known to form complexes with the sequestrants include thiazide diuretics, digoxin, warfarin, and some antibiotics. To reduce formation of sequestrant-drug complexes, oral medications that are known to interact should be administered either 1 hour before the sequestrant or 4 hours after.

50.5.3.1.7 Preparations, Dosage, and Administration.

Colesevelam [Welchol] is supplied in 625-mg tablets for oral use. The initial dosage is 3 tablets (1.9 gm) twice daily or 6 tablets (3.8 gm) once daily. All doses are taken with food and

water. Of note, the dosage for colesevelam is much smaller than that of cholestyramine (8 to 24 gm/day) or colestipol (5 to 30 gm/day).

50.5.3.2 Older Agents: Cholestyramine and Colestipol

Cholestyramine and colestipol have been available for decades, but have been largely replaced by colesevelam. Why? Because colesevelam is better tolerated, does not impede absorption of fat-soluble vitamins, and has minimal effects on other drugs. Although cholestyramine and colestipol are very safe, they frequently cause constipation, abdominal discomfort, and bloating.

Cholestyramine [Questran, Questran Light, Prevalite, LoCHOLEST, Lo-CHOLEST Light] is supplied in powdered form. Patients should be instructed to mix the powder with fluid, because swallowing it dry can cause esophageal irritation and impaction. Appropriate liquids for mixing include water, fruit juices, and soups. Pulpy fruits with a high fluid content (eg, applesauce, crushed pineapple) may also be used. The dosage range is 4 to 16 gm/day.

Colestipol hydrochloride [Colestid] is supplied in granular form (5 gm) and in 1-gm tablets. The dosage for the *granules* is 5 to 30 gm/day administered in one or more doses. Patients should be instructed to mix the granules with fluids or pulpy fruits before ingestion. The dosage for the *tablets* is 2 to 16 gm/day administered in one or more doses. Tablets should be swallowed whole and taken with fluid.

50.5.4 Ezetimibe

Ezetimibe [Zetia] is a new and unique drug for reducing plasma cholesterol. Benefits derive from blocking cholesterol absorption.

50.5.4.1 Mechanism of Action and Effect on Plasma Lipoproteins.

Ezetimibe acts on cells of the brush border of the small intestine to inhibit cholesterol absorption. The drug blocks absorption of dietary cholesterol as well as cholesterol secreted in the bile. Treatment reduces plasma levels of total cholesterol, LDL cholesterol, triglycerides, and apolipoprotein B. In addition, ezetimibe can produce a small *increase* in HDL cholesterol.

50.5.4.2 Therapeutic Use.

Ezetimibe is indicated as an adjunct to diet modification for reducing total cholesterol, LDL cholesterol, and apolipoprotein B in patients with primary hypercholesteremia. The drug is approved for monotherapy and for combined use with a statin. In clinical trials, ezetimibe alone

reduced LDL cholesterol by about 19%, increased HDL cholesterol by 1% to 4%, and decreased TGs by 5% to 10%. When ezetimibe was combined with a statin, the reduction in LDL cholesterol was about 25% greater than with the statin alone. Because ezetimibe is new, we do not yet know if it reduces CV morbidity or mortality.

50.5.4.3 Pharmacokinetics.

Ezetimibe is administered orally, and the amount absorbed is not affected by food. In the small intestine and liver, ezetimibe undergoes extensive conversion to ezetimibe glucuronide, an active metabolite. Both compounds—parent drug and metabolite—are eliminated primarily in the bile. The elimination half-life is about 22 hours.

50.5.4.4 Adverse Effects.

Ezetimibe is generally well tolerated. During clinical trials, the incidence of significant side effects was nearly identical to that seen with placebo. However, during postmarketing surveillance, there have been reports of myopathy, rhabdomyolysis, hepatitis, pancreatitis, and thrombocytopenia. In contrast to the bile-acid sequestrants, ezetimibe does not cause constipation and other adverse GI effects.

50.5.4.5 Drug Interactions.

50.5.4.5.1 Statins.

In patients taking a statin, adding ezetimibe slightly increases the risk of liver damage (as indicated by elevated transaminase levels). If the drugs are combined, transaminase levels should be carefully monitored. Combining ezetimibe with a statin may also increase the risk of myopathy.

50.5.4.5.2 Fibrates.

Both ezetimibe and fibrates (gemfibrozil and fenofibrate) can increase the cholesterol content of bile, and can thereby increase the risk of gallstones. Both also increase the risk of myopathy. Accordingly, combined use is not recommended.

50.5.4.5.3 Bile-Acid Sequestrants.

Cholestyramine (and probably colestipol) can significantly decrease the absorption of ezetimibe. To minimize effects on absorption, ezetimibe should be administered at least 2 hours before a sequestrant or 4 hours after.

50.5.4.5.4 Cyclosporine.

Cyclosporine may greatly increase levels of ezetimibe. If the drugs are combined, careful monitoring is needed.

50.5.4.6 Caution.

In patients with hepatic impairment, availability of ezetimibe is significantly increased. At this time, we do not know if increased availability is harmful. Until more is known, patients with moderate or severe hepatic insufficiency should not be given the drug.

572

50.5.4.7 Preparations, Dosage, and Administration.

573

Ezetimibe [Zetia] is available in 10-mg tablets for oral use. The recommended dosage is 10 mg once a day, taken with or without food. If ezetimibe is combined with a statin, both drugs can be taken at the same time. If ezetimibe is combined with a bile-acid sequestrant, ezetimibe should be taken 2 hours before the sequestrant or 4 hours after.

50.5.5 Fibric Acid Derivatives (Fibrates)

The fibric acid derivatives, also known as fibrates, are the most effective drugs available for lowering triglyceride levels. In addition, they can raise HDL cholesterol, but have little or no effect on LDL cholesterol. Fibrates can increase the risk of bleeding in patients taking warfarin (an anticoagulant) and the risk of rhabdomyolysis in patients taking statins. In the United States, three preparations are available: gemfibrozil [Lopid], fenofibrate [Tricor, others], and fenofibric acid [TriLipix], a new delayed-release preparation noteworthy for being the first and only fibrate *approved* for use with a statin.

50.5.5.1 Gemfibrozil

Gemfibrozil [Lopid] decreases triglyceride (VLDL) levels and raises HDL cholesterol levels. The drug does not reduce LDL cholesterol to a significant degree. Its principal indication is hypertriglyceridemia.

50.5.5.1.1 Effect on Plasma Lipoproteins.

Gemfibrozil decreases plasma TG content by lowering VLDL levels. Maximum reductions in VLDLs range from 40% to 55%, and are achieved within 3 to 4 weeks of treatment.

Gemfibrozil can raise HDL cholesterol by 6% to 10%. In patients with normal TG levels, the drug can produce a small reduction in LDL levels. However, if TG levels are high, gemfibrozil may actually increase LDL levels.

50.5.5.1.2 Mechanism of Action.

Gemfibrozil and other fibrates appear to work by interacting with a specific receptor subtype—known as peroxisome proliferator-activated receptor alpha (PPAR alpha)—present in the liver and brown adipose tissue. Activation of PPAR alpha leads to (1) increased synthesis of lipoprotein lipase (LPL) and (2) reduced production of apolipoprotein C-III (an inhibitor of LPL). Both actions accelerate the clearance of VLDLs, and thereby reduce levels of TGs. How do fibrates elevate HDL levels? By activating PPAR alpha, fibrates increase production of apolipoproteins A-I and A-II, which in turn facilitates HDL formation.

50.5.5.1.3 Therapeutic Use.

Gemfibrozil is used primarily to *reduce high levels of plasma triglycerides* (VLDLs). Treatment is limited to patients who have not responded adequately to weight loss and diet modification. Gemfibrozil can also reduce LDL cholesterol. However, other drugs (statins, cholestyramine, colestipol) are much more effective.

Gemfibrozil can be used to *raise HDL cholesterol*, although it is not approved for this application. When tested in patients with normal LDL cholesterol and low HDL cholesterol, gemfibrozil reduced the risk of major CV events (eg, stroke, fatal and nonfatal MI) by 20%. Because LDL cholesterol was normal, it appears that benefits were due primarily to elevation of HDL cholesterol, along with reduction of plasma triglycerides.

50.5.5.1.4 Adverse Effects.

Gemfibrozil is generally well tolerated. The most common reactions are rashes and GI disturbances (nausea, abdominal pain, diarrhea).

50.5.5.1.4.1 Gallstones.

Gemfibrozil increases biliary cholesterol saturation, thereby increasing the risk of gallstones. Patients should be informed about manifestations of gallbladder disease (eg, upper abdominal discomfort, intolerance of fried foods, bloating) and instructed to notify the prescriber at once if these develop. Patients with pre-existing gallbladder disease should not take the drug.

50.5.5.1.4.2 Myopathy.

Like the statins, gemfibrozil and other fibrates can cause myopathy. Warn patients to report any signs of muscle injury, such as tenderness, weakness, or unusual muscle pain.

50.5.5.1.4.3 Liver Injury.

Gemfibrozil is hepatotoxic. The drug can disrupt liver function and may also pose a risk of liver cancer. Periodic tests of liver function are required.

50.5.5.1.5 Drug Interactions.

Gemfibrozil displaces warfarin from plasma albumin, thereby increasing anticoagulant effects. Prothrombin time (international normalized ratio) should be measured frequently to assess coagulation status. Warfarin dosage may need to be reduced.

Gemfibrozil increases the risk of *statin-induced myopathy*. Accordingly, the combination of a statin with gemfibrozil should be used with great caution, if at all.

50.5.5.1.6 Preparations, Dosage, and Administration.

Gemfibrozil [Lopid] is available in 600-mg tablets. The adult dosage is 600 mg twice a day. Dosing is done 30 minutes before the morning and evening meals.

50.5.5.2 Fenofibrate

50.5.5.2.1 Actions and Uses.

Fenofibrate [Tricor, Antara, Lofibra, Triglide] is indicated for hypertriglyceridemia in patients who have not responded to dietary measures. The drug lowers triglycerides by decreasing levels of VLDLs. Fenofibrate was approved for American use in 1998, but has been available in other countries for years.

50.5.5.2.2 Pharmacokinetics.

Fenofibrate is well absorbed from the GI tract, especially in the presence of food. Once absorbed, the drug is rapidly converted to fenofibric acid, its active form. In the blood, the drug is 98% protein bound. Elimination is the result of hepatic metabolism followed by renal excretion. The plasma half-life is about 20 hours.

50.5.5.2.3 Adverse Effects and Drug Interactions.

The most common adverse effects are rash and GI disturbances. Like gemfibrozil, fenofibrate can cause gallstones and liver injury. In animal models, doses 1 to 6 times the maximum human dose caused cancers of the pancreas and liver. Like gemfibrozil, fenofibrate can increase the risk of bleeding with warfarin and the risk of myopathy with statins.

50.5.5.2.4 Preparations, Dosage, and Administration.

Fenofibrate is available in several formulations that differ with respect to dosage and the impact of food on absorption. Four products are discussed below.

Tricor tablets (48 and 145 mg) are made using NanoCrystal technology to enhance absorption. As a result, dosing can be done with or without food. The dosage range is 48 to 148 mg/day.

Triglide tablets (50 and 160 mg), like TriCor tablets, may be administered with or without food. The dosage range is 50 to 160 mg/day.

Antara capsules, which contain micronized particles, must be administered with food to maximize absorption. The dosage range is 43 to 130 mg/day.

Lofibra capsules (67, 134, and 200 mg) contain micronized particles. Like Antara, *Lofibra* must be administered with food to maximize absorption. The dosage range is 67 to 200 mg/day.

50.5.5.3 Fenofibric Acid

Fenofibric acid [TriLipix], approved in December 2008, is the active metabolite of fenofibrate. Accordingly, the pharmacology of the drug is much like that of the parent compound. Fenofibric acid stands out from other fibrates for being the only group member *approved* for use with a statin. However, just like other fibrates and the statins, fenofibric acid can cause myopathy, and hence combined use with a statin still poses significant myopathy risk. Therefore, the combination must be employed with great care. Fenofibric acid is available in delayed-release capsules (45 and 135 mg). Daily dosages for hypertriglyceridemia range from 45 mg to 135 mg. In patients with renal impairment, a low dosage (45 mg/day) should be used. When combined with a statin for patients with mixed dyslipidemias, fenofibric acid should be dosed at 135 mg/day.

50.5.6 Drug Combinations

50.5.6.1 Lovastatin/Niacin

50.5.6.1.1 Actions and Uses.

Lovastatin (immediate-release) and niacin (extended-release) are available in fixed-dose combinations under the trade name *Advicor*. Lovastatin serves primarily to lower LDL cholesterol; niacin raises HDL cholesterol and lowers TGs. In one clinical trial, using the combination for 12 months lowered LDL cholesterol by 45%, raised HDL cholesterol by 41%, and lowered TGs by 42%. The product has two indications: primary hypercholesterolemia and mixed dyslipidemia. However, it should not be used for initial therapy of either condition. Rather, it should be reserved for patients who have not responded adequately to lovastatin or niacin alone.

573

574

50.5.6.1.2 Adverse Effects.

The principal concerns are *flushing* (from the niacin) and *hepatotoxicity* (from both drugs). Flushing can be reduced by taking aspirin or ibuprofen 30 minutes before dosing. To monitor

liver injury, LFTs should be obtained at baseline, every 6 to 12 weeks for the first 6 months of treatment, and every 6 months thereafter.

Lovastatin poses a very small risk of *myopathy*. Nonetheless, advise patients to report any muscle pain or weakness. Adding a fibrate to the regimen increases the risk of myopathy (because, like the statins, fibrates can promote muscle injury).

50.5.6.1.3 Preparations, Dosage, and Administration.

Advicor is available in three lovastatin/niacin strengths: 20/500 mg, 20/750 mg, and 20/1000 mg. The recommended initial dosage is 20/500 mg once a day at bedtime. At 4-week intervals, the niacin dosage can be increased by 500 mg/day. The maximum dosage is 40/2000 mg. All doses should be taken with a low-fat snack, which can enhance absorption and reduce GI distress.

50.5.6.2 Simvastatin/Niacin

50.5.6.2.1 Actions and Uses.

Simvastatin and extended-release niacin are marketed as a fixed-dose combination under the trade name *Simcor*. The product is indicated for hypercholesterolemia and hypertriglyceridemia. Benefits derive from the actions described above for these drugs individually. Most studies show that simvastatin/niacin is no better than simvastatin alone for lowering LDL cholesterol. However, and importantly, the combination is superior to simvastatin alone for raising HDL cholesterol and, especially, for lowering TGs.

50.5.6.2.2 Adverse Effects.

The most common side effects of Simcor, regardless of the dose, include flushing, pruritus, and headache. These are the classic and most common side effects of niacin.

50.5.6.2.3 Preparations, Dosage, and Administration.

Simcor tablets are available in three simvastatin/niacin strengths: 20/500 mg, 20/750 mg, and 20/1000 mg. Therapy usually starts with the 20/500-mg product, taken once daily at bedtime. Dosing with a low-fat snack is recommended to reduce the incidence and severity of niacin-related stomach upset. If needed and tolerated, the daily niacin dose can be gradually increased to 2000 mg (with 40 mg of simvastatin).

50.5.6.3 Simvastatin/Ezetimibe

50.5.6.3.1 Actions and Uses.

Simvastatin and ezetimibe are available in fixed-dose combination tablets under the trade name *Vytorin*. Following its approval in 2004, the product quickly became one of our “top 10” most-prescribed drugs. Vytorin has only one indication: hypercholesterolemia. Because ezetimibe has a different mechanism of action than simvastatin, the combination can lower cholesterol more effectively than simvastatin alone. Theoretically, this is an extraordinarily rational drug combination. Recall that cholesterol has two main sources: endogenous production by the liver, and dietary sources. Simvastatin reduces endogenous production, and ezetimibe reduces absorption of cholesterol from the diet.

With this combination, the dose of simvastatin required to effectively lower cholesterol may be lower than the dose required when simvastatin is used alone. As a result, the risk of statin-related adverse effects (which is low to start with) can be reduced. Additional benefits of the combination are convenience (take just one pill instead of two) and reduced cost (the combination costs less than both drugs purchased separately).

Despite the advantages of Vytorin, some authorities are concerned that the combination may be less beneficial than simvastatin alone. This concern is based on four facts:

- We have proof that simvastatin *alone* can decrease adverse outcomes (ie, MI and other CV events).
- We have no proof that the combination can decrease adverse outcomes of elevated cholesterol (even though it *can* reduce *levels* of cholesterol).
- In addition to lowering cholesterol, statins have other beneficial actions (eg, they often lower elevated TGs).
- When ezetimibe and simvastatin are combined, cholesterol goals can be met using simvastatin in reduced dosage.

Because the combination permits a reduction in simvastatin dosage, there is concern that, although the target cholesterol goal may be reached, the reduction in adverse outcomes may be smaller than when cholesterol is lowered using simvastatin alone. Until data on adverse outcomes with the combination are available, this concern will remain unresolved.

50.5.6.3.2 Adverse Effects and Drug Interactions.

Vytorin is generally well tolerated. However, myopathy is a concern (because both drugs can cause muscle injury). Concurrent use of a fibrate, which can also cause myopathy, increases the risk. The risk of myopathy and other adverse effects is also increased by inhibitors of CYP3A4, the enzyme that inactivates simvastatin. Because Vytorin contains a statin, the product is contraindicated for women who are pregnant and for patients with liver disease.

50.5.6.3.3 Preparations, Dosage, and Administration.

Vytorin tablets contain 10 mg of ezetimibe plus either 10, 20, 40, or 80 mg of simvastatin. The usual starting dosage is 10 mg ezetimibe/20 mg simvastatin each day. Dosing is done once daily, preferably in the evening. The simvastatin dosage can be increased as needed and tolerated.

50.5.6.4 Pravastatin/Aspirin

Pravastatin tablets and aspirin tablets are available co-packaged under the brand name *Pravigard PAC*. The product is approved for preventing MI, stroke, and death in patients with evidence of cardiovascular or cerebrovascular disease. Pravastatin improves lipid profiles, and aspirin suppresses aggregation of platelets.

Potential side effects include myopathy (from the statin), and bleeding and GI mucosal damage (from the aspirin). Pravigard PAC should not be used by patients under 18 years old, by women who are pregnant, by anyone with severe hepatic or renal impairment, or by any patient for whom aspirin alone is contraindicated.

Each Pravigard PAC package contains 30 pravastatin tablets and 30 buffered aspirin tablets. Six pravastatin/aspirin combinations are available: 20/81 mg, 20/325 mg, 40/81 mg, 40/325 mg, 80/81 mg, and 80/325 mg. The usual dosage is 40/81 mg or 40/325 mg. Administration is done once daily with a full glass of water, with or without food. Although this package may be convenient, please note that we can achieve the same benefits—at much lower cost—by purchasing generic simvastatin and the cheapest buffered aspirin available. The pharmacology of aspirin is discussed in [Chapter 70](#).

50.5.6.5 Atorvastatin/Amlodipine

Atorvastatin and amlodipine (a calcium channel blocker) are available in fixed-dose combination tablets under the trade name *Caduet*. This is the first single product indicated for dyslipidemia combined with hypertension and/or angina. The combination has two advantages over taking each drug separately: fewer pills to swallow and slightly lower cost. Eleven amlodipine/atorvastatin combinations are available: 2.5 mg amlodipine with either 10, 20, or 40 mg atorvastatin; 5 mg amlodipine with either 10, 20, 40, or 80 mg atorvastatin; and 10 mg amlodipine with either 10, 20, 40, or 80 mg atorvastatin. Dosage is individualized on the basis of therapeutic response and tolerance of adverse effects. The pharmacology of amlodipine and other calcium channel blockers is discussed in [Chapter 44](#).

50.5.7 Fish Oil

Consuming fatty fish or fish-oil supplements is associated with a decreased risk of CHD and CHD-related death. Fish oil may also decrease the risk of thrombotic stroke.

Why is fish oil beneficial? Because it contains two “heart healthy” compounds: *eicosapentaenoic acid* (EPA) and *docosahexaenoic acid* (DHA). Structures are shown in [Figure 49-4](#). Both compounds are long-chain, omega-3 polyunsaturated fatty acids, with a methyl group at one end and a carboxyl group at the other. They are called *omega-3 fatty acids* because they have a double bond located three carbons in from the methyl terminus.

How do omega-3 fatty acids help us? The answer is unclear. We know that *high* doses (1 to 4 gm) can lower TG levels. Benefits of *lower* doses (850 mg to 1 gm) may result from reducing platelet aggregation; reducing thrombosis (by effects on platelets and the vascular endothelium); reducing inflammation (which may help stabilize atherosclerotic plaques); and reducing blood pressure and cardiac dysrhythmias.

To reduce the risk of cardiovascular events, the American Heart Association recommends eating at least two servings of fish a week. Fish with high concentrations of EPA and DHA are preferred. Among these are mackerel, halibut, herring, salmon, albacore tuna, and trout. The goal is to take in, on average, about 1 gm of omega-3 fatty acids a day.

Because fish concentrate certain environmental contaminants—especially methylmercury, dioxins, and polychlorinated biphenyls (PCBs)—eating fish carries some risk. Methylmercury can cause heart disease as well as neurologic damage, manifesting as tremor, numbness, tingling,

altered vision, and impaired concentration. Exposure *in utero* or during early childhood can lead to mental retardation, blindness, and seizures. With dioxin and PCBs, carcinogenesis is the major concern. Does this mean we should avoid eating fish? No. For postmenopausal women, and for men who are middle-aged or older,

574

575

Figure 49-4 Structures of omega-3 fatty acids in fish oil.

Eicosapentaenoic acid (EPA)

Docosahexaenoic acid (DHA)

the benefits of fish outweigh the risks. For women who are pregnant or breast-feeding, fish consumption should be limited to 12 ounces a week, and certain species—swordfish, king mackerel, shark, and golden snapper, all of which may have high levels of methylmercury—should be avoided entirely. Young children should limit fish consumption too. For people who like salmon, dioxin exposure can be reduced by eating wild salmon, which contains much less

dioxin than farm-raised salmon. Exposure to all contaminants can be reduced by using fish-oil supplements, which have much less contamination than fish themselves.

50.5.7.1 Lovaza.

Lovaza, formerly sold as *Omacor*, is the trade name for the first preparation of omega-3-acid ethyl esters approved by the FDA. The product, available only by prescription, contains a combination of EPA and DHA. Lovaza is approved as an adjunct to dietary measures to reduce very high levels of TGs (500 mg/dL or greater). When used alone, Lovaza can reduce TG levels by 20% to 50%. Combining it with simvastatin produces a further decrease. Because large doses of omega-3 fatty acids can impair platelet function, leading to prolonged bleeding time, the product should be used with care in patients taking anticoagulants or antiplatelet drugs, including aspirin. Lovaza is supplied in 1-gm, liquid-filled, soft-gelatin capsules that contain approximately 465 mg of EPA and approximately 375 mg of DHA. The recommended dosage is 4 gm/day, taken either all at once (4 capsules) or in two doses (2 capsules twice a day).

50.5.8 Plant Stanol and Sterol Esters

Stanol esters and sterol esters, which are analogs of cholesterol, can reduce intestinal absorption of cholesterol (by 10%), and can thereby reduce levels of LDL cholesterol (by 14%). These compounds do not affect HDL levels or TG levels. ATP III recommends adding plant stanols or sterols to the diet if the basic TLC diet fails to reduce LDL cholesterol to the target level. Where can you get plant stanols and sterols? Two good sources are the *Benecol* brand of margarine, and soft spreads sold under the trade name *Promise*.

50.5.9 Estrogen

In postmenopausal women, estrogen therapy (0.625 mg/day) reduces LDL cholesterol by 15% to 25% and increases HDL cholesterol by 10% to 15%. However, despite these beneficial effects on plasma lipids, estrogen therapy does not reduce CV morbidity or mortality. In fact, when estrogen is combined with a progestin for postmenopausal therapy, the risk of MI and other CV events actually goes up. Accordingly, estrogen therapy is no longer recommended for CV protection in postmenopausal women. The risks and benefits of estrogen therapy are discussed at length in [Chapter 60](#) (Estrogens and Progestins).

50.5.10 Cholestin

Cholestin is the trade name for a dietary supplement that can lower cholesterol levels. The product is made from rice fermented with red yeast. Its principal active ingredient—*lovastatin*—is identical to the active ingredient in Mevacor, a brand-name cholesterol-lowering drug. In addition to lovastatin, Cholestin contains at least seven other HMG-CoA reductase inhibitors (statins).

Several clinical trials have demonstrated that Cholestin can lower cholesterol levels, although none has studied its effects on CV events. In a trial conducted at Tufts University School of Medicine, Cholestin reduced total cholesterol by 11.4% and LDL cholesterol by 21%, and increased HDL cholesterol by 14.6%. Similarly, in a study conducted at the University of California at Los Angeles Medical School, Cholestin reduced total cholesterol by 16% and LDL cholesterol by 22%. Whether Cholestin also reduces the incidence of CHD is unknown.

Information on Cholestin is lacking in four important areas: clinical benefits, adverse effects, drug interactions, and precise mechanism of action. As noted, there are no data on the ability of Cholestin to reduce the risk of MI, stroke, or any other CV event. In contrast, the clinical benefits of prescription statins (lovastatin and all the others) are fully documented. There is little or no information on the adverse effects or drug interactions of Cholestin. In contrast, the safety (and hazards) of prescription statins, as well as their drug interactions, have been studied extensively.

The mechanism by which Cholestin lowers cholesterol levels is only partly understood. The recommended daily dose of Cholestin contains only 5 mg of lovastatin and varying doses of other HMG-CoA reductase inhibitors, compared with 10 mg for the lowest recommended dose of Mevacor. Hence, it seems unlikely that the statins in Cholestin can fully account for the supplement's ability to reduce cholesterol levels. This implies that Cholestin has one or more active ingredients that have not yet been identified. What they are and how they may work is a mystery.

What's the bottom line? Until more is known about Cholestin, stick with statins—medications of proven safety and efficacy. Furthermore, for people with health insurance, using statins is cheaper: Most insurers will cover the cost of statins, but will not pay for Cholestin.

Legal note: The makers of Cholestin are under fire from the FDA. Why? Because the FDA has ruled that, owing to its lovastatin content, Cholestin is subject to the strict regulations that apply to *drugs*—not the lax regulations that apply to nutritional supplements. (The distinction is discussed at length in [Chapter 107](#), Dietary Supplements). Hence, until the manufacturer conducts rigorous

studies on safety, efficacy, and pharmacokinetics, sales of Cholestin must stop. The maker has received numerous warning letters from the FDA, and legal proceedings are ongoing.

50.5.10.1	<div><p>KEY POINTS</p><ul style="list-style-type: none">▪ Lipoproteins are structures that transport lipids (cholesterol and triglycerides [TGs]) in blood.▪ Lipoproteins consist of a hydrophobic core, a hydrophilic shell, plus at least one apolipoprotein, which serves as a recognition site for receptors on cells.▪ Lipoproteins that contain apolipoprotein B-100 transport cholesterol and/or TGs from the liver to peripheral tissues.▪ Lipoproteins that contain apolipoproteins A-I or A-II transport cholesterol from peripheral tissues back to the liver.▪ There are three major types of lipoproteins: VLDLs (very-low-density lipoproteins), LDLs (low-density lipoproteins), and HDLs (high-density lipoproteins).▪ VLDLs transport TGs to peripheral tissues.▪ The contribution of VLDLs to CHD is unclear.▪ LDLs transport cholesterol to peripheral tissues.▪ Elevation of LDL cholesterol greatly increases the risk of CHD.▪ By reducing LDL cholesterol levels, we can arrest or reverse atherosclerosis, and can thereby reduce morbidity and mortality from CHD.▪ HDLs transport cholesterol back to the liver.▪ HDLs protect against CHD.</div>	575
	<div><ul style="list-style-type: none">▪ Atherogenesis is a chronic inflammatory process that begins with accumulation of LDLs beneath the arterial endothelium, followed by oxidation of LDLs.▪ Under ATP III, all adults over the age of 20 should be screened every 5 years for total cholesterol, LDL cholesterol, HDL cholesterol, and TGs.</div>	576

- Under ATP III, treatment of high LDL cholesterol is based on the individual's 10-year risk of having a major coronary event.
- Individuals with established CHD or a CHD risk equivalent (eg, diabetes) are in the highest 10-year risk group.
- The higher the 10-year risk, the lower the LDL goal and the LDL levels at which therapeutic lifestyle changes (TLCs) and drug therapy should be implemented.
- Diet modification along with exercise is the primary method for reducing LDL cholesterol. Drugs are employed only if diet modification and exercise fail to reduce LDL cholesterol to the target level.
- Therapy with cholesterol-lowering drugs must continue lifelong. If these drugs are withdrawn, cholesterol levels will return to pretreatment values.
- Statins (HMG-CoA reductase inhibitors) are the most effective drugs for lowering LDL cholesterol, and they cause few adverse effects.
- Statins can slow progression of CHD, decrease the number of adverse cardiac events, and reduce mortality.
- Statins reduce LDL cholesterol levels by increasing the number of LDL receptors on hepatocytes, thereby enabling hepatocytes to remove more LDLs from the blood. The process by which LDL receptor number is increased begins with inhibition of HMG-CoA reductase, the rate-limiting enzyme in cholesterol synthesis.
- Three statins—atorvastatin, lovastatin, and simvastatin—are metabolized by CYP3A4, and hence their levels can be increased by CYP3A4 inhibitors (eg, cyclosporine, erythromycin, ketoconazole, ritonavir).
- Rarely, statins cause liver damage. Tests of liver function should be done at baseline and every 6 to 12 months thereafter.
- Rarely, statins cause myopathy. Patients who experience unusual muscle pain or soreness should inform the prescriber. A marker for muscle injury—creatinine kinase (CK)—should be measured at baseline and again if signs of myopathy develop.
- Statins should not be used during pregnancy.

- Bile-acid sequestrants (eg, colestevlam) reduce LDL cholesterol levels by increasing the number of LDL receptors on hepatocytes. The mechanism is complex and begins with preventing reabsorption of bile acids in the intestine.
- Bile-acid sequestrants are not absorbed from the GI tract, and hence do not cause systemic adverse effects. However, they can cause constipation and other GI effects. (GI effects with one agent—colestevlam—are minimal.)
- Bile-acid sequestrants form complexes with other drugs, and thereby prevent their absorption. Accordingly, oral medications should be administered 1 hour before the sequestrant or 4 hours after. (Interactions of colestevlam with other drugs are minimal.)
- Ezetimibe lowers LDL cholesterol by reducing cholesterol absorption in the small intestine.
- Like the statins, ezetimibe can cause muscle injury.
- Gemfibrozil and other fibrates are the most effective drugs for lowering TG levels.
- Like the statins, the fibrates can cause muscle injury.
- Nicotinic acid reduces LDL and TG levels and raises HDL levels. Unfortunately, the drug also causes adverse effects in nearly all patients.
- Immediate-release formulations of nicotinic acid cause intense flushing of the face, neck, and ears in most patients. Flushing can be reduced by taking aspirin or ibuprofen 30 minutes before dosing, by dividing the total daily dose into smaller doses taken more often, or by using an extended-release product (eg, Niaspan).
- Nicotinic acid can cause liver injury. The risk is greatest with older sustained-release formulations.

50.5.10.2 Summary of Major Nursing Implications*

50.5.10.... IMPLICATIONS THAT APPLY TO ALL DRUGS THAT LOWER LDL CHOLESTEROL

50.5.10.... Preadministration Assessment

50.5.10.... Baseline Data

Obtain laboratory values for total cholesterol, LDL cholesterol, HDL cholesterol, and TGs (VLDLs).

50.5.10.... Identifying CHD Risk Factors

The patient history and physical examination should identify CHD risk factors. These include smoking, obesity, advancing age (men over 45 years, women over 55 years), family history of premature CHD, a personal history of cerebrovascular or peripheral vascular disease, reduced levels of HDL cholesterol (below 40 mg/dL), and hypertension.

In the past, diabetes was considered a CHD risk factor. However, because the association between diabetes and CHD is so strong, diabetes is now considered a CHD risk *equivalent* (ie, it poses the same 10-year risk of a major coronary event as CHD itself).

50.5.10.... Measures to Enhance Therapeutic Effects

50.5.10.... Diet Modification

Diet modification should precede and accompany drug therapy for elevated LDL cholesterol. **Inform patients about the importance of diet in controlling cholesterol levels and arrange for dietary counseling. Advise patients to limit consumption of cholesterol (to below 200 mg/day) and saturated fat (to below 7% of caloric intake) and to follow the other dietary recommendations listed in [Tables 49-7](#) and [49-8](#).** If these measures fail to reduce LDL cholesterol to the target level, advise patients to add soluble fiber and plant stanols or sterols to the regimen.

576
577

50.5.10....

Exercise

Regular exercise can reduce LDL cholesterol and elevate HDL cholesterol, thereby reducing the risk of CHD. **Help the patient establish an appropriate exercise program.**

50.5.10....

Reduction of CHD Risk Factors

Correctable CHD risk factors should be addressed. **Encourage cigarette smokers to quit. Encourage obese patients to lose weight.** Disease states that promote CHD—diabetes mellitus and hypertension—must be treated.

50.5.10....

Promoting Compliance

Drug therapy for elevated LDL cholesterol must continue lifelong; if drugs are withdrawn, cholesterol levels will return to pretreatment values. **Inform patients about the need for continuous therapy, and encourage them to adhere to the prescribed regimen.**

50.5.10....

HMG-COA REDUCTASE INHIBITORS (STATINS)

Atorvastatin

Fluvastatin

Lovastatin

Pravastatin

Rosuvastatin

Simvastatin

In addition to the implications discussed below, *see above* for implications that apply to all drugs that lower LDL cholesterol.

50.5.10.... Preadministration Assessment

50.5.10.... Therapeutic Goal

Statins, in combination with diet modification and exercise, are used primarily to lower levels of LDL cholesterol. Additional indications are shown in [Table 49-11](#).

50.5.10.... Baseline Data

Obtain a baseline lipid profile, consisting of total cholesterol, LDL cholesterol, HDL cholesterol, and TGs (VLDLs). Also, obtain baseline LFTs and a CK level.

50.5.10.... Identifying High-Risk Patients

Statins are *contraindicated* for patients with viral or alcoholic hepatitis and for women who are pregnant.

Exercise *caution* in patients with nonalcoholic fatty liver disease, in those who consume alcohol to excess, and in those taking fibrates or ezetimibe, or agents that inhibit CYP3A4 (eg, cyclosporine, erythromycin, ketoconazole, ritonavir). Use *rosuvastatin* with *caution* in Asian patients.

50.5.10.... Implementation: Administration

50.5.10.... Route

Oral.

50.5.10.... Administration

Instruct patients to take lovastatin with the evening meal; all other statins can be administered without regard to meals. Advise patients that dosing in the evening is preferred for all statins.

50.5.10.... Ongoing Evaluation and Interventions

50.5.10.... Evaluating Therapeutic Effects

Cholesterol levels should be monitored monthly early in treatment and at longer intervals thereafter.

50.5.10.... Minimizing Adverse Effects

Statins are very well tolerated. Side effects are uncommon, and serious adverse effects—hepatotoxicity and myopathy—are rare.

50.5.10.... Hepatotoxicity.

Statins can injure the liver, but jaundice and other clinical signs are rare. Liver function should be assessed before treatment and every 6 to 12 months thereafter (see [Table 49-10](#)). If serum transaminase becomes persistently excessive (more than 3 times the ULN), statins should be discontinued. Statins should be avoided in patients with alcoholic or viral hepatitis, but may be used in patients with nonalcoholic fatty liver disease.

50.5.10.... Myopathy.

Rarely, statins cause muscle injury. If statins are not withdrawn, injury may progress to severe myositis or potentially fatal rhabdomyolysis. **Inform patients about the risk of myopathy, and instruct them to notify the prescriber if unexplained muscle pain or tenderness develops.** If muscle pain does develop, the CK level should be measured, and, if it is more than 10 times the ULN, the statin should be withdrawn.

50.5.10.... Minimizing Adverse Interactions

The risk of myopathy is increased by (1) gemfibrozil, fenofibrate, and ezetimibe, which promote myopathy themselves; and by (2) inhibitors of CYP3A4—such as cyclosporine, macrolide antibiotics (eg, erythromycin), azole antifungal drugs (eg, ketoconazole), and HIV protease inhibitors (eg, ritonavir)—which can cause statin levels to rise. The combination of a statin with any of these drugs should be used with caution.

50.5.10....	<h2>Use in Pregnancy</h2> <p>Statins are contraindicated during pregnancy. Inform women of child-bearing age about the potential for fetal harm and warn them against becoming pregnant. If pregnancy occurs, statins should be withdrawn.</p>	
50.5.10....	<h2>NICOTINIC ACID (NIACIN)</h2> <p>In addition to the implications discussed below, <i>see above</i> for implications that apply to all drugs that lower LDL cholesterol.</p>	
50.5.10....	<h2>Preadministration Assessment</h2>	
50.5.10....	<h2>Therapeutic Goal</h2> <p>Nicotinic acid, in conjunction with diet modification and exercise, is used to reduce levels of LDL cholesterol, VLDLs, and TGs. It is also used to raise HDL cholesterol.</p>	577
50.5.10....	<h2>Baseline Data</h2> <p>Obtain laboratory values for total cholesterol, LDL cholesterol, HDL cholesterol, and TGs (VLDLs). Obtain a baseline test of liver function.</p>	578
50.5.10....	<h2>Identifying High-Risk Patients</h2> <p>Nicotinic acid is <i>contraindicated</i> for patients with active liver disease or severe or recurrent gout.</p> <p>Exercise <i>caution</i> in patients with diabetes mellitus, asymptomatic hyperuricemia, mild gout, and peptic ulcer disease.</p>	
50.5.10....	<h2>Implementation: Administration</h2>	
50.5.10....	<h2>Formulations</h2> <p>Advise patients to use an immediate-release formulation (eg, Niacor) or an extended-release formulation (eg, Niaspan), but not a long-acting formulation (eg, Slo-Niacin).</p>	

50.5.10....

Route

Oral.

50.5.10....

Administration

Instruct patients to take nicotinic acid with meals to reduce GI upset.

50.5.10....

Measures to Enhance Therapeutic Effects

50.5.10....

Dietary Therapy

Diet modification should precede and accompany drug therapy for elevated TGs and VLDLs. **Inform patients about the importance of diet in controlling lipid levels and arrange for dietary counseling.** In addition to following the guidelines presented above for all drugs that reduce LDL cholesterol, patients with hypertriglyceridemia should restrict consumption of alcohol and other sources of triglycerides.

50.5.10....

Ongoing Evaluation and Interventions

50.5.10....

Evaluating Therapeutic Effects

Blood lipid levels should be monitored monthly early in treatment and at longer (3- to 6-month) intervals thereafter.

50.5.10....

Minimizing Adverse Effects

50.5.10....

Flushing.

Nicotinic acid causes flushing of the face, neck, and ears in most patients. **Advise patients that flushing can be reduced by taking 325 mg of aspirin 30 minutes before each dose, or by using an extended-release product (eg, Niaspan).**

50.5.10....

Hepatotoxicity.

Nicotinic acid may injure the liver, causing jaundice or other symptoms. Liver function should be assessed before treatment and periodically thereafter.

Hepatotoxicity is most likely with long-acting niacin (eg, Slo-Niacin), and much less

likely with immediate-release niacin (eg, Niacor) or extended-release niacin (eg, Niaspan). Use with any statin also increases the risks.

Hyperglycemia.

Nicotinic acid may cause hyperglycemia and reduced glucose tolerance. Blood glucose should be monitored frequently. Exercise caution in patients with diabetes.

Hyperuricemia.

Nicotinic acid can elevate blood levels of uric acid. Exercise caution in patients with gout, and even in patients who have hyperuricemia but no symptoms of gout.

BILE-ACID SEQUESTRANTS

Cholestyramine

Colesevelam

Colestipol

In addition to the implications discussed below, *see above* for implications that apply to all drugs that lower LDL cholesterol.

Preadministration Assessment

Therapeutic Goal

Bile-acid sequestrants, in conjunction with diet modification and exercise (and a statin if necessary), are used to reduce elevated levels of LDL cholesterol.

Baseline Data

Obtain laboratory values for total cholesterol, LDL cholesterol, HDL cholesterol, and TGs (VLDLs).

50.5.10.... Implementation: Administration

50.5.10.... Route

Oral.

50.5.10.... Administration

Instruct patients to mix cholestyramine powder and colestipol granules with water, fruit juice, soup, or pulpy fruit (eg, applesauce, crushed pineapple) to reduce the risk of esophageal irritation and impaction. Inform patients that the sequestrants are not water soluble, and hence the mixtures will be cloudy suspensions, not clear solutions.

50.5.10.... Ongoing Evaluation and Interventions

50.5.10.... Evaluating Therapeutic Effects

Cholesterol levels should be monitored monthly early in treatment and at longer intervals thereafter.

50.5.10.... Minimizing Adverse Effects

50.5.10.... Constipation.

Cholestyramine and *colestipol*—but not *colesevelam*—can cause constipation.

Inform patients that constipation can be minimized by increasing dietary fiber and fluids. A mild laxative may be used if needed. Instruct patients taking cholestyramine or colestipol to notify the prescriber if constipation becomes bothersome, in which case a switch to colesevelam should be considered.

50.5.10.... Vitamin Deficiency.

Cholestyramine and *colestipol*—but not *colesevelam*—can impair absorption of fat-soluble vitamins (A, D, E, and K). Vitamin supplements may be required.

Colesevelam does not reduce vitamin absorption.

50.5.10....	<h2>Minimizing Adverse Interactions</h2> <p><i>Cholestyramine</i> and <i>colestipol</i>—but not <i>colesevelam</i>—can bind with other drugs and prevent their absorption. Advise patients to administer other medications 1 hour before these sequestrants or 4 hours after.</p>	578
50.5.10....	<h2>GEMFIBROZIL</h2>	579
50.5.10....	<h3>Preadministration Assessment</h3>	
50.5.10....	<h3>Therapeutic Goal</h3> <p>Gemfibrozil, in conjunction with diet modification, is used to reduce elevated levels of TGs (VLDLs). The drug is not very effective at lowering LDL cholesterol. It may also be used to raise low levels of HDL cholesterol.</p>	
50.5.10....	<h3>Baseline Data</h3> <p>Obtain laboratory values for total cholesterol, LDL cholesterol, HDL cholesterol, and TGs (VLDLs).</p>	
50.5.10....	<h3>Identifying High-Risk Patients</h3> <p>Gemfibrozil is <i>contraindicated</i> for patients with liver disease, severe renal dysfunction, and gallbladder disease.</p> <p>Use with <i>caution</i> in patients taking statins or warfarin.</p>	
50.5.10....	<h3>Implementation: Administration</h3>	
50.5.10....	<h4>Route</h4> <p>Oral.</p>	
50.5.10....	<h4>Administration</h4> <p>Instruct patients to administer gemfibrozil 30 minutes before the morning and evening meals.</p>	

Ongoing Evaluation and Interventions

Evaluating Therapeutic Effects

Obtain periodic tests of blood lipids.

Minimizing Adverse Effects

Gallstones.

Gemfibrozil increases gallstone development. **Inform patients about symptoms of gallbladder disease (eg, upper abdominal discomfort, intolerance of fried foods, bloating), and instruct them to notify the prescriber if these develop.**

Myopathy.

Gemfibrozil can cause muscle damage. **Warn patients to report any signs of muscle injury, such as tenderness, weakness, or unusual muscle pain.**

Liver Disease.

Gemfibrozil may disrupt liver function. Cancer of the liver may also be a risk. Obtain periodic tests of liver function.

Minimizing Adverse Interactions

Warfarin.

Gemfibrozil enhances the effects of warfarin, thereby increasing the risk of bleeding. Obtain more frequent measurements of prothrombin time and assess the patient for signs of bleeding. Reduction of warfarin dosage may be required, and reassessment and readjustment of the warfarin dosage may be needed if the fibrate is stopped.

Statins.

Gemfibrozil and statins both cause muscle injury. Risks rise when both are used. Use the combination with caution.

* Patient education information is highlighted as **blue text**.

⁵¹CHAPTER 50 Drugs for Angina Pectoris

Angina pectoris is defined as sudden pain beneath the sternum, often radiating to the left shoulder and arm. Anginal pain is precipitated when the oxygen supply to the heart is insufficient to meet oxygen demand. Most often, angina occurs secondary to atherosclerosis of the coronary arteries. Hence, angina should be seen as a symptom of a disease and not as a disease in its own right. In the United States, over 7 million people have chronic stable angina; about 350,000 new cases develop annually.

Drug therapy of angina has two goals: (1) prevention of myocardial infarction (MI) and death and (2) prevention of myocardial ischemia and anginal pain. Two types of drugs are employed to decrease the risk of MI and death: cholesterol-lowering drugs and antiplatelet drugs. These agents are discussed in [Chapters 49](#) and [51](#), respectively.

In this chapter, we focus on antianginal drugs (ie, drugs that prevent myocardial ischemia and anginal pain). There are three main families of antianginal agents: *organic nitrates* (eg, nitroglycerin), *beta blockers* (eg, propranolol), and *calcium channel blockers* (eg, verapamil). In addition, a fourth agent—*ranolazine*—can be combined with these drugs to supplement their effects. Most of the chapter focuses on the organic nitrates. Beta blockers and calcium channel blockers are discussed at length in previous chapters, and hence consideration here is limited to their use in angina. Ranolazine, a new drug with limited indications, is introduced here.

^{51.1} DETERMINANTS OF CARDIAC OXYGEN DEMAND AND OXYGEN SUPPLY

Before discussing angina pectoris, we need to review the major factors that determine cardiac oxygen demand and supply.

^{51.1.1} Oxygen Demand.

The principal determinants of cardiac oxygen demand are heart rate, myocardial contractility, and, most importantly, intramyocardial wall tension. Wall tension is determined by two factors: cardiac preload and cardiac afterload. (Preload and afterload are defined in [Chapter 42](#).) In summary, cardiac oxygen demand is determined by (1) heart rate, (2) contractility, (3) preload, and (4) afterload. Drugs that reduce these factors reduce oxygen demand.

^{51.1.2} Oxygen Supply.

Cardiac oxygen supply is determined by myocardial blood flow. Under resting conditions, the heart extracts nearly all of the oxygen delivered to it by the coronary vessels. Hence, the only way to accommodate an increase in oxygen demand is to increase blood flow. When oxygen demand increases, coronary arterioles dilate; the resultant decrease in vascular resistance allows blood

flow to increase. During exertion, coronary blood flow increases four- to fivefold over the flow rate at rest. It is important to note that myocardial perfusion takes place only during diastole (ie, when the heart relaxes). Perfusion does not take place during systole. Why? Because the vessels that supply the myocardium are squeezed shut when the heart contracts.

51.2 ANGINA PECTORIS: PATHOPHYSIOLOGY AND TREATMENT STRATEGY

Angina pectoris has three forms: (1) *chronic stable angina* (exertional angina), (2) *variant angina* (Prinzmetal's or vasospastic angina), and (3) *unstable angina*. Our focus is on stable angina and variant angina. Consideration of unstable angina is brief.

51.2.1 Chronic Stable Angina (Exertional Angina)

51.2.1.1 Pathophysiology.

Stable angina is triggered most often by an increase in physical activity. Emotional excitement, large meals, and cold exposure may also precipitate an attack. Because stable angina usually occurs in response to strain, this condition is also known as *exertional angina* or *angina of effort*.

The underlying cause of exertional angina is coronary artery disease (CAD), a condition characterized by deposition of fatty plaque in the arterial wall. If an artery is only partially occluded by plaque, blood flow will be reduced and angina pectoris will result. However, if complete vessel blockage occurs, blood flow will stop and MI (heart attack) will result.

580

The impact of CAD on the balance between myocardial oxygen demand and oxygen supply is illustrated in [Figure 50-1](#). As depicted, in both the healthy heart and the heart with CAD, oxygen supply and oxygen demand are in balance during rest. (In the presence of CAD, resting oxygen demand is met through dilation of arterioles distal to the partial occlusion. This dilation reduces resistance to blood flow and thereby compensates for the increase in resistance created by plaque.)

581

The picture is very different during exertion. In the healthy heart, as cardiac oxygen demand rises, coronary arterioles dilate, causing blood flow to increase. The increase keeps oxygen supply in balance with oxygen demand. By contrast, in people with CAD, arterioles in the affected region are already fully dilated during rest. Hence, when exertion occurs, there is no way to increase blood flow to compensate for the increase in oxygen demand. The resultant imbalance between oxygen supply and oxygen demand causes anginal pain.

51.2.1.2 Treatment Strategy.

The goal of antianginal therapy is to reduce the intensity and frequency of anginal attacks. Because anginal pain results from an imbalance between oxygen supply and oxygen demand, logic dictates two possible remedies: (1) increase cardiac oxygen supply or (2) decrease oxygen demand. Since the underlying cause of stable angina is occlusion of the coronary arteries, there is little we can do to increase cardiac oxygen supply. Hence, the first remedy is not a real option. Consequently, all we really can do is *decrease cardiac oxygen demand*. As discussed above, oxygen demand can be reduced with drugs that decrease heart rate, contractility, afterload, and preload.

51.2.1.3 Overview of Therapeutic Agents.

Stable angina can be treated with three main types of drugs: *organic nitrates*, *beta blockers*, and *calcium channel blockers*. As noted above, *ranolazine* can be combined with these drugs for additional benefit. All four groups relieve the pain of stable angina primarily by decreasing cardiac oxygen demand ([Table 50-1](#)). Please note that drugs only provide symptomatic relief; they do not affect the underlying pathology. To reduce the risk of MI, all patients should receive an antiplatelet drug (eg, aspirin) unless it is contraindicated. Other measures to reduce the risk of infarction are discussed later under *Drugs Used to Prevent Myocardial Infarction and Death*.

51.2.1.4 Nondrug Therapy.

Patients should attempt to avoid factors that can precipitate angina. These include overexertion, heavy meals, emotional stress, and exposure to cold.

Figure 50-1 **Effect of exertion on the balance between oxygen supply and oxygen demand in the healthy heart and the heart with CAD.** In the healthy heart, O_2 supply and O_2 demand are always in balance; during exertion, coronary arteries dilate, producing an increase in blood flow to meet the increase in O_2 demand. In the heart with CAD, O_2 supply and O_2 demand are in balance only during rest. During exertion, dilation of coronary arteries cannot compensate for the increase in O_2 demand, and an imbalance results.

TABLE 50-1 Mechanisms of Antianginal Action

Drug Class	Mechanism of Pain Relief	
	Stable Angina	Variant Angina
Nitrates	<i>Decrease oxygen demand</i> by dilating veins, which decreases preload	<i>Increase oxygen supply</i> by relaxing coronary vasospasm
Beta Blockers	<i>Decrease oxygen demand</i> by decreasing heart rate and contractility	Not used
Calcium Channel Blockers	<i>Decrease oxygen demand</i> by dilating arterioles, which decreases afterload (all calcium blockers), and by decreasing heart rate and contractility (verapamil and diltiazem)	<i>Increase oxygen supply</i> by relaxing coronary vasospasm
Ranolazine	<i>Appears to decrease oxygen demand</i> , possibly by helping the myocardium generate energy more efficiently	Not used

Risk factors for stable angina should be corrected. Important among these are smoking, obesity, hypertension, hyperlipidemia, and a sedentary lifestyle. Patients should be strongly encouraged to quit smoking. Overweight patients should be given a restricted-calorie diet; the diet should be low in saturated fats (less than 7% of total caloric intake), and total fat content should not exceed 30% of caloric intake. The target weight is 110% of ideal or less. Patients with a sedentary lifestyle should be encouraged to establish a regular program of aerobic exercise (eg, walking, jogging, swimming, biking). Hypertension and hyperlipidemia are major risk factors and should be treated. These disorders are discussed in [Chapters 46](#) and [49](#), respectively.

51.2.2 Variant Angina (Prinzmetal's Angina, Vasospastic Angina)

51.2.2.1 Pathophysiology.

Variant angina is caused by *coronary artery spasm*, which restricts blood flow to the myocardium. Hence, as in stable angina, pain is secondary to insufficient oxygenation of the heart. In contrast to stable angina, whose symptoms occur primarily at times of exertion, variant angina can produce pain at any time, even during rest and sleep. Frequently, variant angina occurs in conjunction with stable angina. Alternative names for variant angina are *vasospastic angina* and *Prinzmetal's angina*.

51.2.2.2 Treatment Strategy.

The goal is to reduce the incidence and severity of attacks. In contrast to stable angina, which is treated primarily by reducing oxygen demand, variant angina is treated by *increasing cardiac oxygen supply*. This makes sense in that the pain is caused by a reduction in oxygen supply, rather than by an increase in demand. Oxygen supply is increased with vasodilators, which prevent or relieve coronary artery spasm.

51.2.2.3 Overview of Therapeutic Agents.

Vasospastic angina is treated with two groups of drugs: *calcium channel blockers* and *organic nitrates*. Both relax coronary artery spasm. Beta blockers and ranolazine, which are effective in stable angina, are not effective in variant angina. As with stable angina, therapy is symptomatic only; drugs do not alter the underlying pathology.

51.2.3 Unstable Angina

51.2.3.1 Pathophysiology.

Unstable angina is a medical emergency. Symptoms result from severe CAD complicated by vasospasm, platelet aggregation, and transient coronary thrombi or emboli. The patient may present with either (1) symptoms of angina at rest, (2) new-onset exertional angina, or (3) intensification of existing angina. Unstable angina poses a much greater risk of death than stable angina, but a smaller risk of death than MI. The risk of dying is greatest initially and then declines to baseline in about 2 months.

51.2.3.2 Treatment.

In March of 2002, the American College of Cardiology (ACC) and the American Heart Association (AHA) issued updated guidelines for the diagnosis and management of unstable angina. The document—*ACC/AHA 2002 Guideline Update for the Management of Patients with Unstable Angina and Non-ST-Segment Elevation Myocardial Infarction*—is available free online at www.acc.org and www.americanheart.org. According to the guideline, the treatment strategy is to *maintain oxygen supply* and *decrease oxygen demand*. The goal is to reduce pain and prevent progression to MI or death. All patients should be hospitalized. Acute management consists of anti-ischemic therapy combined with antiplatelet and anticoagulation therapy.

Anti-ischemic therapy consists of

- Nitroglycerin—give the first dose sublingually (tablet or spray) and follow with IV therapy.
- A beta blocker—give the first dose IV if chest pain is ongoing. If beta blockers are contraindicated, substitute a nondihydropyridine calcium channel blocker (verapamil or diltiazem).
- Supplemental oxygen—for patients with cyanosis or respiratory distress.
- IV morphine sulfate—if pain is not relieved immediately by nitroglycerin, or if pulmonary congestion or severe agitation is present.
- An angiotensin-converting enzyme inhibitor—but only for patients with persistent hypertension, and only if they have left ventricular dysfunction or congestive heart failure.

Antiplatelet therapy, which should be started promptly, consists of

- Aspirin—continue indefinitely.
- Clopidogrel [Plavix]—continue for at least 1 month.
- Abciximab [ReoPro], a glycoprotein IIb/IIIa inhibitor—but only if angioplasty is planned.
- Eptifibatide [Integrilin] or tirofiban [Aggrastat] (both are glycoprotein IIb/IIIa inhibitors)—but only in high-risk patients with continuing ischemia, and only if angioplasty is *not* planned.

582

Anticoagulant therapy consists of subcutaneous low-molecular-weight heparin (eg, dalteparin [Fragmin]) or intravenous unfractionated heparin.

583

51.3 ORGANIC NITRATES

The organic nitrates are the oldest and most frequently used antianginal drugs. These agents relieve angina by causing vasodilation. Nitroglycerin, the most familiar organic nitrate, will serve as our prototype.

51.3.1 Nitroglycerin

Nitroglycerin has been used to treat angina since 1879. The drug is effective, fast acting, and inexpensive. Despite availability of newer antianginal agents, nitroglycerin remains the drug of choice for relieving acute anginal attacks.

51.3.1.1 Vasodilator Actions

Nitroglycerin acts directly on vascular smooth muscle (VSM) to promote vasodilation. At usual therapeutic doses, the drug acts primarily on *veins*; dilation of arterioles is only modest.

The biochemical events that lead to vasodilation are outlined in [Figure 50-2](#). The process begins with uptake of nitrate by VSM, followed by conversion of nitrate to its active form: *nitric oxide*. As indicated, conversion requires the presence of *sulfhydryl groups*. Nitric oxide then activates guanylyl cyclase, an enzyme that catalyzes the formation of cyclic GMP (cGMP). Through a series of reactions, elevation of cGMP leads to dephosphorylation of light-chain myosin in VSM. (Recall that, in all muscles, phosphorylated myosin interacts with actin to produce contraction.) As a result of dephosphorylation, myosin is unable to interact with actin, and hence VSM relaxes, causing vasodilation. For our purposes, the most important aspect of this sequence is the conversion of nitrate to its active form—nitric oxide—in the presence of a sulfhydryl source.

51.3.1.2 Mechanism of Antianginal Effects

51.3.1.2.1 Stable Angina.

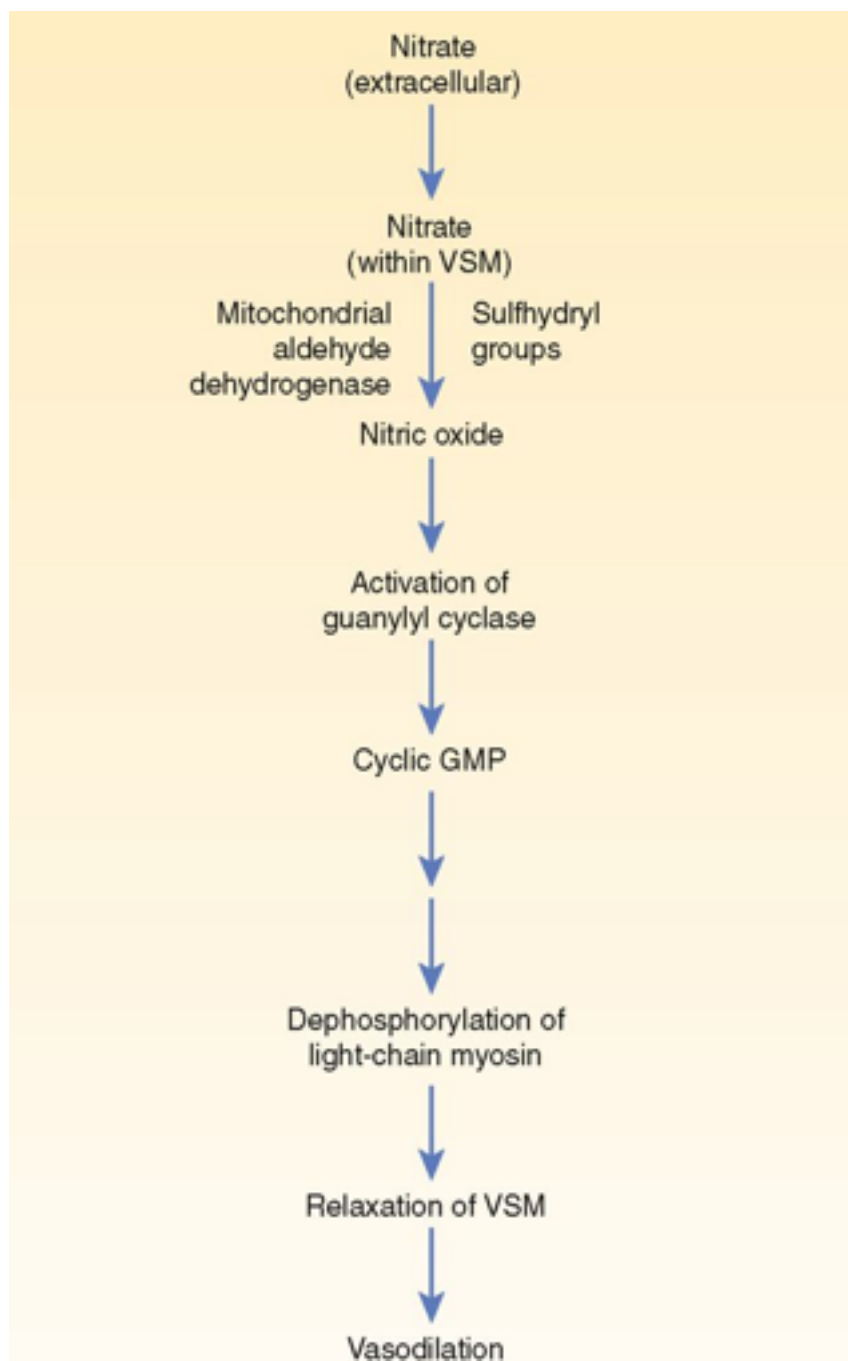

Nitroglycerin decreases the pain of exertional angina primarily by *decreasing cardiac oxygen demand*. Oxygen demand is decreased as follows: By dilating veins, nitroglycerin decreases venous return to the heart, and thereby decreases ventricular filling; the resultant decrease in wall tension (preload) decreases oxygen demand.

In patients with stable angina, nitroglycerin does not appear to increase blood flow to ischemic areas of the heart. This statement is based on two observations. First, nitroglycerin does not dilate atherosclerotic coronary arteries. Second, when nitroglycerin is injected directly into coronary arteries during an anginal attack, it does not relieve pain. Both observations suggest that pain relief results from effects of nitroglycerin on peripheral blood vessels—not from effects on coronary blood flow.

51.3.1.2.2 Variant Angina.

In patients with variant angina, nitroglycerin acts by relaxing or preventing spasm in coronary arteries. Hence, the drug *increases oxygen supply*. It does not reduce oxygen demand.

Figure 50-2 **Biochemistry of nitrate-induced vasodilation.** Note that sulfhydryl groups are needed to catalyze the conversion of nitrate to its active form, nitric oxide. If sulfhydryl groups are depleted from VSM, tolerance to nitrates will occur.

51.3.1.3 Pharmacokinetics

51.3.1.3.1 Absorption.

Nitroglycerin is *highly lipid soluble* and crosses membranes with ease. Because of this property, nitroglycerin can be administered by uncommon routes (sublingual, buccal, transdermal) as well as by more conventional routes (oral, intravenous).

51.3.1.3.2 Metabolism.

Nitroglycerin undergoes *rapid inactivation* by hepatic enzymes (organic nitrate reductases). As a result, the drug has a plasma half-life of only 5 to 7 minutes. When nitroglycerin is administered orally, most of each dose is destroyed on its first pass through the liver.

51.3.1.4 Adverse Effects

Nitroglycerin is generally well tolerated. Principal adverse effects—headache, hypotension, and tachycardia—occur secondary to vasodilation.

51.3.1.4.1 Headache.

Initial therapy can produce severe headache. This response diminishes over the first few weeks of treatment. In the meantime, headache can be reduced with aspirin, acetaminophen, or some other mild analgesic.

51.3.1.4.2 Orthostatic Hypotension.

Relaxation of VSM causes blood to pool in veins when the patient assumes an erect posture. Pooling decreases venous return to the heart, which reduces cardiac output, causing blood pressure to fall. Symptoms of orthostatic hypotension include lightheadedness and dizziness. Patients should be instructed to sit or lie down if these occur. Lying with the feet elevated promotes venous return, and can thereby help restore blood pressure.

51.3.1.4.3 Reflex Tachycardia.

Nitroglycerin lowers blood pressure—primarily by decreasing venous return, and partly by dilating arterioles. By lowering blood pressure, the drug can activate the baroreceptor reflex, thereby causing sympathetic stimulation of the heart. The resultant increase in both heart rate and contractile force increases cardiac oxygen demand, which negates the benefits of therapy. Pretreatment with a beta blocker or verapamil (a calcium channel blocker that directly suppresses the heart) can prevent sympathetic cardiac stimulation.

583

584

51.3.1.5 Drug Interactions

51.3.1.5.1 Hypotensive Drugs.

Nitroglycerin can intensify the effects of other hypotensive agents. Consequently, care should be exercised when nitroglycerin is used concurrently with beta blockers, calcium channel blockers, diuretics, and all other drugs that can lower blood pressure, including inhibitors of phosphodiesterase type 5 (PDE5). Also, patients should be advised to avoid alcohol.

51.3.1.5.2 Phosphodiesterase Type 5 Inhibitors.

As discussed in [Chapter 65](#), PDE5 inhibitors—sildenafil [Viagra], tadalafil [Cialis], and vardenafil [Levitra]—are used for erectile dysfunction. All three drugs can greatly intensify nitroglycerin-induced vasodilation. Life-threatening hypotension can result. Accordingly, concurrent use of PDE5 inhibitors with nitroglycerin is *absolutely contraindicated*.

What's the mechanism of the interaction? Nitroglycerin and the PDE5 inhibitors both increase cGMP (nitrates increase cGMP formation and PDE5 inhibitors decrease cGMP breakdown). Hence, if these drugs are combined, levels of cGMP can rise dangerously high, thereby causing excessive vasodilation and a precipitous drop in blood pressure.

51.3.1.5.3 Beta Blockers, Verapamil, and Diltiazem.

These drugs can suppress nitroglycerin-induced tachycardia. Beta blockers do so by preventing sympathetic activation of beta₁-adrenergic receptors on the heart. Verapamil and diltiazem prevent tachycardia through direct suppression of pacemaker activity in the sinoatrial node.

51.3.1.6 Tolerance

Tolerance to nitroglycerin-induced vasodilation can develop rapidly (over the course of a single day). One possible mechanism is depletion of sulfhydryl groups in VSM: In the absence of sulfhydryl groups, nitroglycerin cannot be converted to nitric oxide, its active form. Another possible mechanism is reversible oxidative injury to mitochondrial aldehyde dehydrogenase, an enzyme needed to convert nitroglycerin into nitric oxide. Patients who develop tolerance to nitroglycerin display cross-tolerance to all other nitrates and vice versa. Development of tolerance is most likely with high-dose therapy and uninterrupted therapy. To prevent tolerance, nitroglycerin and other nitrates should be used in the lowest effective dosages; long-acting formulations (eg, patches, sustained-release preparations) should be used on an intermittent schedule that allows at least 8 drug-free hours every day, usually during the night. If pain occurs

during the nitrate-free interval, it can be managed with sparing use of a short-acting nitrate (eg, sublingual nitroglycerin) or by adding a beta blocker or calcium channel blocker to the regimen. Tolerance can be reversed by withholding nitrates for a short time.

TABLE 50-2 Organic Nitrates: Time Course of Action

Drug and Dosage Form	Onset [*]	Duration [†]
Nitroglycerin		
Sublingual tablets	Rapid (1–3 min)	Brief (30–60 min)
Translingual spray	Rapid (2–3 min)	Brief (30–60 min)
Transmucosal tablets	Rapid (1–2 min)	Long (3–5 hr)
Oral capsules, SR	Slow (20–45 min)	Long (3–8 hr)
Transdermal patches	Slow (30–60 min)	Long (24 hr) [‡]
Topical ointment	Slow (30–60 min)	Long (2–12 hr)
Isosorbide Mononitrate		
Oral tablets, IR	Slow (30–60 min)	Long (6–10 hr)
Oral tablets, SR	Slow (30–60 min)	Long (7–12 hr)
Isosorbide Dinitrate		
Sublingual tablets	Rapid (2–5 min)	Long (1–3 hr)
Oral tablets, IR	Slow (20–40 min)	Long (4–6 hr)
Oral tablets, SR	Slow (30 min)	Long (6–8 hr)
Oral capsules, SR	Slow (30 min)	Long (6–8 hr)
IR = immediate release, SR = sustained release.		

* Nitrates with a *rapid* onset have two uses: (1) termination of an ongoing anginal attack and (2) short-term prophylaxis prior to anticipated exertion. Of the rapid-acting nitrates, nitroglycerin (sublingual or spray) is preferred to the others for terminating an ongoing attack.

† *Long-acting* nitrates are used for sustained prophylaxis (prevention) of anginal attacks. All cause tolerance if used without interruption.

‡ Although patches can release nitroglycerin for up to 24 hours, they should be removed after 12 to 14 hours to avoid tolerance.

51.3.1.7 Preparations and Routes of Administration

Nitroglycerin is available in an assortment of formulations for administration by a variety of routes. This proliferation of dosage forms reflects efforts to delay hepatic metabolism, and thereby prolong therapeutic effects.

All nitroglycerin preparations produce qualitatively similar responses; differences relate only to onset and duration of action ([Table 50-2](#)). With two preparations, effects begin rapidly (in 1 to 5 minutes) and then fade in less than 1 hour. With three others, effects begin slowly but last several hours. Only one preparation has both a rapid onset and long duration.

Applications of specific preparations are based on their time course. Preparations with a *rapid onset* are employed to *terminate an ongoing anginal attack*. When used for this purpose, rapid-acting preparations are administered as soon as pain begins. Rapid-acting preparations can also be used for *acute prophylaxis of angina*. For this purpose, they are taken just prior to anticipated exertion. *Long-acting preparations* are used to provide *sustained protection* against anginal attacks. To provide protection, they are administered on a fixed schedule (but one that permits at least 8 drug-free hours each day).

Trade names and dosages for nitroglycerin preparations are summarized in [Table 50-3](#).

51.3.1.7.1 Sublingual Tablets.

When administered sublingually (beneath the tongue), nitroglycerin is absorbed directly through the oral mucosa and into the bloodstream. Hence, unlike orally administered drugs, which must pass through the liver on their way to the systemic circulation, sublingual nitroglycerin bypasses the liver, and thereby temporarily avoids inactivation. Because the liver is bypassed, sublingual doses can be low (between 0.3 and 0.6 mg). These doses are about 10 times lower than those required when nitroglycerin is taken orally.

584

585

TABLE 50-3 Organic Nitrates: Trade Names and Dosages

Drug and Formulation	Trade Name	Usual Dosage
Nitroglycerin		
Sublingual tablets	Nitrostat, NitroQuick, Nitrotab	0.3–0.6 mg as needed
Translingual spray	Nitrolingual	0.4 mg as needed
Transmucosal tablets	Nitrogard	1–3 mg 3 times daily
Oral capsules, SR	generic only	2.5–6.5 mg 3 or 4 times daily; to avoid tolerance, administer only once or twice daily; do not crush or chew
Transdermal patches	Minitran, Nitrodisc, Nitro-Dur, Nitrek, Transderm-Nitro	1 patch a day; to avoid tolerance, remove after 12–14 hr, allowing 10–12 patch-free hours each day. Patches come in sizes that release 0.1–0.8 mg/hr
Topical ointment	Nitro-Bid	1–2 inches (7.5–40 mg) every 4–8 hr
Intravenous	Nitro-Bid IV, Tridil	5 mcg/min initially, then increased gradually as needed (max 200 mcg/min); tolerance develops with prolonged continuous infusion
Isosorbide Mononitrate		
Oral tablets, IR	ISMO, Monoket	20 mg twice daily; to avoid tolerance, take the first dose upon awakening and the second dose 7 hr later
Oral tablets, SR	Isotrate ER, Imdur	60–240 mg once a day; do not crush or chew
Isosorbide Dinitrate		
Sublingual tablets	Isordil	2.5–15 mg every 4–6 hr; do not crush or chew
Oral tablets, IR	Isordil Titradose	5–80 mg every 6 hr; to avoid tolerance, take only 2 or 3 times daily, with the last dose no later than 7:00 PM
Oral tablets, SR	generic only	40 mg every 6–12 hr; to avoid tolerance, take only once or twice daily (at 8:00 AM and 2:00 PM)
Oral capsules, SR	Dilatrate-SR	40 mg every 6–12 hr; to avoid tolerance, take only once or twice daily (at 8:00 AM and 2:00 PM)
Amyl Nitrite		

Inhalant	generic only	0.18 or 0.3 mL
IR = immediate release, SR = sustained release.		

Effects of sublingual nitroglycerin begin rapidly—in 1 to 3 minutes—and persist up to 1 hour. Because sublingual administration works fast, this route is ideal for (1) terminating an ongoing attack and (2) short-term prophylaxis when exertion is anticipated.

To terminate an acute anginal attack, sublingual nitroglycerin should be administered as soon as pain begins. Administration should not be delayed until the pain has become severe. According to current guidelines, if pain is not relieved in 5 minutes, the patient should call 911 or report to an emergency department, since anginal pain that does not respond to nitroglycerin may indicate MI. While awaiting emergency care, the patient can take 1 more tablet, and then a third tablet 5 minutes later.

Sublingual administration is unfamiliar to most patients. Accordingly, education is needed. The patient should be instructed to place the tablet under the tongue and leave it there while it dissolves. Nitroglycerin tablets formulated for sublingual use are ineffective if swallowed.

Nitroglycerin tablets are chemically unstable and can lose effectiveness over time. Shelf life can be prolonged by storing tablets in a tightly closed, dark container. Under these conditions, most tablets made today remain effective for at least 24 months after the container is first opened.* As a rule, nitroglycerin tablets should be discarded after this time. Patients should be instructed to write the date of opening on the container and to discard unused tablets 24 months later.

* Nitroglycerin tablets sold as NitroQuick are only stable for 8 to 10 months, rather than 24 months.

51.3.1.7.2 Sustained-Release Oral Capsules.

Sustained-release oral capsules are intended for long-term prophylaxis only; these formulations cannot act fast enough to terminate an ongoing anginal attack. Sustained-release capsules contain a large dose of nitroglycerin that is slowly absorbed across the GI wall. In theory, doses are large enough so that amounts of nitroglycerin sufficient to produce a therapeutic response will survive passage through the liver. Because they produce sustained blood levels of nitroglycerin, these formulations can cause tolerance. To reduce the risk of tolerance, these products should be taken only once or twice daily. Patients should be instructed to swallow sustained-release capsules intact.

51.3.1.7.3 Transdermal Delivery Systems.

Nitroglycerin patches look like Band-Aids and contain a reservoir from which nitroglycerin is slowly released. Following release, the drug is absorbed through the skin and then into the blood. The rate of release is constant for any particular transdermal patch and, depending upon the patch used, can range from 0.1 to 0.8 mg/hr. Effects begin within 30 to 60 minutes and persist as long as the patch remains in place (up to 14 hours). Patches are applied once daily to a hairless area of skin. The site should be rotated to avoid local irritation.

585

586

Tolerance develops if patches are used continuously (24 hours a day every day). Accordingly, a daily “patch-free” interval of 10 to 12 hours is recommended. This can be accomplished by applying a new patch each morning, leaving it in place for 12 to 14 hours, and then removing it in the evening.

Because of their long duration, patches are well suited for sustained prophylaxis. Since patches have a delayed onset, they cannot be used to abort an ongoing attack.

51.3.1.7.4 Translingual Spray.

Nitroglycerin can be delivered to the oral mucosa using a metered-dose spray device. Each activation delivers a 0.4-mg dose. Indications for nitroglycerin spray are the same as for sublingual tablets: suppression of an acute anginal attack and prophylaxis of angina when exertion is anticipated. As with sublingual tablets, no more than three doses should be administered within a 15-minute interval. *Patients should be instructed not to inhale the spray.*

51.3.1.7.5 Transmucosal (Buccal) Tablets.

Administration of transmucosal nitroglycerin tablets consists of placing the tablet between the upper lip and the gum, or in the buccal area between the cheek and the gum. The tablet adheres to the oral mucosa and slowly dissolves over 3 to 5 hours. As the tablet dissolves, nitroglycerin is absorbed directly through the oral mucosa and then into the blood, thereby bypassing the liver. Like sublingual nitroglycerin, transmucosal nitroglycerin has a rapid onset. Hence, transmucosal administration can be used to terminate an ongoing anginal attack and to provide short-term prophylaxis prior to exertion. In addition, since the effects of transmucosal nitroglycerin are prolonged, this formulation can be used for sustained prophylaxis. Patients should be instructed not to chew or swallow these tablets.

51.3.1.7.6 Topical Ointment.

Topical nitroglycerin ointment is used for sustained protection against anginal attacks. The ointment is applied to the skin of the chest, back, abdomen, or anterior thigh. (Since nitroglycerin acts primarily by dilating peripheral veins, there is no mechanistic advantage to applying topical nitroglycerin directly over the heart.) Following topical application, nitroglycerin is absorbed through the skin and then into the blood. Effects begin within 20 to 60 minutes and may persist up to 12 hours.

Nitroglycerin ointment (2%) is dispensed from a tube, and the length of the ribbon squeezed from the tube determines dosage. (One inch contains about 15 mg of nitroglycerin.) The usual adult dosage is 1 to 2 inches applied every 4 to 8 hours. The ointment should be spread over an area at least 2.5 inches by 3.5 inches and then covered with plastic wrap. Sites of application should be rotated to minimize skin irritation. As with other long-acting formulations, uninterrupted use can cause tolerance.

51.3.1.7.7 Intravenous Infusion.

Intravenous nitroglycerin is employed only rarely to treat angina pectoris. When used for angina, IV nitroglycerin is limited to patients who have failed to respond to other medications. Additional uses of IV nitroglycerin include treatment of heart failure associated with acute MI, treatment of perioperative hypertension, and production of controlled hypotension for surgery.

Intravenous nitroglycerin has a very short duration of action, and hence continuous infusion is required. The infusion rate is 5 mcg/min initially and then is increased gradually until an adequate response has been achieved. Heart rate and blood pressure must be monitored continuously.

Stock solutions of nitroglycerin must be diluted for IV use. Since ampules of nitroglycerin prepared by different manufacturers can differ in both volume and nitroglycerin concentration, the label must be read carefully when dilutions are made.

Administer using a glass IV bottle and the administration set provided by the manufacturer. Nitroglycerin absorbs into standard polyvinyl chloride tubing, and hence this tubing should be avoided.

51.3.1.8 Discontinuing Nitroglycerin

Long-acting preparations (transdermal patches, topical ointment, sustained-release oral tablets or capsules) should be discontinued slowly. If they are withdrawn abruptly, vasospasm may result.

51.3.1.9 Summary of Therapeutic Uses

51.3.1.9.1 Acute Therapy of Angina.

For acute treatment of angina pectoris, nitroglycerin is administered in sublingual tablets, transmucosal tablets, and a translingual spray. All three formulations can be used to abort an ongoing anginal attack and to provide prophylaxis in anticipation of exertion.

51.3.1.9.2 Sustained Therapy of Angina.

For sustained prophylaxis against angina, nitroglycerin is administered in the following formulations: transdermal patches, topical ointment, transmucosal tablets, and sustained-release oral capsules.

51.3.1.9.3 Intravenous Therapy.

Intravenous nitroglycerin is indicated for perioperative control of blood pressure, production of controlled hypotension during surgery, and treatment of heart failure associated with acute MI. In addition, IV nitroglycerin is used to treat unstable angina and chronic angina when symptoms cannot be controlled with preferred medications.

51.3.2 Isosorbide Mononitrate and Isosorbide Dinitrate

Both of these drugs have pharmacologic actions identical to those of nitroglycerin. Both drugs are used for angina, both are taken orally, and both produce headache, hypotension, and reflex tachycardia. Differences between them relate only to route of administration and time course of action. Time course determines whether a particular drug or dosage form will be used for acute therapy, sustained prophylaxis, or both. As with nitroglycerin, tolerance can develop to long-acting preparations. To avoid tolerance, long-acting preparations should be used on an intermittent schedule that allows at least 8 drug-free hours a day. Time courses are summarized in [Table 50-2](#), and trade names and dosages are summarized in [Table 50-3](#).

51.3.3 Amyl Nitrite

Amyl nitrite is an ultrashort-acting agent used to treat acute episodes of angina pectoris. The drug has the same mechanism as nitroglycerin. Amyl nitrite is a volatile liquid dispensed in glass ampules. For administration, 1 ampule (0.18 or 0.3 mL) is crushed, allowing the volatile compound to be inhaled. Effects begin within 30 seconds and terminate in 3 to 5 minutes. Amyl nitrite is highly flammable and hence should not be used near flame. The drug is reputed to intensify sexual orgasm and has been abused for that purpose (see [Chapter 39](#)).

51.4 BETA BLOCKERS

Beta blockers (eg, propranolol, metoprolol) are first-line drugs for *angina of effort*, but are *not* effective against vasospastic angina. When administered on a fixed schedule, beta blockers can provide sustained protection against effort-induced anginal pain. Exercise tolerance is increased and the frequency and intensity of anginal attacks are lowered. All of the beta blockers appear equally effective. In addition to reducing anginal pain, beta blockers decrease the risk of death, especially in patients with a prior MI.

Beta blockers reduce anginal pain primarily by *decreasing cardiac oxygen demand*. This is accomplished mainly through blockade of beta₁ receptors in the heart, which decreases heart rate and contractility. Beta blockers reduce oxygen demand further by causing a modest reduction in arterial pressure (afterload). In addition to decreasing oxygen demand, beta blockers help increase oxygen supply. How? By slowing heart rate, they increase time in diastole, and thereby increase the time during which blood flows through myocardial vessels. (Recall that blood does not flow in these vessels during systole.) In patients taking vasodilators (eg, nitroglycerin), beta blockers provide the additional benefit of blunting reflex tachycardia.

For treatment of stable angina, dosage should be low initially and then gradually increased. The dosing goal is to reduce resting heart rate to 50 to 60 beats/min, and limit exertional heart rate to about 100 beats/min. Beta blockers should not be withdrawn abruptly, since doing so can increase the incidence and intensity of anginal attacks, and may even precipitate MI.

586

587

Beta blockers can produce a variety of adverse effects. Blockade of cardiac beta₁ receptors can produce *bradycardia*, *decreased atrioventricular (AV) conduction*, and *reduction of contractility*. Consequently, beta blockers should not be used by patients with sick sinus syndrome, heart failure, or second-degree or third-degree AV block. Blockade of beta₂ receptors in the lung can promote bronchoconstriction. Accordingly, beta blockers should be avoided by patients with asthma. If an asthmatic individual absolutely must use a beta blocker, a beta₁-selective agent (eg, metoprolol) should be chosen. Beta blockers can mask signs of hypoglycemia, and therefore must be used with

caution in patients with diabetes. Through effects on the central nervous system, these drugs can cause *insomnia, depression, bizarre dreams, and sexual dysfunction*.

The basic pharmacology of the beta blockers is discussed in [Chapter 18](#).

51.5 CALCIUM CHANNEL BLOCKERS

The calcium channel blockers (CCBs) used most frequently are *verapamil, diltiazem, and nifedipine* (a dihydropyridine-type calcium channel blocker). Accordingly, our discussion focuses on these three drugs. *All three* can block calcium channels in VSM, primarily in arterioles. The result is arteriolar dilation and reduction of peripheral resistance (afterload). In addition, all three can relax coronary vasospasm. *Verapamil* and *diltiazem* also block calcium channels in the heart, and can thereby decrease heart rate, AV conduction, and contractility.

Calcium channel blockers are used to treat both stable angina and variant angina. In *variant angina*, these drugs promote relaxation of coronary artery spasm, thereby *increasing cardiac oxygen supply*. In *stable angina*, they promote relaxation of peripheral arterioles; the resultant decrease in afterload *reduces cardiac oxygen demand*. Verapamil and diltiazem can produce modest additional reductions in oxygen demand by suppressing heart rate and contractility.

The major adverse effects of the CCBs are cardiovascular. Dilation of peripheral arterioles lowers blood pressure, and can thereby induce *reflex tachycardia*. This reaction is greatest with nifedipine and minimal with verapamil and diltiazem. Because of their suppressant effects on the heart, verapamil and diltiazem must be used cautiously in patients taking beta blockers and in patients with bradycardia, heart failure, or AV block. These precautions do not apply to nifedipine or other dihydropyridines.

The basic pharmacology of the CCBs is discussed in [Chapter 44](#).

51.6 RANOLAZINE

51.6.1 Actions and Therapeutic Use

Ranolazine [Ranexa] represents the first new class of antianginal agents to be approved in more than 25 years. In clinical trials, the drug reduced the number of angina episodes per week and increased exercise tolerance. However, these benefits were modest, and were smaller in women than in men. Unlike most other antianginal drugs, ranolazine does not reduce heart rate, blood pressure, or vascular resistance. However, it *can* prolong the QT interval, and is subject to multiple drug interactions. How does ranolazine work? We know it can reduce accumulation of sodium and calcium in myocardial cells, and might thereby help the myocardium use energy more efficiently. However, the exact mechanism of action is unknown. Because of its limited efficacy

and a risk of dysrhythmias (see below), ranolazine is not indicated for first-line therapy. Rather, it should be reserved for patients who have not responded adequately to nitrates, beta blockers, or CCBs, and should always be combined with at least one of these agents.

51.6.2 Pharmacokinetics

Absorption from the GI tract is highly variable, but not affected by food. Plasma levels peak 2 to 5 hours after dosing. In the liver, ranolazine undergoes rapid and extensive metabolism, mainly by CYP3A4 (the 3A4 isozyme of cytochrome P450). The drug has a plasma half-life of 7 hours, and is excreted in the urine (75%) and feces (25%), almost entirely as metabolites.

51.6.3 Adverse Effects

51.6.3.1 QT Prolongation.

Ranolazine can cause a dose-related increase in the QT interval, and may thereby increase the risk of torsades de pointes, a serious ventricular dysrhythmia. Accordingly, the drug is contraindicated for patients with pre-existing QT prolongation and for those taking other drugs that can increase the QT interval. In addition, ranolazine is contraindicated for patients at risk of developing high levels of the drug—namely, patients with hepatic impairment or those taking drugs that inhibit CYP3A4. The issue of drug-induced QT prolongation is discussed further in [Chapter 7](#) (Adverse Drug Reactions and Medication Errors).

51.6.3.2 Elevation of Blood Pressure.

In patients with severe renal impairment, ranolazine can raise blood pressure by about to 15 mm Hg. Accordingly, blood pressure should be monitored often in these people.

51.6.3.3 Other Adverse Effects.

The most common adverse effects are constipation (8%), dizziness (5%), nausea (4%), and headache (3%).

51.6.4 Drug Interactions

51.6.4.1 CYP3A4 Inhibitors.

Agents that inhibit CYP3A4 can increase levels of ranolazine, and can thereby increase the risk of torsades de pointes. Accordingly, moderate or strong CYP3A4 inhibitors should be avoided. Among these agents are grapefruit juice, HIV protease inhibitors (eg, ritonavir), macrolide

antibiotics (eg, erythromycin), azole antifungal drugs (eg, itraconazole), and some calcium channel blockers (but not amlodipine).

51.6.4.2 QT Drugs.

Drugs that prolong the QT interval (eg, quinidine, sotalol) can increase the risk of torsades de pointes in patients taking ranolazine, and hence should be avoided. [Table 7-2](#) (see [Chapter 7](#)) presents a comprehensive list of QT drugs.

51.6.4.3 Calcium Channel Blockers.

Most CCBs—but not amlodipine—can inhibit CYP3A4, and can thereby increase levels of ranolazine. Accordingly, when combined use of ranolazine and a CCB is indicated, amlodipine is the only CCB that should be used.

51.6.5 Preparations, Dosage, and Administration

Ranolazine [Ranexa] is formulated in extended-release tablets (500 and 1000 mg) that should be swallowed intact, with or without food. Dosing begins at 500 mg twice daily, and may be increased to a maximum of 1000 mg twice daily. Ranolazine should be used in combination with a nitrate, beta blocker, or the CCB amlodipine.

587

51.7 REVASCULARIZATION THERAPY: CABG AND PCI

588

If drug therapy of angina fails to control symptoms, surgical revascularization should be considered. The two principal forms of revascularization are coronary artery bypass grafting (CABG) and percutaneous coronary intervention (PCI).

51.7.1 Coronary Artery Bypass Graft Surgery

CABG surgery is used to increase blood flow to ischemic areas of the heart. In this procedure, one end of a segment of healthy blood vessel (internal mammary artery or saphenous vein) is grafted onto the aorta, and the other end is connected to the diseased coronary artery at a point distal to the region of atherosclerotic plaque. Hence, the graft constitutes a shunt whereby blood flow can circumvent the occluded section of a diseased coronary vessel. Following surgery, most patients remain in the hospital for a week, and then recuperate for another 6 weeks at home. Once considered exotic, CABG surgery is now commonplace; more than 300,000 Americans undergo the procedure each year.

Vessel blockage can recur over time, thereby requiring repeat surgery. When an artery is used for the graft, the incidence of reblockage is only 4% after 10 years. In contrast, when a vein is used, the incidence of reblockage is nearly 50% after 10 years.

A relatively new procedure, called *minimally invasive direct coronary artery bypass* (MIDCAB) surgery, is an alternative to CABG surgery for some patients. MIDCAB surgery is much less invasive than CABG surgery, and therefore faster and cheaper. Furthermore, MIDCAB surgery is performed on the beating heart, and hence, heart-lung bypass machinery is not needed. At this time, MIDCAB surgery is used only to bypass blockage in the left ascending coronary artery.

51.7.2 Percutaneous Coronary Intervention

PCI is an alternative to CABG surgery for patients with stable angina. As performed today, PCI typically consists of two steps: balloon angioplasty followed by stenting. In balloon angioplasty, a miniature catheter containing a deflated balloon is inserted into the femoral artery, threaded up into the aorta, and then manipulated into the occluded coronary artery. The balloon is then inflated, thereby flattening the obstruction and allowing blood to flow. After the vessel has been opened with the balloon, the cardiologist implants a stent (a tiny tube made of stainless steel mesh) to help prevent restenosis. (Restenosis is caused by hyperplasia of neointimal cells and constrictive remodeling of the injured artery.) To further reduce the risk of restenosis, most stents employed today are coated with sirolimus or paclitaxel—drugs that suppress the proliferation and migration of neointimal cells. The incidence of restenosis with either drug-eluting stent is much lower than with bare-metal stents—and restenosis with the sirolimus-eluting stent is lower than with the paclitaxel-eluting stent.

51.7.3 Comparison of CABG Surgery with PCI

CABG surgery and PCI are equally safe and almost equally effective. The 5-year survival rate after either procedure is about 90%. However, in other respects, the procedures differ substantially. Compared with PCI, CABG surgery is more traumatic and more expensive, it requires a longer hospital stay, and recovery is slower. On the other hand, CABG surgery is more effective: coronary blood flow is better, relief of angina is superior, exercise tolerance is higher, and patients require less antianginal medication. Moreover, the incidence of reblockage after CABG surgery is lower. At this time, CABG surgery is considered the treatment of choice for patients with multivessel disease. For patients with single-vessel disease, either procedure is generally appropriate; the choice is based on patient preference.

51.8 SUMMARY OF TREATMENT MEASURES

51.8.1 Guidelines for Management of Chronic Stable Angina

In 1999, three organizations—the American Heart Association, the American College of Cardiology, and the American College of Physicians—American Society of Internal Medicine—joined forces to produce the first national guidelines on the management of chronic stable angina. The 1999 guidelines were updated in 2002 and again in 2007. Both updates—*ACC/AHA 2002 Guideline Update for the Management of Patients with Chronic Stable Angina*, and *2007 Chronic Angina Focused Update of the ACC/AHA 2002 Guidelines for the Management of Patients with Chronic Stable Angina*—are available free online at circ.ahajournals.org. The discussion below reflects recommendations in these guidelines.

Treatment of stable angina has two objectives: (1) prevention of MI and death, and (2) reduction of cardiac ischemia and associated anginal pain. Although both goals are desirable, prevention of MI and death is clearly more important. Hence, if two treatments are equally effective at decreasing anginal pain, but one also decreases the risk of death, then the latter is preferred.

51.8.1.1 Drugs Used to Prevent Myocardial Infarction and Death

We now have medical treatments that can decrease the risk of MI and death in patients with chronic stable angina. Therapy directed at prevention of MI and death is a new paradigm in the management of stable angina, and all practitioners should become familiar with it.

51.8.1.1.1 Antiplatelet Drugs.

These agents decrease platelet aggregation and thereby decrease the risk of thrombus formation in coronary arteries. The most effective agents are *aspirin* and *clopidogrel*. In patients with stable angina, low-dose aspirin produces a 33% decrease in the risk of adverse cardiovascular events. Benefits of clopidogrel seem equal to those of aspirin, although they are not as well documented. The guidelines recommend that all patients with stable angina take 75 to 162 mg of aspirin daily, unless there is a specific reason not to. Aspirin, clopidogrel, and other antiplatelet drugs are discussed in [Chapter 51](#).

51.8.1.1.2 Cholesterol-Lowering Drugs.

Elevated cholesterol is a major risk factor for coronary atherosclerosis. Drugs that lower cholesterol can slow the progression of CAD, stabilize atherosclerotic plaques, and even cause plaque regression. Therapies that reduce cholesterol are associated with decreased mortality from coronary heart disease. For example, in patients with established CAD, taking

simvastatin can decrease the risk of mortality by 35%. Because of the well-established benefits of cholesterol-lowering therapy, the guidelines recommend that all patients with stable angina receive a cholesterol-lowering drug. The pharmacology of the cholesterol-lowering drugs is discussed in [Chapter 49](#).

588

589

51.8.1.1.3

Angiotensin-Converting Enzyme (ACE) Inhibitors.

There is strong evidence that, in patients with CAD, ACE inhibitors greatly reduce the incidence of adverse outcomes. In the Heart Outcomes Prevention Evaluation (HOPE) trial, for example, ramipril reduced the incidence of stroke, MI, and cardiovascular death. Among one subset of patients—those with diabetes—benefits were particularly striking. Ramipril decreased the risk of stroke by 33%, MI by 22%, and cardiovascular death by 37%; also, the drug reduced the risk of nephropathy, retinopathy, and other microvascular complications of diabetes. Because of these well-documented benefits, the guidelines now recommend ACE inhibitors for most patients with established CAD, and especially for those with diabetes. The pharmacology of the ACE inhibitors is discussed in [Chapter 43](#).

51.8.1.2

Antianginal Agents: Drugs Used to Reduce Anginal Pain

The goal of antianginal therapy is to achieve complete (or nearly complete) elimination of anginal pain—along with a return to normal activities. This should be accomplished with a minimum of adverse drug effects.

The basic strategy of antianginal therapy is to provide baseline protection using one or more long-acting drugs (beta blocker, calcium channel blocker [CCB], long-acting nitrate) supplemented with sublingual nitroglycerin when breakthrough pain occurs. A flow plan for drug selection is shown in [Figure 50-3](#). As indicated, treatment is approached sequentially. Progression from one step to the next is based on patient response. Some patients can be treated with a single long-acting drug, some require two or three, and some require revascularization.

Initial treatment consists of sublingual nitroglycerin plus a long-acting antianginal drug. As indicated in [Figure 50-3](#), beta blockers are the preferred agents for baseline therapy. Why? Because they can decrease mortality, especially in patients with a prior MI. In addition to providing prophylaxis, beta blockers suppress nitrate-induced reflex tachycardia.

If a beta blocker is inadequate, or if there are contraindications to beta blockade, a long-acting CCB should be added or substituted. Because CCBs do not promote bronchoconstriction, they are preferred to beta blockers for patients with asthma. Dihydropyridine-type CCBs (eg, nifedipine) lack cardiosuppressant actions, and hence are safer than beta blockers for patients with bradycardia, AV block, or heart failure. When a CCB is to be *combined* with a beta

blocker, a dihydropyridine is preferred to verapamil or diltiazem. Why? Because verapamil and diltiazem will intensify the cardiosuppressant actions of the beta blocker, whereas a dihydropyridine will not.

If a CCB is inadequate, or if there are contraindications to calcium channel blockade, a long-acting nitrate (eg, transdermal nitroglycerin) should be added or substituted. However, because tolerance can develop quickly, these nitrate preparations are less well suited than beta blockers or CCBs for continuous protection.

Note that, as we proceed along the drug-selection flow plan, drugs are *added* to the regimen, resulting in treatment with two or more agents. Combination therapy increases our chances of success because oxygen demand is decreased by

Figure 50-3 Flow plan for antianginal drug selection in patients with chronic stable angina.¹ Avoid short-acting dihydropyridines.² At any point in this process, based on coronary anatomy, severity of angina symptoms, and patient preference, it is reasonable to consider evaluation for coronary revascularization (PCI or CABG). Unless a patient is documented to have left main, three-vessel, or two-vessel CAD with significant stenosis of the proximal left anterior descending coronary artery, there is no demonstrated survival advantage associated with CABG or PCI in low-risk patients with chronic stable angina. Accordingly, medical therapy should be attempted in most patients before considering PCI or CABG.

(Adapted from Gibbons RJ, Chatterjee K, Daley J, et al: ACC/AHA 2002 guideline update for the management of patients with chronic stable angina: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to Update the 1999 Guidelines for the Management of Patients with Chronic Stable Angina]. 2002. Available online at circ.ahajournals.org).

multiple mechanisms: beta blockers reduce heart rate and contractility; CCBs reduce afterload (by dilating arterioles); and nitrates reduce preload (by dilating veins).

If combined treatment with a beta blocker, CCB, and long-acting nitrate fails to provide relief, CABG surgery or PCI may be indicated. Note that these invasive procedures should be considered only after more conservative treatment has been tried.

589

TABLE 50-4 Choosing Between Beta Blockers and Calcium Channel Blockers for Treating Angina in Patients Who Have a Coexisting Condition

Coexisting Condition	Recommended Treatment (Alternative Treatment)	Drugs to Avoid
Medical Conditions		
Systemic hypertension	Beta blockers (long-acting, slow-release CCBs)	
Migraine or vascular headache	Beta blockers (verapamil or diltiazem)	
Asthma or COPD with bronchospasm	Verapamil or diltiazem	Beta blockers
Hyperthyroidism	Beta blockers	
Raynaud's disease	Long-acting, slow-release CCBs	Beta blockers
Type 1 diabetes	Beta blockers, particularly if prior MI, or long-acting, slow-release CCBs	
Type 2 diabetes	Beta blockers or long-acting, slow-release CCBs	
Depression	Long-acting, slow-release CCBs	Beta blockers
Mild peripheral vascular disease	Beta blockers or long-acting, slow-release CCBs	
Severe peripheral vascular disease with ischemia at rest	Long-acting, slow-release CCBs	Beta blockers
Cardiac Dysrhythmias and Conduction Abnormalities		
Sinus bradycardia	Long-acting, slow-release CCBs that do not decrease heart rate	Beta blockers, diltiazem, verapamil
Sinus tachycardia (not due to heart failure)	Beta blockers	
Supraventricular tachycardia	Verapamil, diltiazem, or beta blockers	
AV block	Long-acting, slow-release CCBs that do not slow AV conduction	Beta blockers, diltiazem, verapamil
Rapid atrial fibrillation (with digoxin)	Verapamil, diltiazem, or beta blockers	
Ventricular dysrhythmias	Beta blockers	
Left Ventricular Dysfunction		
Heart failure		
Mild (LVEF $\geq 40\%$)	Beta blockers	

Moderate to severe (LVEF <40%)	Amlodipine or felodipine (nitrates)	Diltiazem, verapamil
Left-sided valvular heart disease		
Mild aortic stenosis	Beta blockers	
Aortic insufficiency	Long-acting, slow-release dihydropyridine CCBs	
Mitral regurgitation	Long-acting, slow-release dihydropyridine CCBs	
Mitral stenosis	Beta blockers	
Hypertrophic cardiomyopathy	Beta blockers, verapamil, diltiazem	Dihydropyridine CCBs, nitrates
Adapted from Gibbons RJ, Chatterjee K, Daley J, et al: ACC/AHA 2002 Guideline Update for the Management of Patients with Chronic Stable Angina: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Update the 1999 Guidelines for the Management of Patients with Chronic Stable Angina). 2002. Available online at circ.ahajournals.org/ .		
AV = atrioventricular, CCB = calcium channel blocker, COPD = chronic obstructive pulmonary disease, LVEF = left ventricular ejection fraction, MI = myocardial infarction.		

How should we treat angina in patients who have a coexisting condition? The antianginal drugs employed—nitrates, beta blockers, and CCBs—are the same ones used in patients who have angina alone. However, when selecting among these drugs, we must consider the coexisting disorder as well as the angina. For example, as noted above, in patients with asthma, CCBs are preferred to beta blockers (because beta blockers promote bronchoconstriction, whereas CCBs do not). [Table 50-4](#) lists over 20 coexisting conditions, and indicates which antianginal agents to use as well as which ones to avoid.

51.8.1.3 Reduction of Risk Factors

The treatment program should reduce anginal risk factors: smokers should quit; obese patients should lose weight; sedentary patients should get aerobic exercise; and patients with diabetes, hypertension, or high cholesterol should receive appropriate therapy.

51.8.1.3.1 Smoking.

Smoking increases the risk of cardiovascular mortality by 50%. Fortunately, smoking cessation greatly decreases cardiovascular risk. Accordingly, all patients who smoke should be strongly encouraged to quit. Drugs employed as an aid to smoking cessation are discussed in [Chapter 39](#).

51.8.1.3.2 High Cholesterol.

As noted, high cholesterol levels increase the risk of adverse cardiovascular events, and therapies that reduce cholesterol reduce that risk. Accordingly, all patients with high cholesterol levels should receive cholesterol-lowering therapy.

51.8.1.3.3 Hypertension.

High blood pressure increases the risk of cardiovascular mortality, and lowering blood pressure reduces the risk. Accordingly, all patients with hypertension should receive treatment. Blood pressure should be reduced to 140/90 mm Hg or less. In patients with additional risk factors (eg, diabetes, heart failure, retinopathy), the target blood pressure is 130/80 mm Hg or less. Management of hypertension is discussed in [Chapter 46](#).

51.8.1.3.4 Diabetes.

Both type 1 (insulin-dependent) and type 2 (non–insulin-dependent) diabetes increase the risk of cardiovascular mortality. Type 1 increases the risk 3- to 10-fold; type 2 increases the risk 2- to 4-fold. Although there is good evidence that tight glycemic control decreases the risk of microvascular complications of diabetes, there is little evidence to show that tight glycemic control decreases the risk of cardiovascular complications. Nonetheless, it is prudent to strive for optimal glycemic control.

590

591

51.8.1.3.5 Obesity.

Obesity is associated with an increased risk of coronary disease and mortality; weight reduction is likely to reduce that risk. Accordingly, a program of diet and exercise is recommended for all patients whose body weight exceeds 120% of ideal. Weight reduction is especially important for patients with diabetes, hypertension, and hypertriglyceridemia. Obesity and its management are discussed in [Chapter 81](#).

51.8.1.3.6 Physical Inactivity.

Increased physical activity has multiple benefits. In patients with chronic stable angina, exercise increases exercise tolerance and the sense of well-being, and decreases anginal symptoms, cholesterol levels, and objective measures of ischemia. Accordingly, the guidelines recommend that patients perform 30 to 60 minutes of a moderate-intensity activity 3 to 4 times a week. Such activities include walking, jogging, cycling, and other aerobic exercises. Exercise by moderate- to high-risk patients should be medically supervised.

51.8.2 Management of Variant Angina

Treatment of vasospastic angina can proceed in three steps. For initial therapy, either a calcium channel blocker or a long-acting nitrate is selected. If either drug alone is inadequate, then combined therapy with a calcium channel blocker *plus* a nitrate should be tried. If the combination fails to control symptoms, CABG surgery may be indicated. Beta blockers are not effective in vasospastic angina.

51.8.2.1 KEY POINTS

- Anginal pain occurs when cardiac oxygen supply is insufficient to meet oxygen demand.
- Cardiac oxygen demand is determined by heart rate, contractility, preload, and afterload. Drugs that reduce these factors can help relieve anginal pain.
- Cardiac oxygen supply is determined by myocardial blood flow. Drugs that increase oxygen supply will reduce anginal pain.
- Angina pectoris has three forms: chronic stable angina, variant (vasospastic) angina, and unstable angina.
- The underlying cause of stable angina is coronary artery atherosclerosis.
- The underlying cause of variant angina is coronary artery spasm.
- Drugs relieve pain of stable angina by decreasing cardiac oxygen demand. They do not increase oxygen supply.
- Drugs relieve pain of variant angina by increasing cardiac oxygen supply. They do not decrease oxygen demand.
- Nitroglycerin and other organic nitrates are vasodilators.
- To cause vasodilation, nitroglycerin must first be converted to nitric oxide, its active form. This reaction requires a sulfhydryl source.
- Nitroglycerin relieves pain of stable angina by dilating veins, which decreases venous return, which decreases preload, which decreases oxygen demand.
- Nitroglycerin relieves pain of variant angina by relaxing coronary vasospasm, which increases oxygen supply.

- Nitroglycerin is highly lipid soluble, and therefore is readily absorbed through the skin and oral mucosa.
- Nitroglycerin undergoes very rapid inactivation in the liver. Hence, when the drug is administered orally, most of each dose is destroyed before reaching the systemic circulation.
- When nitroglycerin is administered sublingually, it is absorbed directly into the systemic circulation, and therefore temporarily bypasses the liver. Hence, to produce equivalent effects, sublingual doses can be much smaller than oral doses.
- Nitroglycerin causes three characteristic side effects: headache, orthostatic hypotension, and reflex tachycardia. All three occur secondary to vasodilation.
- Reflex tachycardia from nitroglycerin can be prevented with a beta blocker, verapamil, or diltiazem.
- Continuous use of nitroglycerin can produce tolerance within 24 hours. The mechanism may be depletion of sulfhydryl groups.
- To prevent tolerance, nitroglycerin should be used in the lowest effective dosage, and long-acting formulations should be used on an intermittent schedule that allows at least 8 drug-free hours every day, usually during the night.
- Nitroglycerin preparations that have a rapid onset (eg, sublingual nitroglycerin) are used to abort an ongoing anginal attack and to provide acute prophylaxis when exertion is expected. Administration is PRN.
- Nitroglycerin preparations that have a long duration (eg, patches, sustained-release oral capsules) are used for extended protection against anginal attacks. Administration is on a fixed schedule (but one that allows at least 8 drug-free hours a day).
- Nitroglycerin should be used cautiously with most vasodilators, and must not be used at all with sildenafil [Viagra] and other PDE5 inhibitors.
- Beta blockers prevent pain of stable angina primarily by decreasing heart rate and contractility, which reduces cardiac oxygen demand.
- Beta blockers are administered on a fixed schedule, not PRN.
- Beta blockers are not used for variant angina.

- Calcium channel blockers relieve pain of stable angina by reducing cardiac oxygen demand. Two mechanisms are involved. First, all CCBs relax peripheral arterioles, and thereby decrease afterload. Second, verapamil and diltiazem reduce heart rate and contractility (in addition to decreasing afterload).
- Calcium channel blockers relieve pain of variant angina by increasing cardiac oxygen supply. The mechanism is relaxation of coronary artery spasm.
- When a CCB is combined with a beta blocker, a dihydropyridine (eg, nifedipine) is preferred to verapamil or diltiazem. Why? Because verapamil and diltiazem will intensify cardiosuppression caused by the beta blocker, whereas a dihydropyridine will not.
- Ranolazine appears to reduce anginal pain by helping the heart generate energy more efficiently.

591

- Ranolazine should not be used alone. Rather, it should be combined with a nitrate, a beta blocker, or the CCB amlodipine.
- Ranolazine increases the QT interval, and may thereby pose a risk of torsades de pointes, a serious ventricular dysrhythmia.
- In patients with chronic stable angina, treatment has two objectives: (1) prevention of MI and death and (2) prevention of anginal pain.
- The risk of MI and death can be decreased with two types of drugs: (1) antiplatelet agents (eg, aspirin) and (2) cholesterol-lowering drugs.
- Anginal pain is prevented with one or more long-acting antianginal drugs (beta blocker, calcium channel blocker, long-acting nitrate) supplemented with sublingual nitroglycerin when breakthrough pain occurs.
- As a rule, revascularization with CABG surgery or PCI is indicated only after treatment with two or three antianginal drugs has failed.

592

51.8.2.2 Summary of Major Nursing Implications*

51.8.2.2.1 NITROGLYCERIN

51.8.2.2... Preadministration Assessment

51.8.2.2... Therapeutic Goal

Reduction of the frequency and intensity of anginal attacks.

51.8.2.2... Baseline Data

Obtain baseline data on the frequency and intensity of anginal attacks, the location of anginal pain, and the factors that precipitate attacks.

The patient interview and physical examination should identify risk factors for angina pectoris, including treatable contributing pathophysiologic conditions (eg, hypertension, hyperlipidemia).

51.8.2.2... Identifying High-Risk Patients

Use with *caution* in hypotensive patients and patients taking drugs that can lower blood pressure, including alcohol and antihypertensive medications. Use with sildenafil [Viagra] and other PDE5 inhibitors is *contraindicated*.

51.8.2.2... Implementation: Administration

51.8.2.2... Routes and Administration

51.8.2.2... Sublingual Tablets.

51.8.2.2... Use.

Prophylaxis or termination of an acute anginal attack.

51.8.2.2... Technique of Administration.

Instruct patients to place the tablet under the tongue and leave it there until fully dissolved; the tablet should not be swallowed.

Instruct patients to call 911 or go to an emergency department if pain is not relieved in 5 minutes. While awaiting emergency care, they can take 1 more tablet, and then a third tablet 5 minutes later.

Instruct patients to store tablets in a dark, tightly closed bottle that contains no other medications. Instruct patients to write the date of opening on the bottle and to discard unused medication after 24 months. (Products sold as Nitro-Quick should be discarded after 8 to 10 months).

51.8.2.2...

Sustained-Release Oral Capsules.

51.8.2.2...

Use.

Sustained protection against anginal attacks.

To avoid tolerance, administer only once or twice daily.

51.8.2.2...

Technique of Administration.

Instruct patients to swallow these preparations intact, without chewing or crushing.

51.8.2.2...

Transdermal Delivery Systems.

51.8.2.2...

Use.

Sustained protection against anginal attacks.

51.8.2.2...

Technique of Administration.

Instruct patients to apply transdermal patches to a hairless area of skin, using a new patch and a different site each day.

Instruct patients to remove the patch after 12 to 14 hours, allowing 10 to 12 “patch-free” hours each day. This will prevent tolerance.

51.8.2.2...

Translingual Spray.

51.8.2.2...

Use.

Prophylaxis or termination of an acute anginal attack.

51.8.2.2...

Technique of Administration.

Instruct patients to direct the spray against the oral mucosa. Warn patients not to inhale the spray.

51.8.2.2...

Transmucosal (Buccal) Tablets.

51.8.2.2...

Uses.

(1) Prophylaxis or termination of an acute anginal attack and (2) sustained prophylaxis.

51.8.2.2...

Technique of Administration.

Instruct patients to place the transmucosal tablet between the upper lip and the gum or in the buccal area between the cheek and the gum. Inform patients that the tablet will adhere to the oral mucosa and slowly dissolve over 3 to 5 hours. To achieve sustained prophylaxis, a tablet should be administered every 3 to 8 hours.

51.8.2.2...

Topical Ointment.

51.8.2.2...

Use.

Sustained protection against anginal attacks.

Before applying a new dose, remove ointment remaining from the previous dose.

51.8.2.2...

Technique of Administration.

(1) Squeeze a ribbon of ointment of prescribed length onto the applicator paper provided; (2) using the applicator paper, spread the ointment over an area at least 2.5 inches by 3.5 inches (application may be made to the chest, back, abdomen, upper arm, or anterior thigh); and (3) cover the ointment with plastic wrap. Avoid touching the ointment.

Rotate the application site to minimize local irritation.

51.8.2.2...	Intravenous.	
51.8.2.2...	<p>Uses.</p> <p>(1) Angina pectoris refractory to more conventional therapy, (2) perioperative control of blood pressure, (3) production of controlled hypotension during surgery, and (4) heart failure associated with acute MI.</p>	592
51.8.2.2...	<p>Technique of Administration.</p> <p>Perform IV administration using a glass IV bottle and the administration set provided by the manufacturer; avoid standard IV tubing. Dilute stock solutions before use.</p> <p>Administer by continuous infusion. The rate is slow initially (5 mg/min) and then gradually increased until an adequate response is achieved.</p> <p>Monitor cardiovascular status constantly.</p>	593
51.8.2.2...	<p>Terminating Therapy</p> <p>Warn patients against abrupt withdrawal of long-acting preparations (transdermal systems, topical ointment, sustained-release tablets and capsules).</p>	
51.8.2.2...	Implementation: Measures to Enhance Therapeutic Effects	
51.8.2.2...	Reducing Risk Factors	
51.8.2.2...	<p>Precipitating Factors.</p> <p>Advise patients to avoid activities that are likely to elicit an anginal attack (eg, overexertion, heavy meals, emotional stress, cold exposure).</p>	
51.8.2.2...	<p>Weight Reduction.</p> <p>Help overweight patients develop a restricted-calorie diet. The diet should be low in saturated fats, and total fat should not exceed 30% of caloric intake. Target weight is 110% of ideal or less.</p>	

51.8.2.2...

Exercise.

Encourage patients who have a sedentary lifestyle to establish a regular program of aerobic exercise (eg, walking, jogging, swimming, biking).

51.8.2.2...

Smoking Cessation.

Strongly encourage patients to quit smoking.

51.8.2.2...

Contributing Disease States.

Ensure that patients with contributing pathology (especially hypertension or hypercholesterolemia) are receiving appropriate treatment.

51.8.2.2...

Ongoing Evaluation and Interventions

51.8.2.2...

Evaluating Therapeutic Effects

Have the patient keep a record of the frequency and intensity of anginal attacks, the location of anginal pain, and the factors that precipitate attacks.

51.8.2.2...

Minimizing Adverse Effects

51.8.2.2...

Headache.

Inform patients that headache will diminish with continued drug use. Advise patients that headache can be relieved with aspirin, acetaminophen, or some other mild analgesic.

51.8.2.2...

Orthostatic Hypotension.

Inform patients about symptoms of hypotension (eg, dizziness, lightheadedness), and advise them to sit or lie down if these occur. Inform patients that hypotension can be minimized by moving slowly when changing from a sitting or supine position to an upright posture.

51.8.2.2...

Reflex Tachycardia.

This reaction can be suppressed by concurrent treatment with a beta blocker, verapamil, or diltiazem.

51.8.2.2...

Minimizing Adverse Interactions

51.8.2.2...

Hypotensive Agents, Including PDE5 Inhibitors.

Nitroglycerin can interact with other hypotensive drugs to produce excessive lowering of blood pressure. **Advise patients to avoid alcohol.** Exercise caution when nitroglycerin is used in combination with beta blockers, calcium channel blockers, diuretics, and all other drugs that can lower blood pressure.

Combining nitroglycerin with a PDE5 inhibitor (eg, sildenafil [Viagra]) can cause life-threatening hypotension. Accordingly, these combinations are absolutely contraindicated.

51.8.2.2.2

ISOSORBIDE MONONITRATE AND ISOSORBIDE DINITRATE

Both drugs have pharmacologic actions identical to those of nitroglycerin. Differences relate only to dosage forms, routes of administration, and time course of action. Hence, the implications presented for nitroglycerin apply to these drugs as well.

* Patient education information is highlighted as **blue text**.

⁵²CHAPTER 51 Anticoagulant, Antiplatelet, and Thrombolytic Drugs

The drugs discussed in this chapter are used to prevent formation of thrombi (intravascular blood clots) and dissolve thrombi that have already formed. These drugs act in several ways: some suppress coagulation, some inhibit platelet aggregation, and some promote clot degradation. They all interfere with normal hemostasis. As a result, they all carry a significant risk of bleeding.

^{52.1}COAGULATION: PHYSIOLOGY AND PATHOPHYSIOLOGY

^{52.1.1} Hemostasis

Hemostasis is the physiologic process by which bleeding is stopped. Hemostasis occurs in two stages: (1) formation of a platelet plug, followed by (2) reinforcement of the platelet plug with fibrin. Both processes are set in motion by blood vessel injury.

^{52.1.1.1} Stage One: Formation of a Platelet Plug.

Platelet aggregation is initiated when platelets come in contact with collagen on the exposed surface of a damaged blood vessel. In response to contact with collagen, platelets adhere to the site of vessel injury. Adhesion initiates platelet *activation*, which in turn leads to massive platelet *aggregation*.

Platelet aggregation is a complex process that ends with formation of *fibrinogen bridges* between *glycoprotein IIb/IIIa (GP IIb/IIIa) receptors* on adjacent platelets ([Fig. 51-1](#)). In order for these bridges to form, GP IIb/IIIa receptors must first undergo activation—that is, they must undergo a configurational change that allows them to bind with fibrinogen. As indicated in [Figure 51-1A](#), activation of GP IIb/IIIa can be stimulated by multiple factors, including thromboxane A₂ (TXA₂), thrombin, collagen, platelet activation factor, and ADP. Under the influence of these factors, GP IIb/IIIa changes its shape, binds with fibrinogen, and thereby causes aggregation ([Fig. 51-1B](#)). The aggregated platelets constitute a plug that stops bleeding. This plug is unstable, however, and must be reinforced with *fibrin* if protection is to last.

^{52.1.1.2} Stage Two: Coagulation.

Coagulation is defined as production of *fibrin*, a thread-like protein that reinforces the platelet plug. Fibrin is produced by two convergent pathways ([Fig. 51-2](#)), referred to as the *contact activation pathway* (also known as the *intrinsic pathway*) and the *tissue factor pathway* (also known as the *extrinsic pathway*). As shown in [Figure 51-2](#), the two pathways converge at factor

Xa, after which they employ the same final series of reactions. In both pathways, each reaction in the sequence amplifies the reaction that follows. Hence, once this sequence is initiated, it becomes self-sustaining and self-reinforcing.

The *tissue factor pathway* is turned on by trauma to the vascular wall, which triggers release of tissue factor,* also known as *tissue thromboplastin*. Tissue factor then combines with and thereby activates factor VII, which in turn activates factor X, which then catalyzes the conversion of *prothrombin* (factor II) into *thrombin* (factor IIa). As shown in [Figure 51-2](#), factor IIa (thrombin) then does three things. First, it catalyzes the conversion of fibrinogen into fibrin. Second, it catalyzes the conversion of factor V into *its* active form (Va), a compound that greatly increases the activity of factor Xa, even though it has no direct catalytic activity of its own. Third, factor IIa catalyzes the conversion of factor VIII into *its* active form (VIIIa), a compound that greatly increases the activity of factor IXa in the contact activation pathway.

The *contact activation pathway* is turned on when blood makes contact with collagen that has been exposed as a result of trauma to a blood vessel wall. Collagen contact stimulates conversion of factor XII into its active form, XIIa (see [Figure 51-2](#)). Factor XIIa then activates factor XI, which activates factor IX, which activates factor X. After this, the contact activation pathway is the same as the tissue factor pathway. As noted, factor VIIIa, which is produced under the influence of prothrombin, greatly increases the activity of factor IXa, even though it has no direct catalytic activity of its own.

594

Figure 51-1 Mechanism of platelet aggregation and actions of antiplatelet drugs. **A**, Multiple factors—TXA₂, thrombin, collagen, PAF, and ADP—promote activation of the GP IIb/IIIa receptor. Each platelet has 50,000 to 80,000 GP IIb/IIIa receptors, although only one is shown. **B**, Activation of the GP IIb/IIIa receptor permits binding of fibrinogen, which then causes aggregation by forming cross-links between platelets. After aggregation occurs, the platelet plug is reinforced with fibrin (not shown). (AA = arachidonic acid, ADP = adenosine diphosphate, GP IIb/IIIa = glycoprotein IIb/IIIa receptor, PAF = platelet activation factor, TXA₂ = thromboxane A₂.)

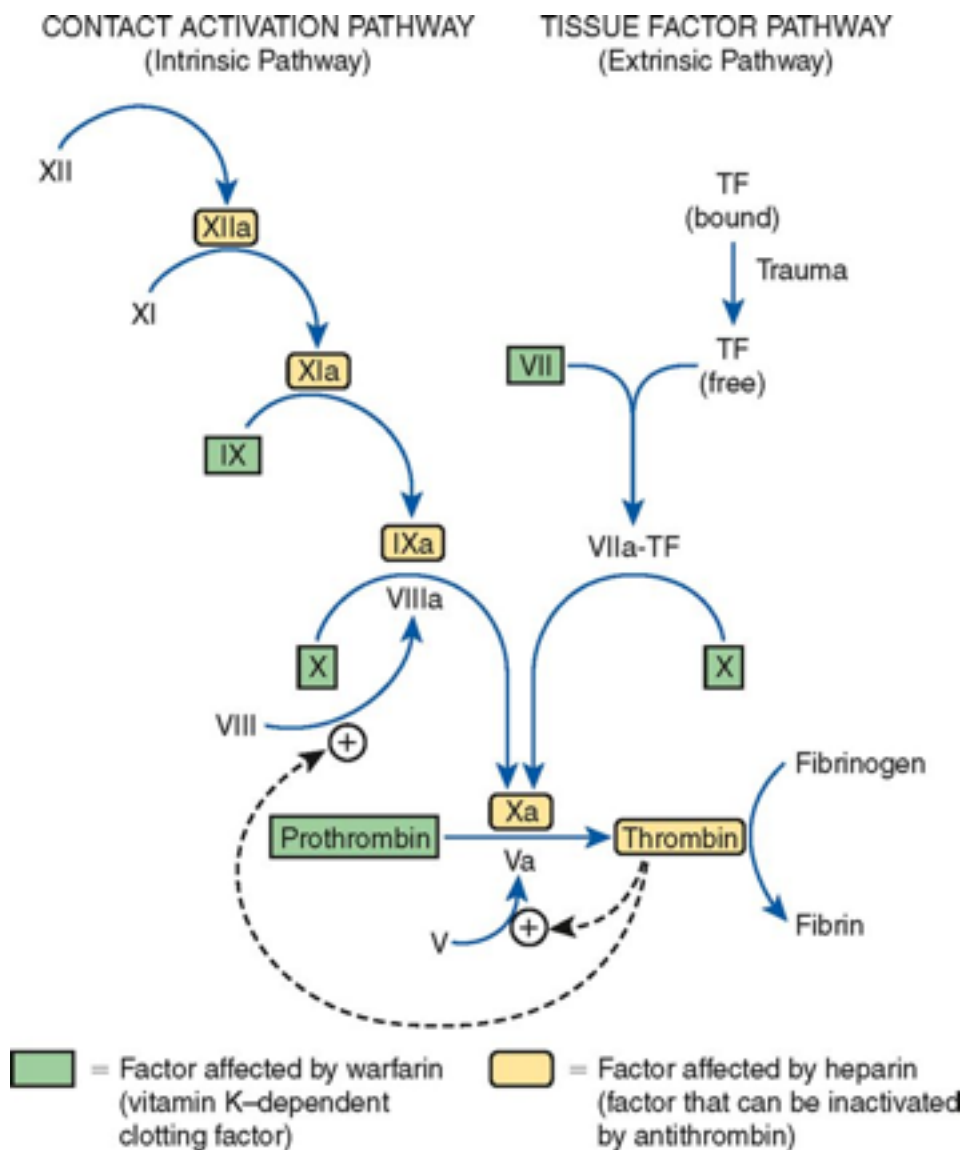

Figure 51-2 Outline of coagulation pathways showing factors affected by warfarin and heparin. TF = tissue factor. Common names for factors shown in roman numerals: V = proaccelerin, VII = proconvertin, VIII = antihemophilic factor, IX = Christmas factor, X = Stuart factor, XI = plasma thromboplastin antecedent, and XII = Hageman factor. The letter “a” after a factor's name (eg, factor VIIIa) indicates the active form of the factor.

Important to our understanding of anticoagulant drugs is the fact that *four coagulation factors*—*factors VII, IX, X, and II (prothrombin)*—*require vitamin K for their synthesis*. These factors appear in green boxes in [Figure 51-2](#). The significance of the vitamin K–dependent factors will become apparent when we discuss warfarin, an oral anticoagulant.

* FYI: the term *tissue factor* refers not to a single compound but rather to a complex of several compounds, including a proteolytic enzyme and phospholipids released from tissue membranes.

52.1.1.3 Keeping Hemostasis Under Control.

To protect against widespread coagulation, the body must inactivate any clotting factors that stray from the site of vessel injury. This inactivation is accomplished with *antithrombin* (formerly known as *antithrombin III*), a protein that forms a complex with clotting factors, and thereby inhibits their activity. The clotting factors that can be neutralized by antithrombin appear in yellow in [Figure 51-2](#). As we shall see, antithrombin is intimately involved in the action of *heparin*, an injectable anticoagulant drug.

52.1.1.4 Physiologic Removal of Clots.

As healing of an injured vessel proceeds, removal of the clot is eventually necessary. The body accomplishes this with *plasmin*, an enzyme that degrades the fibrin meshwork of the clot. Plasmin is produced through the activation of its precursor, *plasminogen*. The *thrombolytic drugs* (eg, streptokinase, alteplase) act by promoting conversion of plasminogen into plasmin.

52.1.2 Thrombosis

A thrombus is a blood clot formed within a blood vessel or within the heart. Thrombosis (thrombus formation) reflects pathologic functioning of hemostatic mechanisms.

52.1.2.1 Arterial Thrombosis.

Formation of an arterial thrombus begins with adhesion of platelets to the arterial wall. (Adhesion is stimulated by damage to the wall or rupture of an atherosclerotic plaque.) Following adhesion, platelets release ADP and TXA₂, and thereby attract additional platelets to the evolving thrombus. With continued platelet aggregation, occlusion of the artery takes place. As blood flow comes to a stop, the coagulation cascade is initiated, causing the original plug to undergo reinforcement with fibrin. The consequence of an arterial thrombus is localized tissue injury owing to lack of perfusion.

52.1.2.2 Venous Thrombosis.

Venous thrombi develop at sites where blood flow is slow. Stagnation of blood initiates the coagulation cascade, resulting in the production of fibrin, which enmeshes red blood cells and platelets to form the thrombus. The typical venous thrombus has a long tail that can break off to produce an *embolus*. Such emboli travel within the vascular system and become lodged at faraway sites, frequently the pulmonary arteries. Hence, unlike an arterial thrombus, whose harmful effects are localized, injury from a venous thrombus occurs secondary to embolization at a site distant from the original thrombus.

596

597

TABLE 51-1 Overview of Drugs for Thromboembolic Disorders

Generic Name	Trade Name	Route	Action	Therapeutic Use
ANTICOAGULANTS			Anticoagulants decrease formation of fibrin	Used primarily to prevent <i>venous</i> thrombosis
Vitamin K Antagonist				
Warfarin	Coumadin	PO		
Factor Xa and Thrombin Inhibitors				
Heparin		subQ, IV		
LMW Heparins*				
Dalteparin	Fragmin	subQ		
Enoxaparin	Lovenox	subQ		
Tinzaparin	Innohep	subQ		
Selective Factor Xa Inhibitors				
Fondaparinux	Arixtra	subQ		
Rivaroxaban†	Xarelto	PO		
Direct Thrombin Inhibitors				
Argatroban	Acova	IV		
Bivalirudin	Angiomax	IV		
Lepirudin	Refludan	IV		
Desirudin	Ipravask	subQ		
Dabigatran†	Pradaxa	PO		
ANTIPLATELET DRUGS			Antiplatelet drugs suppress platelet aggregation	Used primarily to prevent <i>arterial</i> thrombosis
Cyclooxygenase Inhibitor				
Aspirin		PO		
Adenosine Diphosphate Receptor Antagonists				
Clopidogrel	Plavix	PO		
Prasugrel†	Effient	PO		
Ticlopidine	Ticlid	PO		
Glycoprotein IIb/IIIa Receptor Antagonists				

Abciximab	ReoPro	IV		
Eptifibatide	Integrilin	IV		
Tirofiban	Aggrastat	IV		
Other Antiplatelet Drugs				
Dipyridamole	Persantine	PO		
Cilostazol	Pletal	PO		
THROMBOLYTIC DRUGS				
Alteplase	Activase	IV	Thrombolytic drugs	Used to dissolve
Streptokinase	Streptase	IV, IA	promote	newly formed
Reteplase	Retavase	IV	breakdown of	thrombi
Tenecteplase	TNKase	IV	fibrin	
IA = intra-arterial (into an occluded artery); LMW = low molecular weight.				

* LMW heparins inactivate factor Xa more effectively than they inactivate thrombin.

† Not approved in the United States.

52.2 OVERVIEW OF DRUGS FOR THROMBOEMBOLIC DISORDERS

The drugs considered in this chapter fall into three major groups: (1) anticoagulants, (2) antiplatelet drugs, and (3) thrombolytic drugs. *Anticoagulants* (eg, heparin, warfarin) disrupt the coagulation cascade, and thereby suppress production of fibrin. *Antiplatelet drugs* (eg, aspirin, clopidogrel) inhibit platelet aggregation. *Thrombolytic drugs* (eg, alteplase, streptokinase) promote lysis of fibrin, and thereby cause dissolution of thrombi. Drugs that belong to these groups are listed in [Table 51-1](#).

Although the anticoagulants and the antiplatelet drugs both suppress thrombosis, they do so by different mechanisms. As a result, they differ in their effects and applications. The *antiplatelet drugs* are most effective at preventing *arterial* thrombosis, whereas *anticoagulants* are most effective against *venous* thrombosis.

52.3 ANTICOAGULANTS

By definition, anticoagulants are drugs that *reduce formation of fibrin*. Two basic mechanisms are involved. One anticoagulant—warfarin—inhibits the *synthesis* of clotting factors, including factor X and thrombin. All other anticoagulants inhibit the *activity* of clotting factors (either factor Xa, thrombin, or both).

597

Traditionally, anticoagulants have been grouped into two major classes: *oral anticoagulants* and *parenteral anticoagulants*. This scheme was reasonable because, until recently, all oral

598

anticoagulants belonged to just one pharmacologic class: the vitamin K antagonists, of which warfarin is the principal member. Today, however, anticoagulants in two other pharmacologic classes—factor Xa inhibitors and direct thrombin inhibitors—can also be administered by mouth (see [Table 51-1](#)). Hence, grouping the anticoagulants by route of administration makes less sense than in the past. Accordingly, in this chapter, these drugs are grouped only by pharmacologic class, and not by whether they are given orally or by injection.

52.4 HEPARIN AND HEPARIN DERIVATIVES

All of the drugs in this section share the same mechanism of action. Specifically, they greatly enhance the activity of antithrombin, a protein that inactivates two major clotting factors: thrombin and factor Xa. In the absence of thrombin and factor Xa, production of fibrin is reduced, and hence clotting is suppressed.

52.4.1 Heparin (Unfractionated)

Heparin is a rapid-acting anticoagulant administered only by injection. Heparin differs from warfarin (an oral anticoagulant) in several respects, including mechanism, time course, indications, and management of overdose.

52.4.1.1 Source

Heparin is present in various mammalian tissues. The heparin employed clinically is prepared from two sources: lungs of cattle and intestines of pigs. The anticoagulant activity of heparin from either source is equivalent. Although heparin occurs naturally, its physiologic role is unknown.

52.4.1.2 Chemistry

Heparin is not a single molecule, but rather a mixture of long polysaccharide chains, with molecular weights that range from 3000 to 30,000. The active region is a unique pentasaccharide (five-sugar) sequence found randomly along the chain. An important feature of heparin's structure is the presence of many negatively charged groups. Because of these negative charges, heparin is highly polar, and hence cannot readily cross membranes.

52.4.1.3 Mechanism of Anticoagulant Action

Heparin suppresses coagulation by helping antithrombin inactivate clotting factors, primarily thrombin and factor Xa. As shown in [Figure 51-3](#), binding of heparin to antithrombin produces a conformational change in antithrombin that greatly enhances its ability to inactivate both

thrombin and factor Xa. However, the process of inactivating these two clotting factors is not identical. In order to inactivate thrombin, heparin must simultaneously bind with both thrombin and antithrombin, thereby forming a ternary complex (see [Fig. 51-3](#)). In contrast, in order to inactivate factor Xa, heparin binds only with antithrombin; heparin itself does not bind with factor Xa.

By promoting the inactivation of thrombin and factor Xa, heparin ultimately suppresses formation of fibrin. Since fibrin forms the framework of thrombi in *veins*, heparin is especially useful for prophylaxis of *venous thrombosis*. Because thrombin and factor Xa are inhibited as soon as they bind with the heparin-antithrombin complex, the anticoagulant effects of heparin develop *quickly* (within minutes of IV administration). This contrasts with warfarin, whose full effects are not seen for *days*.

52.4.1.4 Pharmacokinetics

52.4.1.4.1 Absorption and Distribution.

Because of its polarity and large size, heparin is unable to cross membranes, including those of the GI tract. Consequently, heparin cannot be absorbed if given orally, and therefore must be given by injection (IV or subQ). Since it cannot cross membranes, heparin does not traverse the placenta and does not enter breast milk.

52.4.1.4.2 Protein and Tissue Binding.

Heparin binds nonspecifically to plasma proteins, mononuclear cells, and endothelial cells. As a result, plasma levels of free heparin can be highly variable following IV or subQ administration. Because of this variability, intensive monitoring is required (see below).

52.4.1.4.3 Metabolism and Excretion.

Heparin undergoes hepatic metabolism followed by renal excretion. Under normal conditions, the half-life is short (about 1.5 hours). However, in patients with hepatic or renal disease, the half-life is increased.

52.4.1.4.4 Time Course.

Therapy is initiated with a bolus IV injection, and effects begin immediately. Duration of action is brief (hours) and varies with dosage. Effects are prolonged in patients with hepatic or renal impairment.

52.4.1.5 Therapeutic Uses

Heparin is a preferred anticoagulant for use during *pregnancy* and in situations that require rapid onset of anticoagulant effects, including *pulmonary embolism* (PE), *evolving stroke*, and *massive deep vein thrombosis* (DVT). In addition, heparin is used for patients undergoing *open heart surgery* and *renal dialysis*; during these procedures, heparin serves to prevent coagulation in devices of extracorporeal circulation (heart-lung machines, dialyzers). Low-dose therapy is used to *prevent postoperative venous thrombosis*. Heparin may also be useful for treating *disseminated intravascular coagulation*, a complex disorder in which fibrin clots form throughout the vascular system and in which bleeding tendencies may be present; bleeding can occur because massive fibrin production consumes available supplies of clotting factors. Heparin is also used as an adjunct to thrombolytic therapy of *acute myocardial infarction* (MI).

52.4.1.6 Adverse Effects

52.4.1.6.1 Hemorrhage.

Bleeding develops in about 10% of patients and is the principal complication of treatment. Hemorrhage can occur at any site and may be fatal. Patients should be monitored closely for signs of blood loss. These include reduced blood pressure, increased heart rate, bruises, petechiae, hematomas, red or black stools, cloudy or discolored urine, pelvic pain (suggesting ovarian hemorrhage), headache or faintness (suggesting cerebral hemorrhage), and lumbar pain (suggesting adrenal hemorrhage). If bleeding develops, heparin should be withdrawn. Severe overdose can be treated with *protamine sulfate* (see below).

The risk of hemorrhage can be decreased in several ways. First, dosage should be carefully controlled so that the activated partial thromboplastin time (see below) does not exceed 2 times the control value. In addition, candidates for heparin therapy should be screened for risk factors (see *Warnings and*

598

Figure 51-3 Mechanism of action of heparin, LMW heparins, and fondaparinux. All three drugs share a pentasaccharide sequence that allows them to bind with—and thereby activate—antithrombin, a protein that inactivates two major clotting factors: thrombin and factor Xa. All three drugs enable antithrombin to inactivate factor Xa, but only heparin also facilitates inactivation of thrombin. *Upper Panel:* Unfractionated heparin binds with antithrombin, thereby causing a conformational change in antithrombin that greatly increases its ability to interact with factor Xa and thrombin. As shown, when the heparin-antithrombin complex binds with thrombin, heparin changes its conformation such that both heparin and antithrombin come in contact with thrombin. Formation of this ternary complex is necessary for thrombin inactivation. Inactivation of factor Xa is different: it only requires contact between activated antithrombin and factor Xa; contact between heparin and factor Xa is unnecessary. *Middle Panel:* Low-molecular-weight (LMW) heparins have the same pentasaccharide sequence as unfractionated heparin, and hence can bind with and thereby activate antithrombin. However, in contrast to unfractionated heparin, which promotes inactivation of both thrombin and factor Xa, most molecules of LMW heparin can only inactivate factor Xa; they are unable to inactivate thrombin. Why? Because most molecules of LMW heparin are too small to form a ternary complex with thrombin and antithrombin. *Lower Panel:* Fondaparinux is a synthetic pentasaccharide

identical in structure to the antithrombin binding sequence found in unfractionated heparin and LMW heparins. Being even smaller than LMW heparins, fondaparinux is too small to form a ternary complex with thrombin, and hence can only inactivate factor Xa.

Contraindications). Finally, antiplatelet drugs (eg, aspirin) should be avoided.

600

52.4.1.6.2 Heparin-Induced Thrombocytopenia.

Heparin-induced thrombocytopenia (HIT) is a potentially fatal immune-mediated disorder characterized by reduced platelet counts (thrombocytopenia) and a seemingly paradoxical *increase* in thrombotic events. The underlying cause is development of antibodies against heparin–platelet protein complexes. These antibodies activate platelets and damage the vascular endothelium, thereby promoting both thrombosis and a rapid loss of circulating platelets. Thrombus formation poses a risk of DVT, PE, cerebral thrombosis, and MI. Ischemic injury secondary to thrombosis in the limbs may require amputation of an arm or leg. Coronary thrombosis can be fatal. The primary treatment for HIT is discontinuation of heparin and, if anticoagulation is still needed, substitution of a nonheparin anticoagulant, typically lepirudin or argatroban. The incidence of HIT is between 1% and 3% among patients who receive heparin for more than 4 days.

HIT should be suspected whenever platelet counts fall significantly or when thrombosis develops despite adequate anticoagulation. Accordingly, to reduce the risk of HIT, patients should be monitored for signs of thrombosis and for reductions in platelets. Platelet counts should be determined frequently (2 to 3 times a week) during the first 3 weeks of heparin use, and monthly thereafter. If severe thrombocytopenia develops (platelet count below 100,000/mm₃), heparin should be discontinued.

52.4.1.6.3 Hypersensitivity Reactions.

Because commercial heparin is extracted from animal tissues, these preparations may be contaminated with antigens that can promote allergy. Possible allergic responses include chills, fever, and urticaria. Anaphylactic reactions are rare. To minimize the risk of severe reactions, patients should receive a small test dose of heparin prior to the full therapeutic dose.

52.4.1.6.4 Other Adverse Effects.

Subcutaneous administration may produce *local irritation* and *hematoma*. *Vasospastic reactions* that persist for several hours may develop after 1 or more weeks of treatment. Long-term, high-dose therapy may cause *osteoporosis*.

52.4.1.7 Warnings and Contraindications

52.4.1.7.1 Warnings.

Heparin must be used with extreme caution in all patients who have a high likelihood of bleeding. Among these are individuals with hemophilia, increased capillary permeability, dissecting aneurysm, peptic ulcer disease, severe hypertension, or threatened abortion. Heparin must also be used cautiously in patients with severe disease of the liver or kidneys.

52.4.1.7.2 Contraindications.

Heparin is contraindicated for patients with thrombocytopenia and uncontrollable bleeding. In addition, heparin should be avoided both during and immediately after surgery of the eye, brain, or spinal cord. Lumbar puncture and regional anesthesia are additional contraindications.

52.4.1.8 Drug Interactions

In heparin-treated patients, platelet aggregation is the major remaining defense against hemorrhage. Aspirin and other drugs that depress platelet function will weaken this defense, and hence must be employed with caution.

52.4.1.9 Protamine Sulfate for Heparin Overdose

Protamine sulfate is an antidote to severe heparin overdose. Protamine is a small protein that has multiple positively charged groups. These groups bond ionically with the negative groups on heparin, thereby forming a heparin-protamine complex that is devoid of anticoagulant activity. Neutralization of heparin occurs immediately and lasts for 2 hours, after which additional protamine may be needed. Protamine is administered by slow IV injection (no faster than 20 mg/min or 50 mg in 10 minutes). Dosage is based on the fact that 1 mg of protamine will inactivate 100 units of heparin. Hence, for each 100 units of heparin in the body, 1 mg of protamine should be injected.

52.4.1.10 Laboratory Monitoring

The objective of anticoagulant therapy is to reduce blood coagulability to a level that is low enough to prevent thrombosis but not so low as to promote spontaneous bleeding. Because heparin levels can be highly variable, achieving this goal is difficult, and requires careful control of dosage based on frequent tests of coagulation. The laboratory test employed most commonly

is the *activated partial thromboplastin time* (aPTT). The normal value for the aPTT is 40 seconds. At therapeutic levels, heparin *increases* the aPTT by a factor of 1.5 to 2, making the aPTT 60 to 80 seconds. Since heparin has a rapid onset and brief duration, if an aPTT value should fall outside the therapeutic range, coagulability can be quickly corrected through an adjustment in dosage: if the aPTT is too long (more than 80 seconds), the dosage should be lowered; conversely, if the aPTT is too short (less than 60 seconds), the dosage should be increased. Measurements of aPTTs should be made frequently (every 4 to 6 hours) during the initial phase of therapy. Once an effective dosage has been established, one aPTT measurement a day will suffice.

52.4.1.11 Unitage and Preparations

52.4.1.11.1 Unitage.

Heparin is prescribed in units, not in milligrams. The heparin unit is an index of anticoagulant activity, and is defined as the amount of heparin that will prevent 1 mL of sheep plasma from coagulating for 1 hour. Heparin is prescribed in units because heparin preparations tend to differ from one another in anticoagulant activity when compared on a milligram basis.

52.4.1.11.2 Preparations.

Heparin sodium is supplied in single-dose vials; multidose vials; and unit-dose, preloaded syringes that have their own needles. Concentrations range from 1000 to 40,000 units/mL. Heparin sodium for use in heparin locks [Hep-Lock] is supplied in *dilute* solutions (10 and 100 units/mL) that are too weak to produce systemic anticoagulant effects.

52.4.1.12 Dosage and Administration

52.4.1.12.1 General Considerations.

Heparin is administered by injection only. Two routes are employed: *intravenous* (either intermittent or continuous) and *subcutaneous*. Intramuscular injection causes hematoma and must not be used. Heparin is not administered orally because heparin is too large and too polar to permit intestinal absorption.

Dosage varies with the application. Postoperative prophylaxis of thrombosis, for example, requires relatively small doses. In other situations, such as open heart surgery, much larger doses are used. The dosages given below are for “general anticoagulant therapy.” As a rule, the aPTT should be employed as a guideline for dosage titration; increases in the aPTT of 1.5-

to 2-fold are therapeutic. Since heparin is formulated in widely varying concentrations, you must read the label with care to ensure that dosing is correct.

600

601

TABLE 51-2 Comparison of Unfractionated Heparin with Low-Molecular-Weight Heparin

Property	Unfractionated Heparin	Low-Molecular-Weight Heparin
Molecular weight range	3000–30,000	1000–9000
Mean molecular weight	12,000–15,000	4000–5000
Mechanism of action	Inactivation of factor Xa and thrombin	Preferential inactivation of factor Xa
Routes	IV, subQ	subQ only
Nonspecific binding	Widespread	Minimal
Laboratory monitoring	aPTT monitoring is essential	No aPTT monitoring required
Dosage	Dosage must be adjusted on basis of aPTT	Dosage is fixed
Setting for use	Hospital	Hospital or home
Cost	\$3/day for heparin itself, but hospitalization and aPTT monitoring greatly increase the real cost	\$14/day for LMW heparin, but home use and absence of aPTT monitoring greatly reduce the real cost

52.4.1.12.2 Intermittent IV Therapy.

Intermittent IV heparin is administered via an indwelling needle with a rubber-capped port (heparin lock). Therapy is initiated with a dose of 10,000 units. Subsequent doses of 5000 to 10,000 units are given every 4 to 6 hours. The aPTT should be taken 1 hour before each injection until dosage is stabilized. To avoid venous injury, the site of the heparin lock should be moved every 2 or 3 days. When heparin is administered intermittently, plasma levels of the drug will fluctuate, possibly causing alternating periods of excessive and insufficient anticoagulation.

52.4.1.12.3 Continuous IV Infusion.

Intravenous infusion provides steady levels of heparin, and therefore is preferred to intermittent injections. Dosing consists of a bolus (5000 to 10,000 units), followed by infusion at a rate of 1000 units/hr. During the initial phase of treatment, the aPTT should be measured once every 4 hours and the infusion rate adjusted accordingly. To decrease the risk of

overdose, when heparin solutions are prepared, the amount made up should be sufficient for no more than a 6-hour infusion. Heparin should be infused using an electric pump, and the rate should be checked every 30 to 60 minutes.

52.4.1.12.4 Deep SubQ Injection.

Subcutaneous injections are made deep into the fatty layer of the abdomen (but not within 2 inches of the umbilicus). The heparin solution should be drawn up using a 20- to 22-gauge needle. This needle is then discarded and replaced with a small needle ($\frac{1}{2}$ to $\frac{5}{8}$ inch, 25 or 26 gauge) to make the injection. Following administration, firm but gentle pressure should be applied to the injection site for 1 to 2 minutes. The initial subQ dose is 10,000 to 20,000 units (preceded immediately by an IV loading dose of 5000 units). The initial subQ dose is followed by either (1) 8000 to 10,000 units every 8 hours or (2) 15,000 to 20,000 units every 12 hours. Dosage is adjusted on the basis of aPTTs taken 4 to 6 hours after each injection. The injection site should be rotated.

52.4.1.12.5 Low-Dose Therapy.

Heparin in low doses is given for prophylaxis against postoperative thromboembolism. The initial dose (5000 units subQ) is given 2 hours prior to surgery. Additional doses of 5000 units are given every 8 to 12 hours for 7 days (or until the patient is ambulatory). Low-dose heparin is also employed as adjunctive therapy for patients with MI. During low-dose therapy, monitoring of the aPTT is not usually required.

52.4.2 Low-Molecular-Weight Heparins

52.4.2.1 Group Properties

Low-molecular-weight (LMW) heparins are simply heparin preparations composed of molecules that are shorter than those found in unfractionated heparin. LMW heparins are as effective as unfractionated heparin and are easier to use. Why? Because LMW heparins can be given on a fixed-dose schedule and don't require aPTT monitoring. As a result, LMW heparins can be used at home, whereas unfractionated heparin must be given in a hospital. Because of these advantages, LMW heparins are now considered first-line therapy for prevention and treatment of DVT. In the United States, three LMW heparins are available: enoxaparin [Lovenox], dalteparin [Fragmin], and tinzaparin [Innohep]. Differences between LMW heparins and unfractionated heparin are summarized in [Table 51-2](#).

52.4.2.1.1 Production.

LMW heparins are made by depolymerizing unfractionated heparin (ie, breaking unfractionated heparin into smaller pieces). Molecular weights in LMW preparations range between 1000 and 9000, with a mean of 4000 to 5000. In comparison, molecular weights in unfractionated heparin range between 3000 and 30,000, with a mean of 12,000 to 15,000.

52.4.2.1.2 Mechanism of Action.

Anticoagulant activity of LMW heparin is mediated by the same active pentasaccharide sequence that mediates anticoagulant action of standard heparin. However, because LMW heparin molecules are short, they do not have quite the same effect as standard heparin. Specifically, whereas standard heparin is equally good at inactivating factor Xa *and* thrombin, *LMW heparins preferentially inactivate factor Xa*, being much less able to inactivate thrombin. Why the difference? In order to inactivate thrombin, a heparin chain must not only contain the pentasaccharide sequence that activates antithrombin, it must also be long enough to provide a binding site for thrombin. This binding site is necessary because inactivation of thrombin requires simultaneous binding of thrombin with heparin and antithrombin (see [Fig. 51-3](#)). In contrast to standard heparin chains, most (but not all) LMW heparin chains are too short to allow thrombin binding, and hence LMW heparins are less able to inactivate thrombin.

52.4.2.1.3 Therapeutic Use.

LMW heparins are *approved* for (1) prevention of DVT following abdominal surgery, hip replacement surgery, or knee replacement surgery; (2) treatment of established DVT, with or without PE; and (3) prevention of ischemic complications in patients with unstable angina, non-Q-wave MI, and ST-elevation MI (STEMI). In addition, these drugs have been used extensively *off label* to prevent DVT after general surgery and in patients with multiple trauma and acute spinal injury. When used for prophylaxis or treatment of DVT, LMW heparins are at least as effective as unfractionated heparin, and possibly more effective.

601

602

52.4.2.1.4 Pharmacokinetics.

Compared with unfractionated heparin, LMW heparins have higher bioavailability and longer half-lives. Bioavailability is higher because LMW heparins do not undergo nonspecific binding to proteins and tissues, and hence are more available for anticoagulant effects. Half-lives are prolonged (up to 6 times longer than that of unfractionated heparin) because LMW

heparins undergo less binding to macrophages, and hence undergo slower clearance by the liver. Because of increased bioavailability, plasma levels of LMW heparin are highly predictable. As a result, these drugs can be given on a fixed schedule with no need for routine monitoring of coagulation. Because of their long half-lives, LMW heparins can be given just once or twice a day.

52.4.2.1.5 Administration, Dosing, and Monitoring.

LMW heparins are administered subQ. Dosage is based on body weight. Because plasma levels of LMW heparins are predictable for any given dose, these drugs can be administered on a fixed schedule without laboratory monitoring. This contrasts with unfractionated heparin, which requires dosage adjustments on the basis of aPTT measurements. Because LMW heparins have an extended half-life, dosing can be done once or twice daily. For prophylaxis of DVT, dosing is begun in the perioperative period and continued 5 to 10 days.

52.4.2.1.6 Adverse Effects and Interactions.

Bleeding is the major adverse effect. However, the incidence of bleeding complications is less than with unfractionated heparin. Despite the potential for bleeding, LMW heparins are considered safe for outpatient use. Like unfractionated heparin, LMW heparins can cause immune-mediated *thrombocytopenia*. As with unfractionated heparin, overdose with LMW heparins can be treated with protamine sulfate.

Like unfractionated heparin, LMW heparins can cause *severe neurologic injury*, including permanent paralysis, when given to patients undergoing spinal puncture or spinal or epidural anesthesia. Neurologic injury results from pressure on the spinal cord generated by an epidural or spinal bleed. The risk of serious harm is increased by concurrent use of antiplatelet drugs (eg, aspirin, ticlopidine) or warfarin. Patients should be monitored closely for signs of neurologic impairment.

52.4.2.1.7 Cost.

LMW heparins cost more than unfractionated heparin (eg, about \$63/day for dalteparin vs. \$8/day for unfractionated heparin). However, since LMW heparins can be used at home and don't require monitoring of the aPTT, the overall cost of treatment is far less than with unfractionated heparin.

52.4.2.2 Individual Preparations

In the United States, three LMW heparins are available: enoxaparin, dalteparin, and tinzaparin. Additional LMW heparins are available in other countries. Each preparation is unique. Hence clinical experience with one may not apply fully to the others.

52.4.2.2.1 Enoxaparin.

Enoxaparin [Lovenox] was the first LMW heparin available in the United States. The drug is prepared by depolymerization of unfractionated porcine heparin. Molecular weights range between 2000 and 8000.

Enoxaparin is approved for prevention of DVT following hip and knee replacement surgery or abdominal surgery in patients considered at high risk of thromboembolic complications (eg, obese patients, those over age 40, and those with malignancy or a history of DVT or pulmonary embolism). The drug is also approved for preventing ischemic complications in patients with unstable angina, non-Q-wave MI, or STEMI. Administration is by deep subQ injection. For patients with normal renal function (or moderate renal impairment), dosages are as follows:

- *Prevention of DVT after hip or knee replacement surgery*—30 mg every 12 hours starting 12 to 24 hours after surgery and continuing 7 to 10 days
- *Prevention of DVT after abdominal surgery*—40 mg once daily, beginning 2 hours before surgery and continuing 7 to 10 days
- *Treatment of established DVT*—1 mg/kg every 12 hours for 7 days
- *Patients with unstable angina or non-Q-wave MI*—1 mg/kg every 12 hours (in conjunction with oral aspirin, 100 to 325 mg once daily) for 2 to 8 days
- *Patients with acute STEMI*—30 mg by IV bolus plus 1 mg/kg subQ, followed by 1 mg/kg subQ every 12 hours for up to 8 days

For patients with severe renal impairment, dosage should be reduced.

In the event of overdose, hemorrhage can be controlled with protamine sulfate. The dosage is 1 mg of protamine sulfate for each milligram of enoxaparin administered.

52.4.2.2.2 Dalteparin.

Dalteparin [Fragmin] was the second LMW heparin to be marketed in the United States. The drug is prepared by depolymerization of porcine heparin. Molecular weights range between 2000 and 9000, the mean being 5000. Approved indications are prevention of DVT following hip replacement surgery or abdominal surgery in patients considered at high risk of thromboembolic complications, prevention of ischemic complications in patients with unstable angina or non-Q-wave MI, and management of symptomatic venous thromboembolism (VTE). Administration is by deep subQ injection. Dosages are as follows:

- *Prevention of DVT after hip replacement surgery*—2500 anti-factor Xa international units (IU) 1 or 2 hours before surgery, 2500 IU that evening (at least 6 hours after the first dose), and then 5000 IU once daily for 5 to 10 days.
- *Prevention of DVT after abdominal surgery*—2500 IU once daily for 5 to 10 days, starting 1 to 2 hours before surgery.
- *Patients with unstable angina or non-Q-wave MI*—120 IU/kg (but not more than 10,000 IU total) every 12 hours for 5 to 8 days. Concurrent therapy with aspirin (75 to 165 mg/day) is required.
- *Patients with symptomatic VTE*—200 IU/kg (but not more than 18,000 IU total) once daily for 1 month, then 150 IU/kg (but not more than 18,000 IU total) once daily for months 2 through 6.

Overdose is treated with 1 mg of protamine sulfate for every 100 anti-factor Xa IU of dalteparin administered.

52.4.2.2.3 Tinzaparin.

Tinzaparin [Innohep] is indicated for acute symptomatic DVT (with or without PE) and should be used in conjunction with warfarin. Tinzaparin has a mean molecular weight of 6500 and a half-life of 3 to 4 hours. Excretion is via the urine. In clinical trials, bleeding developed in 0.8% of patients and thrombocytopenia in 1%. Eight men experienced priapism (persistent erection). Recent data indicate that, in elderly patients with renal impairment, tinzaparin *increases* the risk of death, and hence should be avoided in this population. Tinzaparin is supplied in 2-mL vials containing 20,000 anti-factor Xa IU/mL. Administration is by subQ injection in the abdominal region. The recommended dosage is 175 anti-Xa IU/kg once daily for 6 or more days. Warfarin should be initiated when appropriate, usually 1 to 3 days after

starting tinzaparin. When warfarin has taken effect, as indicated by an international normalized ratio (INR; see below) of 2 or more for 2 consecutive days, tinzaparin can be discontinued. Overdose is treated with 1 mg of protamine sulfate for every 100 anti-factor Xa IU of dalteparin administered.

52.5 SELECTIVE FACTOR Xa INHIBITORS

Unlike heparin, which inactivates thrombin *and* factor Xa, the drugs discussed below—fondaparinux and rivaroxaban—produce *selective inhibition of factor Xa*. Like heparin, fondaparinux acts by an *indirect* mechanism (activation of antithrombin). In contrast, rivaroxaban binds *directly* with factor Xa to cause inactivation. Of greater importance, rivaroxaban is dosed orally, whereas fondaparinux is dosed by injection. In contrast to heparin, the selective factor Xa inhibitors do not require anticoagulant monitoring. Fondaparinux was approved in 2001. Rivaroxaban is under investigation.

52.5.1 Fondaparinux

52.5.1.1 Actions.

Fondaparinux [Arixtra] is a synthetic, subQ anticoagulant that enhances the activity of antithrombin, and thereby causes *selective inhibition of activated factor X* (factor Xa). As a result, production of thrombin is inhibited, and hence coagulation is suppressed.

602

Fondaparinux is closely related in structure and function to heparin and the LMW heparins. Structurally, fondaparinux is a pentasaccharide identical to the antithrombin-binding region of the heparins. Hence, like the heparins, fondaparinux is able to induce a conformational change in antithrombin, thereby increasing antithrombin's activity—but only against factor Xa, not against thrombin. Why is fondaparinux selective for factor Xa? Because the drug is quite small—even smaller than the LMW heparins. As a result, it is too small to form a complex with both antithrombin and thrombin, and hence cannot reduce thrombin activity (see [Fig. 51-3](#)).

603

Fondaparinux has no effect on prothrombin time, aPTT, bleeding time, or platelet aggregation.

52.5.1.2 Therapeutic Use.

Fondaparinux is approved for (1) preventing DVT following hip fracture surgery, hip replacement surgery, or knee replacement surgery; (2) treating acute PE (in conjunction with warfarin); and (3) treating acute DVT (in conjunction with warfarin). The drug is somewhat more effective than enoxaparin (an LMW heparin) at preventing DVT, but may cause slightly

more bleeding. Fondaparinux is administered just once a day. Routine laboratory monitoring is unnecessary. Anticoagulation may persist for 2 to 4 days after the last dose.

52.5.1.3 Pharmacokinetics.

Fondaparinux is administered subQ, and bioavailability is 100%. Plasma levels peak 2 hours after injection. The drug is eliminated by the kidneys with a half-life of 17 to 21 hours. The half-life is increased by renal dysfunction.

52.5.1.4 Adverse Effects.

As with other anticoagulants, *bleeding* is the biggest concern. The risk is increased by advancing age and renal impairment. Fondaparinux should be used with caution in patients with moderate renal impairment (creatinine clearance 30 to 50 mL/min/1.73 m²) and avoided in patients with severe renal impairment (creatinine clearance below 30 mL/min/1.73 m²). The drug should also be avoided in patients weighing less than 50 kg. Why? Because low body weight increases bleeding risk. Aspirin and other drugs that interfere with hemostasis should be used with caution. In contrast to overdose with heparin or LMW heparins, overdose with fondaparinux cannot be treated with protamine sulfate.

Fondaparinux does not promote immune-mediated HIT, although it still can lower platelet counts. During clinical trials, *thrombocytopenia* developed in 3% of patients. Platelet counts should be monitored and, if they fall below 100,000/mm³, fondaparinux should be discontinued.

In patients undergoing anesthesia using an epidural or spinal catheter, fondaparinux (as well as other anticoagulants) can cause *spinal or epidural hematoma*, which can result in permanent paralysis. However, in clinical trials, when fondaparinux was administered no sooner than 2 hours after catheter removal, no hematomas were reported.

52.5.1.5 Preparations, Dosage, and Administration.

Fondaparinux [Arixtra] is available in single-dose, pre-filled syringes (2.5, 5, 7.5, and 10 mg). Dosing is done once daily by subQ injection. For *prevention of DVT*, the recommended dosage is 2.5 mg/day, starting 6 to 8 hours after surgery. The usual duration is 5 to 9 days. For *treatment of acute DVT or acute PE*, dosage is based on body weight: daily dosage is 5 mg for patients under 50 kg, 7.5 mg for patients 50 to 100 kg, and 10 mg for patients over 100 kg. The usual duration is 5 to 9 days.

52.5.2 Rivaroxaban

Rivaroxaban [Xarelto] is an investigational *oral* anticoagulant that causes *selective inhibition of factor Xa*. Unlike fondaparinux, which acts indirectly (by activating antithrombin), rivaroxaban binds directly with the active center of factor Xa, and thereby inhibits production of thrombin. In contrast to warfarin (the only oral anticoagulant used in the United States), rivaroxaban has few significant drug interactions, and does not require monitoring of anticoagulant activity. In a series of trials known as RECORD (Regulation of Coagulation in Orthopedic Surgery to Prevent Deep Vein Thrombosis and Pulmonary Embolism), rivaroxaban was compared with enoxaparin (an LMW heparin) in patients who had undergone hip or knee replacement surgery. The result? Patients who received rivaroxaban (10 mg once daily) were much less likely to experience DVT, VTE, PE, or death, compared with patients who received enoxaparin (40 mg once daily or 30 mg twice daily). With both drugs, the incidence of major bleeding episodes was low (0.2%). Other trials are evaluating rivaroxaban in patients with acute coronary syndrome and patients with atrial fibrillation at high risk of stroke.

52.6 DIRECT THROMBIN INHIBITORS

The anticoagulants discussed in this section work by direct inhibition of thrombin. Hence, they differ from the heparin-like anticoagulants, which inhibit thrombin indirectly (by enhancing the activity of antithrombin). Three direct thrombin inhibitors—bivalirudin, lepirudin, and argatroban—are administered by continuous IV infusion; one—desirudin—is administered subQ; and one—dabigatran—is administered PO. Only the subQ and PO drugs are suitable for outpatient use.

52.6.1 Bivalirudin

52.6.1.1 Therapeutic Use.

Bivalirudin [Angiomax], formerly known as *hirulog*, is an IV anticoagulant given in combination with aspirin to prevent clot formation in patients with unstable angina who are undergoing coronary angioplasty. At this time, the standard therapy for these patients is aspirin combined with a platelet GP IIb/IIIa inhibitor combined with low-dose, unfractionated heparin. Bivalirudin, an alternative to heparin in this regimen, has been studied only in combination with aspirin; it has not been studied in combination with GP IIb/IIIa inhibitors. In one trial—the Hirulog Angioplasty Study—bivalirudin plus aspirin was compared with heparin plus aspirin. Bivalirudin was at least as effective as heparin at preventing ischemic complications (MI, abrupt vessel closure, death), and caused fewer bleeding complications. In a subgroup of patients—those with postinfarction angina—bivalirudin was significantly *more* effective than heparin.

52.6.1.2 Mechanism of Action.

Bivalirudin is a *direct*, reversible inhibitor of thrombin—in contrast to heparin, which acts *indirectly* by facilitating the actions of antithrombin. Bivalirudin binds with and inhibits thrombin that is free in the blood as well as thrombin that is bound to clots. In contrast, heparin inhibits only free thrombin. By inhibiting thrombin, bivalirudin prevents (1) the conversion of fibrinogen into fibrin and (2) the activation of factor XIII, thereby preventing the conversion of soluble fibrin into insoluble fibrin. Bivalirudin is a synthetic, 20–amino acid peptide chemically related to *hirudin*, an anticoagulant isolated from the saliva of leeches.

52.6.1.3 Adverse Effects.

The most common side effects are back pain (42%), nausea (15%), hypotension (12%), and headache (12%). Other relatively common effects (incidence greater than 5%) include vomiting, abdominal pain, pelvic pain, anxiety, nervousness, insomnia, bradycardia, and fever.

Bleeding is the effect of greatest concern. However, compared with heparin, bivalirudin causes fewer incidents of major bleeding (3.7% vs. 9.3%) and fewer patients require transfusions (2% vs. 5.7%). Coadministration of bivalirudin with heparin, warfarin, or thrombolytic drugs increases the risk of bleeding.

52.6.1.4 Pharmacokinetics.

With IV dosing, anticoagulation begins immediately. Drug levels are maintained by continuous infusion. Bivalirudin is eliminated primarily by renal excretion, and partly by proteolytic cleavage. The half-life is short (25 minutes) in patients with normal renal function, but may be longer in patients with renal impairment. Coagulation returns to baseline about 1 hour after stopping the infusion. Anticoagulation can be monitored by measuring activated clotting time.

52.6.1.5 Comparison with Heparin.

Bivalirudin is just as effective as heparin and has several advantages: it works independently of antithrombin, inhibits clot-bound thrombin as well as free thrombin, and causes less bleeding and fewer ischemic events. However, the drug also has two disadvantages. First, there is little information on using bivalirudin with GP IIb/IIIa inhibitors, the antiplatelet drugs employed most commonly during angioplasty. In the absence of such data, cardiologists may be reluctant to switch from heparin. Second, bivalirudin is more expensive than heparin: One single-use vial, good for a full course of treatment, costs about \$420, compared with \$10 for an equivalent

course of heparin. However, the manufacturer estimates that reductions in bleeding and ischemic complications would save, on average, \$500 to \$1000 per patient, which would more than offset the greater cost of bivalirudin. The bottom line? Bivalirudin works as well as heparin, is safer, and may be equally cost-effective, but more clinical experience is needed before the drug is likely to replace heparin as the preferred anticoagulant in patients undergoing angioplasty.

52.6.1.6 Preparations, Dosage, and Administration.

Bivalirudin [Angiomax] is supplied as a lyophilized powder (250 mg) for reconstitution in sterile water. Dosing consists of an initial IV bolus (1 mg/kg) followed by a 4-hour infusion (2.5 mg/kg/hr). If necessary, the drug may be infused for up to 20 additional hours at a rate of 0.2 mg/kg/hr. Treatment should begin just prior to angioplasty. Dosage should be reduced in patients with severe renal impairment. All patients should take aspirin (300 to 325 mg).

52.6.2 Lepirudin

Like bivalirudin, lepirudin [Refludan] is an intravenous anticoagulant that works by direct inhibition of thrombin. The drug is indicated for prophylaxis and treatment of thrombosis in patients with heparin-induced thrombocytopenia (HIT). As discussed above, when HIT develops, the primary treatment is to withdraw heparin and substitute a nonheparin anticoagulant—usually lepirudin or argatroban. In clinical trials, lepirudin produced effective anticoagulation in about 80% of patients, and thereby significantly reduced the risk of death and new thrombotic complications. Like other anticoagulants, lepirudin poses a risk of bleeding. The risk is increased by liver dysfunction, renal insufficiency, recent stroke or surgery, and recent therapy with thrombolytic drugs. Dosing consists of an initial IV bolus (0.4 mg/kg infused over 15 to 20 seconds) followed by a continuous infusion (0.15 mg/kg/hr) for 2 to 10 days. Dosage should be titrated to achieve an aPTT ratio (ie, the ratio between the patient's aPTT and a reference aPTT) of 1.5 to 2.5. Treatment is expensive: One week of therapy costs about \$4700.

603

604

52.6.3 Argatroban

Like bivalirudin and lepirudin, argatroban (formerly available as Acova) is an intravenous anticoagulant that works by direct inhibition of thrombin. Like lepirudin, the drug is indicated for prophylaxis and treatment of thrombosis in patients with HIT. In clinical trials, argatroban reduced development of new thrombosis and permitted restoration of platelet counts. Like other anticoagulants, argatroban poses a risk of hemorrhage. About 12% of patients experience hematuria. Allergic reactions (dyspnea, cough, rash), which develop in 10% of patients, occur

almost exclusively in those receiving either thrombolytic drugs (eg, streptokinase) or contrast media for coronary angioplasty. Argatroban has a short half-life (about 45 minutes) owing to rapid metabolism by the liver. Treatment is monitored by measuring the aPTT. When infusion of argatroban is discontinued, the aPTT returns to baseline in 2 to 4 hours.

Argatroban is supplied in 2.5-mL single-dose vials (100 mg/mL) intended for dilution followed by continuous IV infusion. In patients with normal liver function, the initial infusion rate is 2 mcg/kg/min. In patients with liver dysfunction, the initial rate is only 0.5 mcg/kg/min. Dosage is adjusted to maintain the aPTT at 1.5 to 3 times the baseline value. As with lepirudin, treatment is expensive: The cost for the first day alone is over \$550.

52.6.4 Desirudin

Desirudin [Ipravask] is a direct thrombin inhibitor similar to bivalirudin, lepirudin, and argatroban. However, unlike the other three drugs, which are given by IV infusion, desirudin is given by subQ injection. Desirudin is indicated for prevention of DVT in patients undergoing elective hip replacement surgery. In clinical trials, patients experienced fewer thromboembolic events than those given unfractionated heparin or enoxaparin.

Desirudin is completely absorbed following subQ injection, achieving peak plasma levels in 1 to 3 hours. Elimination is primarily by renal secretion, and partly by proteolytic cleavage. In patients with normal renal function, the elimination half-life is 2 to 3 hours. By contrast, in those with severe renal impairment, the half-life is greatly prolonged (up to 12 hours).

As with other anticoagulants, hemorrhage is the adverse effect of greatest concern. In clinical trials, the incidence of hemorrhage was 30% in the desirudin group, compared with 33% in the enoxaparin group and 20% in the heparin group. Less serious effects include wound secretion (4%), injection site mass (4%), anemia (3%), nausea (2%), and deep thrombophlebitis (2%).

In patients undergoing spinal or epidural anesthesia, desirudin may cause spinal or epidural hematoma, which can result in long-term or even permanent paralysis. Hematoma risk is increased by use of other drugs that impair hemostasis (eg, nonsteroidal anti-inflammatory drugs, antiplatelet drugs, warfarin, heparin). Patients should be monitored for signs of neurologic impairment, and given immediate treatment if they develop.

Desirudin [Ipravask] is supplied as a lyophilized powder (15 mg) in single-use vials. Immediately after reconstitution (with 0.5 mL of 3% mannitol in sterile water), the drug is administered by deep subQ injection into the thigh or abdominal wall. For patients with normal renal function, the dosage is 15 mg every 12 hours, beginning 5 to 15 minutes before hip surgery (but after induction

of regional block anesthesia, if used). For patients with *moderate* renal impairment (creatinine clearance 31 to 60 mL/min/1.73 m²), dosage is reduced to 5 mg every 12 hours. For those with *severe* renal impairment (creatinine clearance less than 31 mL/min/1.73 m²), dosage is reduced to 1.7 mg every 12 hours. For all patients, the usual duration of treatment is 9 to 12 days.

52.6.5 Dabigatran

Dabigatran etexilate [Pradaxa] is an *oral* prodrug that undergoes rapid conversion to dabigatran, a reversible, direct inhibitor of thrombin. In contrast to warfarin—the only oral anticoagulant currently used in the United States—dabigatran has three major advantages: it does not require monitoring of anticoagulation; there is little risk of adverse interactions; and, since responses are predictable, the same dose can be used for all patients, regardless of weight or age. In clinical trials, dabigatran has been compared with enoxaparin (a LMW heparin) in patients who had undergone knee and hip replacements. The result? Both drugs were comparable with respect to preventing VTE and VTE-related mortality—and both carried the same risk of major bleeding (about 1%). Trials of dabigatran are underway in patients with acute coronary syndromes and atrial fibrillation. Dabigatran is approved in Canada and Europe, but is not yet approved here.

52.7 WARFARIN

Warfarin [Coumadin, Jantoven], a vitamin K antagonist, is the only oral anticoagulant currently available in the United States. Two others—dabigatran [Pradaxa], a direct thrombin inhibitor, and rivaroxaban [Xarelto], a factor Xa inhibitor—are nearing approval (see above).

Warfarin is similar to heparin in some respects and quite different in others. Like heparin, warfarin is used to prevent thrombosis. In contrast to heparin, warfarin has a delayed onset, which makes it inappropriate for emergencies. However, because it doesn't require injection, warfarin is well suited for long-term prophylaxis. Like heparin, warfarin carries a significant risk of hemorrhage, which is amplified by the many drug interactions to which warfarin is subject.

52.7.1 History

The history of warfarin underscores the potential hazards of oral anticoagulants. The warfarin story began with the observation that ingesting spoiled clover silage could induce bleeding in cattle. The causative agent was identified as bishydroxycoumarin (dicumarol). Research into derivatives of dicumarol led to the synthesis of warfarin. When warfarin was first developed, clinical use was ruled out owing to concerns about hemorrhage. So, instead of becoming a medicine, warfarin was used to kill rats. The drug proved especially effective in this application

and remains one of our most widely used rodenticides. Clinical interest in warfarin was renewed following the report of a failed suicide attempt using huge doses of a warfarin-based rat poison. The clinical trials triggered by that event soon demonstrated that warfarin could be employed safely to treat humans.

52.7.2 Mechanism of Action

Warfarin suppresses coagulation by decreasing production of four clotting factors, namely, factors VII, IX, X, and prothrombin. These factors are known as *vitamin K–dependent clotting factors*, because an active form of vitamin K is needed to make them. Warfarin works by inhibiting *vitamin K–epoxide reductase complex 1* (VKORC1), the enzyme needed to convert vitamin K to the required active form. Because of its mechanism, warfarin is referred to as a *vitamin K antagonist*, a term that is somewhat misleading. Why? Because the term implies antagonism of vitamin K *actions*, not antagonism of vitamin K *activation*. In therapeutic doses, warfarin reduces production of vitamin K–dependent clotting factors by 30% to 50%.

52.7.3 Pharmacokinetics

52.7.3.1 Absorption, Distribution, and Elimination.

Warfarin is readily absorbed following oral dosing. Once in the blood, about 99% of warfarin binds to albumin. Warfarin molecules that remain free (unbound) can readily cross membranes, including those of the placenta and milk-producing glands. Warfarin is inactivated in the liver, mainly by CYP2C9, the 2C9 isozyme of cytochrome P450. Metabolites are excreted in the urine and feces.

52.7.3.2 Time Course.

Although warfarin acts quickly to inhibit clotting factor *synthesis*, noticeable *anticoagulant effects* are delayed. Why? Because warfarin has no effect on clotting factors already in circulation. Hence, until these clotting factors decay, coagulation remains unaffected. Since decay of clotting factors occurs with a half-life of 6 hours to 2.5 days (depending on the clotting factor under consideration), initial responses may not be evident until 8 to 12 hours after the first dose. Peak effects take several days to develop.

After warfarin is discontinued, coagulation remains inhibited for 2 to 5 days. Why? Because warfarin has a long half-life (1.5 to 2 days), and hence synthesis of new clotting factors remains suppressed, despite stopping dosing.

52.7.4 Therapeutic Uses

Warfarin is employed most frequently for long-term prophylaxis of thrombosis. Specific indications are (1) prevention of venous thrombosis and associated pulmonary embolism, (2) prevention of thromboembolism in patients with prosthetic heart valves, and (3) prevention of thrombosis during atrial fibrillation. For all of these indications, warfarin is the oral anticoagulant of choice. The drug has also been used to reduce the risk of recurrent transient ischemic attacks (TIAs) and recurrent MI. Because onset of effects is delayed, warfarin is not useful in emergencies. When rapid action is needed, anticoagulant therapy can be initiated with heparin.

52.7.5 Monitoring Treatment

The anticoagulant effects of warfarin are evaluated by monitoring *prothrombin time* (PT)—a coagulation test that is especially sensitive to alterations in vitamin K–dependent factors. The average pretreatment value for PT is 12 seconds. Treatment with warfarin prolongs PT.

Traditionally, PT test results have been reported as a *PT ratio*, which is simply the ratio of the patient's PT to a control PT. However, there is a serious problem with this form of reporting: test results can vary widely among laboratories. The underlying cause of variability is thromboplastin, a critical reagent employed in the PT test. To ensure that test results from different laboratories are comparable, results are now reported in terms of an INR. The INR is determined by multiplying the observed PT ratio by a correction factor specific to the particular thromboplastin preparation employed for the test.

The objective of treatment is to raise the INR to an appropriate value. Recommended INR ranges are summarized in [Table 51-3](#). As indicated, an INR of 2 to 3 is appropriate for most patients—although for some the target INR is 3 to 4.5. If the INR is below the recommended range, warfarin dosage should be increased. Conversely, if the INR is above the recommended range, dosage should be reduced. Unfortunately, since warfarin has a delayed onset and prolonged duration of action, the INR cannot be altered quickly: Once the dosage has been changed, it may take a week or more to reach the desired INR.

PT must be determined frequently during warfarin therapy. PT should be measured daily during the first 5 days of treatment, twice a week for the next 1 to 2 weeks, once a week for the next 1 to 2 months, and every 2 to 4 weeks thereafter. In addition, PT should be determined whenever a drug that interacts with warfarin is added to or deleted from the regimen.

Concurrent therapy with heparin can influence PT values. To minimize this influence, blood for PT determinations should be drawn no sooner than 5 hours after an IV injection of heparin, and no sooner than 24 hours after a subQ injection.

PT can now be monitored at home. Two monitoring devices are available: *CoaguChek* and the *ProTime Microcoagulation System*. These small, hand-held machines are easy to use and provide reliable results. Both devices determine PT and INR values. In addition, the ProTime meter can be programmed by the prescriber with upper and lower INR values appropriate for the individual patient. When this is done, the meter will display either *In Range*, *INR High*, or *INR Low*, depending on the degree of anticoagulation. Home monitoring is more convenient than laboratory monitoring and gives patients a sense of empowerment. In addition, it improves anticoagulation control. In theory, home monitoring should help reduce bleeding (from excessive anticoagulation) and thrombosis (from insufficient anticoagulation). The CoaguChek meter costs about \$1300 and the ProTime meter costs about \$2000. Each test costs about \$10.

TABLE 51-3 Monitoring Warfarin Therapy: Recommended Ranges of Prothrombin Time–Derived Values

Condition Being Treated	Recommended Ranges	
	Observed PT Ratio [*]	INR [†]
Acute myocardial infarction [‡]	1.3–1.5	2–3
Atrial fibrillation [‡]	1.3–1.5	2–3
Valvular heart disease [‡]	1.3–1.5	2–3
Pulmonary embolism	1.3–1.5	2–3
Venous thrombosis [§]	1.3–1.5	2–3
Tissue heart valves [‡]	1.3–1.5	2–3
Mechanical heart valves	1.5–2	3–4.5
Systemic embolism		
Prevention	1.3–1.5	2–3
Recurrent	1.5–2	3–4.5

* Observed PT ratio = ratio of patient's PT to a control PT value. In this particular case, the reagent used to determine the control PT value is one of the preparations of rabbit brain

thromboplastin employed in the United States. Had a different preparation of thromboplastin been used, the observed PT ratio could be very different.

† INR = international normalized ratio. This value is calculated from the observed PT ratio. The INR is equivalent to the PT ratio that would have been obtained if the patient's PT has been compared to a PT value obtained using the International Reference Preparation, a standardized human brain thromboplastin prepared by the World Health Organization. In contrast to PT ratios, INR values are comparable from one laboratory to the next throughout the United States and the rest of the world.

‡ For prevention of systemic embolism.

§ Prophylaxis in high-risk surgery; treatment.

52.7.6 Adverse Effects

52.7.6.1 Hemorrhage.

Bleeding is the major complication of warfarin therapy. Hemorrhage can occur at any site. Patients should be monitored closely for signs of bleeding. (For specific signs, refer to the discussion of heparin-induced hemorrhage above.) If bleeding develops, warfarin should be discontinued. Severe overdose can be treated with *vitamin K* (see below). Patients should be encouraged to carry identification (eg, Medic Alert bracelet) to inform emergency personnel of warfarin use.

Several measures can reduce the risk of bleeding. Candidates for treatment must be carefully screened for risk factors (see *Warnings and Contraindications* below). Prothrombin time must be measured frequently. A variety of drugs can potentiate warfarin's effects (see below), and hence must be used with care. Patients should be given detailed verbal and written instructions regarding signs of bleeding, dosage size and timing, and scheduling of PT tests. When a patient is incapable of accurate self-medication, a responsible individual must supervise treatment. Patients should be advised to make a record of each dose, rather than relying on memory. A soft toothbrush can reduce gingival bleeding. An electric razor can reduce cuts from shaving.

Warfarin intensifies bleeding during surgery. Accordingly, surgeons must be informed of warfarin use. Patients anticipating elective procedures should discontinue warfarin several days prior to the appointment. If an emergency procedure must be performed, injection of vitamin K can help suppress bleeding.

605

606

Does warfarin increase bleeding during dental surgery? Yes, but not that much. Accordingly, most patients needn't interrupt warfarin for dental procedures, including dental surgery. However, it is important that the INR be in the target range.

52.7.6.2 Fetal Hemorrhage and Teratogenesis from Use During Pregnancy.

Warfarin can cross the placenta and affect the developing fetus. Fetal hemorrhage and death have occurred. In addition, warfarin can cause gross malformation, central nervous system (CNS) defects, and optic atrophy. Accordingly, *warfarin is classified in Food and Drug Administration Pregnancy Risk Category X: The risks to the developing fetus outweigh any possible benefits of treatment.* Women of child-bearing age should be informed about the potential for teratogenesis and advised to postpone pregnancy. If pregnancy occurs, the possibility of termination should be discussed. If an anticoagulant is needed during pregnancy, heparin, which does not cross the placenta, should be employed.

52.7.6.3 Use During Lactation.

Warfarin enters breast milk. Women should be advised against breast-feeding.

52.7.6.4 Other Adverse Effects.

Adverse effects other than hemorrhage are uncommon. Possible undesired responses include skin necrosis, alopecia, urticaria, dermatitis, fever, GI disturbances, and red-orange discoloration of urine, which must not be confused with hematuria. Long-term warfarin use (more than 12 months) may weaken bones, and thereby increase the risk of fractures.

52.7.7 Drug Interactions

52.7.7.1 General Considerations.

Warfarin is subject to a large number of clinically significant adverse interactions—perhaps more than any other drug. As a result of interactions, anticoagulant effects may be reduced to the point of permitting thrombosis, or they may be increased to the point of causing hemorrhage. Patients must be informed about the potential for hazardous interactions and instructed to avoid *all* drugs not specifically approved by the prescriber. This prohibition includes prescription drugs and over-the-counter preparations.

Interactions between warfarin and other drugs are summarized in [Table 51-4](#). As indicated, the interactants fall into three major categories: (1) *drugs that increase anticoagulant effects*, (2)

drugs that promote bleeding, and (3) *drugs that decrease anticoagulant effects*. The major mechanisms by which anticoagulant effects can be *increased* are (1) displacement of warfarin from plasma albumin and (2) inhibition of the hepatic enzymes that degrade warfarin. The major mechanisms for *decreasing* anticoagulant effects are (1) acceleration of warfarin degradation through induction of hepatic drug-metabolizing enzymes, (2) increased synthesis of clotting factors, and (3) inhibition of warfarin absorption. Mechanisms by which drugs can *promote bleeding*, and thereby complicate anticoagulant therapy, include (1) inhibition of platelet aggregation, (2) inhibition of the coagulation cascade, and (3) generation of GI ulcers.

The existence of an interaction between warfarin and another drug does not absolutely preclude using the combination. Such an interaction does mean, however, that the combination must be used with due caution. The potential for harm is greatest when an interacting drug is being added to or deleted from the regimen. At these times, prothrombin time must be monitored, and the dosage of warfarin adjusted to compensate for the impact of removing or adding an interacting drug.

52.7.7.2 Specific Interacting Drugs.

Of the many drugs listed in [Table 51-4](#), a few are especially likely to produce interactions of clinical significance. Three are discussed below.

52.7.7.2.1 Heparin.

The interaction of heparin with warfarin is obvious: Being an anticoagulant itself, heparin directly increases the bleeding tendencies brought on by warfarin. Combined therapy with heparin plus warfarin must be performed with care.

52.7.7.2.2 Aspirin.

Aspirin inhibits platelet aggregation. By blocking aggregation, aspirin can suppress formation of the platelet plug that initiates hemostasis. To make matters worse, aspirin can act directly on the GI tract to cause ulcers, thereby initiating bleeding. Hence, when the antifibrin effects of warfarin are coupled with the antiplatelet and ulcerogenic effects of aspirin, the potential for hemorrhagic disaster is substantial. Accordingly, patients should be warned specifically against using any product that contains aspirin, unless the provider has prescribed aspirin therapy. Drugs similar to aspirin (eg, indomethacin, ibuprofen) should be avoided as well.

52.7.7.2.3 Nonaspirin Antiplatelet Drugs.

Like aspirin, other antiplatelet drugs can increase the risk of bleeding with warfarin. Accordingly, these drugs (eg, clopidogrel, dipyridamole, ticlopidine, abciximab) should be used with caution.

52.7.7.2.4 Acetaminophen.

In the past, acetaminophen was considered safe for patients on warfarin. In fact, acetaminophen was routinely recommended as an aspirin substitute for patients who needed a mild analgesic. Now, however, it appears that acetaminophen can increase the risk of bleeding: Compared with nonusers of acetaminophen, those who take just 4 regular-strength tablets a day for a week are 10 times more likely to have a dangerously high INR. Unlike aspirin, which promotes bleeding by inhibiting platelet aggregation, acetaminophen is believed to act by inhibiting warfarin degradation, thereby raising warfarin levels. At this time, the interaction between acetaminophen and warfarin has not been proved. Nonetheless, when the drugs are combined, the INR should be monitored closely.

52.7.7.2.5 Other Notable Interactions.

Several drugs, including *phenobarbital*, *carbamazepine*, and *rifampin*, are powerful inducers of hepatic drugmetabolizing enzymes. As a result, these drugs can accelerate warfarin degradation, thereby decreasing anticoagulant effects. Accordingly, if one of these drugs is added to the regimen, warfarin dosage must be increased. Of equal importance, when an inducer is withdrawn, causing rates of drug metabolism to decline, a compensatory decrease in warfarin dosage must be made.

Intravaginal miconazole can intensify the anticoagulant effects of warfarin. (Miconazole is the antifungal agent found in Monistat brand vaginal suppositories and cream, used for vaginal candidiasis [yeast infection].) One woman using the combination reported bruising, bleeding gums, and a nosebleed. We have long known that *systemic* miconazole (as well as other azole antifungal agents) can inhibit the metabolism of warfarin, and can thereby cause warfarin levels to rise. Apparently, intravaginal miconazole can be absorbed in amounts sufficient to do the same. Because of this interaction, women taking warfarin should not use intravaginal miconazole. If the drugs must be used concurrently, anticoagulation should be monitored closely and warfarin dosage reduced as indicated.

606

607

TABLE 51-4 Interactions Between Warfarin and Other Drugs

Drug Category	Mechanism of Interaction	Representative Interacting Drugs
Drugs that <i>increase</i> the effects of warfarin	Displacement of warfarin from albumin	Aspirin and other salicylates Sulfonamides
	Inhibition of warfarin degradation	Acetaminophen Amiodarone Azole antifungal agents Cimetidine Disulfiram Sulfonamides
	Decreased synthesis of clotting factors	Certain parenteral cephalosporins, including cefoperazone and cefamandole
Drugs that <i>promote bleeding</i>	Inhibition of platelet aggregation	Abciximab Aspirin and other salicylates Cilostazol Clopidogrel Dipyridamole Eptifibatide Prasugrel [*] Ticlopidine Tirofiban
		Antimetabolites Heparin
		Aspirin Glucocorticoids Indomethacin Phenylbutazone

Drugs that <i>decrease</i> the effects of warfarin	Induction of drug-metabolizing enzymes	Carbamazepine Phenobarbital Phenytoin Rifampin
	Promotion of clotting factor synthesis	Oral contraceptives Vitamin K ₁
	Reduction of warfarin absorption	Cholestyramine Colestipol

* Investigational in the United States.

Like the azole antifungal agents, *cimetidine* (a drug for ulcers) and *disulfiram* (a drug for alcoholism) can inhibit warfarin metabolism, and can thereby increase anticoagulant effects.

Vitamin K increases clotting factor synthesis, and can thereby decrease anticoagulant effects.

Sulfonamide antibacterial drugs can displace warfarin from albumin, and thereby increase anticoagulant effects.

Leflunomide [Arava], a drug for arthritis, can significantly increase the INR in just a few days, probably by inhibiting warfarin degradation. Case reports suggest that two other antiarthritic agents—*glucosamine* and *chondroitin*—may also potentiate warfarin action.

52.7.8 Warnings and Contraindications

Like heparin, warfarin is contraindicated for patients with severe thrombocytopenia or uncontrollable bleeding and for patients undergoing lumbar puncture, regional anesthesia, or surgery of the eye, brain, or spinal cord. Also like heparin, warfarin must be used with extreme caution in patients at high risk of bleeding, including those with hemophilia, increased capillary permeability, dissecting aneurysm, GI ulcers, and severe hypertension, and in women anticipating abortion. In addition, warfarin is contraindicated in the presence of vitamin K deficiency, liver disease, and alcoholism—conditions that can disrupt hepatic synthesis of clotting factors. Warfarin is also contraindicated during pregnancy and lactation.

52.7.9 Vitamin K₁ for Warfarin Overdose

The effects of warfarin overdose can be overcome with vitamin K₁ (phytonadione). Vitamin K₁ antagonizes warfarin's actions and can thereby reverse warfarin-induced inhibition of clotting factor synthesis. (Vitamin K₃—menadione—has no effect on warfarin action.)

Vitamin K may be given orally or IV; subQ administration is less effective and should be avoided. Intravenous vitamin K acts faster than oral vitamin K, but can cause severe anaphylactoid reactions, characterized by flushing, hypotension, and cardiovascular collapse. To reduce this risk, vitamin K should be diluted and infused slowly.

As a rule, small doses—2.5 mg PO or 0.5 to 1 mg IV—are preferred. Why? Because large doses (eg, 10 mg PO) can cause prolonged resistance to warfarin, thereby hampering restoration of anticoagulation once bleeding is controlled.

607

608

If vitamin K fails to control bleeding, levels of clotting factors can be raised quickly by infusing fresh whole blood, fresh-frozen plasma, or plasma concentrates of vitamin K–dependent clotting factors.

52.7.10 What About Dietary Vitamin K?

Like medicinal vitamin K, dietary vitamin K can reduce the anticoagulant effects of warfarin. Rich dietary sources include mayonnaise, canola oil, soybean oil, and green leafy vegetables. Must patients avoid these foods? No. But they should keep intake of vitamin K constant. If vitamin K intake does increase, then warfarin dosage should be increased as well. Conversely, if vitamin K intake decreases, the warfarin dosage should decrease too.

52.7.11 Contrasts Between Warfarin and Heparin

Although heparin and warfarin are both anticoagulants, they differ in important ways. Whereas warfarin is given orally, heparin is given by injection. Although both drugs decrease fibrin formation, they do so by different mechanisms: heparin inactivates thrombin and factor Xa, whereas warfarin inhibits synthesis of clotting factors. Heparin and warfarin differ markedly with respect to time course of action: effects of heparin begin and fade rapidly, whereas effects of warfarin begin slowly but then persist several days. Different tests are used to monitor therapy: changes in aPTT are used to monitor heparin treatment; changes in PT are used to monitor warfarin. Finally, these drugs differ with respect to management of overdose: protamine is given

to counteract heparin; vitamin K₁ is given to counteract warfarin. These differences are summarized in [Table 51-5](#).

52.7.12 Dosage

52.7.12.1 Basic Considerations.

Dosage requirements for warfarin vary widely among individuals, and hence dosage must be tailored to each patient. Traditionally, dosage adjustments have been done empirically (ie, by trial and error). Dosing is usually begun at 2 to 5 mg/day. Maintenance dosages, which typically range from 2 to 10 mg/day, are determined by the target INR value. For most patients, dosage should be adjusted to produce an INR between 2 and 3.

52.7.12.2 Genetics and Dosage Adjustment.

Patients with variant genes that code for VKORC1 and CYP2C9 are at increased risk of warfarin-induced bleeding, and hence require reduced doses. As noted above, VKORC1 is the target enzyme that warfarin inhibits, and CYP2C9 is the enzyme that metabolizes warfarin. Variations in VKORC1 increase the enzyme's sensitivity to inhibition by warfarin, and variations in CYP2C9 delay warfarin breakdown. With either variation, effects of warfarin are increased. To reduce the risk of bleeding, the FDA now recommends—but does not require—that patients undergo genetic testing for these variants. Dosage reductions based on this information can be determined using the online calculator at www.warfarindosing.org.

52.7.13 Preparations

Warfarin sodium [Coumadin, Jantoven] is available in tablets (1, 2, 2.5, 3, 4, 5, 6, 7.5, and 10 mg) for oral use. In addition, warfarin is available in a formulation for parenteral dosing, which is not commonly done.

TABLE 51-5 Summary of Contrasts Between Heparin and Warfarin

	Heparin	Warfarin
Mechanism of action	Activates antithrombin, which then inactivates thrombin and factor Xa	Inhibits synthesis of vitamin K–dependent clotting factors, including prothrombin and factor X
Route	IV or subQ	PO
Onset	Rapid (minutes)	Slow (hours)
Duration	Brief (hours)	Prolonged (days)
Monitoring	aPTT*	PT†
Antidote for overdose	Protamine	Vitamin K ₁

* aPTT = Activated partial thromboplastin time.

† PT = Prothrombin time. Test results are reported as a PT ratio or an INR (international normalized ratio).

52.8 ANTIPLATELET DRUGS

Antiplatelet drugs suppress platelet aggregation. Since a platelet core constitutes the bulk of an *arterial thrombus*, the principal indication for the antiplatelet drugs is prevention of thrombosis in *arteries*. In contrast, the principal indication for anticoagulants (eg, heparin, warfarin) is prevention of thrombosis in veins.

There are three major groups of antiplatelet drugs: aspirin (a “group” with one member), ADP receptor antagonists, and GP IIb/IIIa receptor antagonists. As indicated in [Figure 51-1](#), aspirin and the ADP antagonists affect only one pathway in platelet activation, and hence their antiplatelet effects are limited. In contrast, the GP IIb/IIIa antagonists block the final common step in platelet activation, and hence have powerful antiplatelet effects. Properties of the major classes of antiplatelet drugs are summarized in [Table 51-6](#).

52.8.1 Aspirin

The basic pharmacology of aspirin is discussed in [Chapter 70](#). Consideration here is limited to aspirin's role in preventing arterial thrombosis.

52.8.1.1 Mechanism of Antiplatelet Action.

Aspirin suppresses platelet aggregation by causing *irreversible inhibition of cyclooxygenase*, an enzyme required by platelets to synthesize thromboxane A₂ (TXA₂). As noted, TXA₂ is one of the factors that can promote platelet activation. In addition to activating platelets, TXA₂ acts on vascular smooth muscle to promote vasoconstriction. Both actions promote hemostasis. By inhibiting cyclooxygenase, aspirin suppresses both TXA₂-mediated vasoconstriction and platelet aggregation, thereby reducing the risk of arterial thrombosis. Since inhibition of cyclooxygenase by aspirin is irreversible, and since platelets lack the machinery to synthesize new cyclooxygenase, the effects of a single dose of aspirin persist for the life of the platelet (7 to 10 days).

In addition to inhibiting the synthesis of TXA₂, aspirin can inhibit synthesis of *prostacyclin* by the blood vessel wall. Since prostacyclin has effects that are exactly opposite to those of TXA₂—namely, suppression of platelet aggregation and promotion of vasodilation—suppression of prostacyclin synthesis can partially offset the beneficial effects of aspirin therapy. Fortunately, aspirin is able to inhibit synthesis of TXA₂ at doses that are lower than those needed to inhibit synthesis of prostacyclin. Accordingly, if we keep the dosage of aspirin *low* (325 mg/day or less), we can minimize inhibition of prostacyclin production while maintaining inhibition of TXA₂ production.

608
609

TABLE 51-6 Properties of the Major Classes of Antiplatelet Drugs

	Aspirin, a Cyclooxygenase Inhibitor	Adenosine Diphosphate Receptor Blockers	Glycoprotein IIb/IIIa Receptor Blockers
Representative drug	Aspirin	Clopidogrel [Plavix]	Tirofiban [Aggrastat]
Mechanism of antiplatelet action	Irreversibly inhibits cyclooxygenase, and thereby blocks synthesis of TXA ₂	Irreversibly blocks receptors for ADP	Reversibly blocks receptors for GP IIb/IIIa
Route	PO	PO	IV infusion
Duration of effects	Effects persist 7–10 days after the last dose	Effects persist 7–10 days after the last dose	Effects stop within 4 hr of stopping the infusion
Cost	\$3/month	\$87/month	\$1000/course

52.8.1.2 Indications for Antiplatelet Therapy.

Antiplatelet therapy with aspirin has multiple indications of proven efficacy, namely

- *Ischemic stroke* (to reduce the risk of death and nonfatal stroke)
- *Transient ischemic attacks* (to reduce the risk of death and nonfatal stroke)
- *Chronic stable angina* (to reduce the risk of MI and sudden death)
- *Unstable angina* (to reduce the combined risk of death and nonfatal MI)
- *Coronary stenting* (to prevent reocclusion)
- *Acute MI* (to reduce the risk of vascular mortality)
- *Previous MI* (to reduce the combined risk of death and nonfatal MI)
- *Primary prevention of MI* (to prevent a first MI in men and in women age 65 and older)

In all of these situations, prophylactic therapy with aspirin can reduce morbidity, and possibly mortality. Primary prevention of MI is discussed further immediately below.

52.8.1.2.1 Primary Prevention of MI.

In January of 2002, the U.S. Preventive Services Task Force (USPSTF) issued updated guidelines on the use of aspirin for primary prevention of MI. The USPSTF noted that the benefit/risk ratio is most favorable for people at high risk of MI, defined as a 3% (or higher) risk of a cardiovascular event within the next 5 years.* For these people, daily aspirin lowers the risk of MI by 28%. Unfortunately, although aspirin lowers the risk of MI, it does *not* reduce the risk of death. Cardiovascular risk is based on five factors—age, gender, cholesterol levels, blood pressure, and smoking status—and can be calculated using an online risk assessment tool, such as those at www.med-decisions.com and www.intmed.mcw.edu/clincalc/heartrisk.html. Although the optimal aspirin dosage for primary prevention is unknown, low doses (eg, 81 mg/day) appear as effective as higher ones.

* Data from the Women's Health Study, released in 2005, show that aspirin does *not* prevent a first MI in middle-aged women, but does protect women 65 and older.

52.8.1.3 Adverse Effects.

Even in low doses, aspirin increases the risk of GI bleeding and hemorrhagic stroke. Among middle-aged people taking aspirin for 5 years, the estimated rate of major GI bleeding episodes is 2 to 4 per 1000 patients, and the rate of hemorrhagic stroke is 0 to 2 episodes per 1000 patients. Use of enteric-coated or buffered aspirin may *not* reduce the risk of GI bleeding. Benefits of treatment must be weighed against bleeding risks. If GI bleeding occurs, adding a proton pump inhibitor (eg, omeprazole [Prilosec]) to reduce gastric acidity can help.

52.8.1.4 Dosing.

Dosage for preventing cardiovascular events should be low. Maximal inhibition of platelet cyclooxygenase, and hence maximal effects on platelet function, can be produced in a few days by taking 81 mg/day. Dosages above 81 mg/day offer no increase in benefits, but do increase the risk of GI bleeding and stroke. Accordingly, for *chronic therapy*, a dosage of 81 mg/day is probably adequate. A higher dosage (eg, 325 mg/day) is indicated for *initial* treatment of an acute event, such as MI, in order to establish full antiplatelet effects rapidly—after which 81 mg/day can be taken for maintenance.

52.8.2 Adenosine Diphosphate Receptor Antagonists

Two ADP receptor antagonists—clopidogrel and ticlopidine—are currently approved, and a third agent—prasugrel—may be approved soon. All three drugs cause irreversible blockade of ADP receptors on the platelet surface, and thereby prevent ADP-stimulated aggregation (see [Fig. 51-1](#)). Indications for clopidogrel include recent stroke and acute coronary syndromes. Ticlopidine is approved only to prevent stroke. Both drugs are taken orally, and both can cause potentially fatal hematologic effects, although the risks are much higher with ticlopidine.

52.8.2.1 Clopidogrel

Clopidogrel [Plavix] is an oral antiplatelet drug with effects similar to those of aspirin. The drug is taken to prevent stenosis of coronary stents, and for secondary prevention of MI, ischemic stroke, and other vascular events. Use is widespread: In 2007, total sales were around \$8 billion.

609

610

52.8.2.1.1 Antiplatelet Actions.

Clopidogrel blocks ADP receptors on platelets, and thereby prevents ADP-stimulated aggregation. As with aspirin, antiplatelet effects are irreversible, and hence persist for the life of the platelet. Effects begin 2 hours after the first dose, and plateau after 3 to 7 days of

treatment. At the recommended dosage, platelet aggregation is inhibited by 40% to 60%. Platelet function and bleeding time return to baseline about 7 to 10 days after the last dose.

52.8.2.1.2 Pharmacokinetics.

Clopidogrel is rapidly absorbed from the GI tract, both in the presence and absence of food. Bioavailability is about 50%. Clopidogrel is inactive as administered and must be converted to its active form in the liver, in part through the actions of CYP2C19 (the 2C19 isozyme of cytochrome P450). The primary metabolite found in blood is a carboxylic acid derivative. However, neither the parent drug nor this derivative affects platelet aggregation. The metabolite responsible for inhibiting aggregation has not been identified.

52.8.2.1.3 Therapeutic Use.

Clopidogrel is used widely to prevent blockage of coronary artery stents, and to reduce thrombotic events—MI, ischemic stroke, and vascular death—in patients with acute coronary syndromes and in those with atherosclerosis documented by recent MI, recent stroke, or established peripheral arterial disease. In the Clopidogrel Versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) trial, which enrolled 19,185 high-risk patients, clopidogrel (75 mg once daily) was slightly better than aspirin (325 mg once daily) at reducing the combined risk of MI, ischemic stroke, or vascular death. The trial indicated that, for every 1000 patients treated for 1 year, clopidogrel would prevent 24 vascular events, compared with 19 for aspirin. However, even though clopidogrel is slightly more effective than aspirin, it is much more expensive: A 1-month supply costs about \$87, compared with \$3 for aspirin. Accordingly, it would seem best to reserve clopidogrel for patients who cannot tolerate aspirin or haven't responded to it adequately.

52.8.2.1.4 Adverse Effects and Interactions.

Clopidogrel is generally well tolerated. Adverse effects are about the same as with aspirin. The most common effects are abdominal pain (6%), dyspepsia (5%), diarrhea (5%), and rash (4%). Compared with aspirin, clopidogrel causes less intracranial hemorrhage (0.4% vs. 0.5%) and less GI bleeding (2% vs. 2.7%). In contrast to ticlopidine (see below), clopidogrel does not cause neutropenia or granulocytopenia. However, it *can* cause thrombotic thrombocytopenic purpura (TTP), usually during the first 2 weeks of treatment. At least 11 cases have been reported, including one that was fatal. Fortunately, the risk of TTP is low—even lower than with ticlopidine. Clopidogrel should be used with caution in patients taking

other drugs that promote bleeding (eg, heparin, warfarin, aspirin, and other nonsteroidal anti-inflammatory drugs).

Omeprazole [Prilosec] and other *proton pump inhibitors* (PPIs) may reduce the antiplatelet effects of clopidogrel. (Some clopidogrel patients take PPIs to reduce gastric acidity, and thereby reduce the risk of GI bleeding.) PPIs may lower clopidogrel effects by inhibiting CYP2C19, the liver enzyme that helps convert clopidogrel to its active form.

52.8.2.1.5 Preparations, Dosage, and Administration.

Clopidogrel [Plavix] is available in 75-mg tablets. The maintenance dosage is 75 mg once a day, taken with or without food. A 300-mg loading dose may be used for some patients. Dosage needn't be changed for elderly patients or those with renal impairment. To prevent a possible rebound effect when clopidogrel is withdrawn, some experts recommend that the dosage be tapered, by giving 75 mg every other day for a few weeks. However, there is no proof that doing so is needed.

52.8.2.2 Ticlopidine

52.8.2.2.1 Actions.

Ticlopidine [Ticlid] is a chemical relative of clopidogrel, but causes more adverse hematologic effects. Like clopidogrel, ticlopidine causes irreversible inhibition of platelet aggregation.

52.8.2.2.2 Uses.

Ticlopidine has only one approved indication: prevention of thrombotic stroke. The drug is at least as beneficial as aspirin, but is much more expensive. More importantly, ticlopidine can cause life-threatening adverse effects. Accordingly, the drug should be reserved for patients who have not responded to aspirin or cannot use aspirin because of intolerance.

52.8.2.2.3 Pharmacokinetics.

Ticlopidine is well absorbed following oral administration. Antiplatelet effects begin within 48 hours and become maximal in about a week. The drug undergoes extensive hepatic metabolism followed by renal excretion. Ticlopidine has a long half-life (4 to 5 days). Effects persist for 7 to 10 days after drug withdrawal (ie, until new platelets have been synthesized).

52.8.2.2.4 Adverse Effects.

52.8.2.2.4.1 Hematologic Effects.

Ticlopidine can cause life-threatening hematologic reactions, including neutropenia/agranulocytosis and TTP.

Neutropenia develops in 2.4% of patients, and is sometimes severe. Rarely, agranulocytosis develops. Both effects reverse within 1 to 3 weeks after drug withdrawal.

TTP occurs in 0.02% of patients with coronary stents who are taking ticlopidine. The mortality rate is 20% to 30%. TTP is characterized by thrombocytopenia, fever, anemia, renal dysfunction, and neurologic disturbances. The risk is highest during the first few weeks of treatment. After 12 weeks, the risk is very low. Patients should be instructed to report potential signs of TTP (eg, unusual bleeding, bruising, rash).

To reduce the risk from hematologic reactions, complete blood counts and a white cell differential should be obtained every 2 weeks during the first 12 weeks of treatment, and at any sign of infection. Ticlopidine should be withdrawn if neutropenia, agranulocytosis, or TTP develops.

52.8.2.2.4.2 Other Adverse Effects.

The most common side effects are *GI disturbances* (diarrhea, abdominal pain, flatulence, nausea, dyspepsia) and *dermatologic reactions* (rash, purpura, pruritus).

52.8.2.2.5 Preparations and Dosage.

Ticlopidine [Ticlid] is available in 250-mg tablets. The recommended dosage is 250 mg twice a day, taken with food.

52.8.2.3 Prasugrel

Prasugrel [Effient] is an investigational agent similar to clopidogrel. Like clopidogrel, prasugrel blocks ADP receptors on platelets, and thereby causes irreversible inhibition of aggregation. Also like clopidogrel, prasugrel is a prodrug that undergoes conversion to its active form in the liver. In one trial, known as Triton-TIMI, prasugrel was compared directly with clopidogrel. The goal with both drugs was to prevent thrombotic complications in patients with acute coronary syndrome who were scheduled for percutaneous coronary intervention (PCI). The

result? Compared with patients taking clopidogrel, patients taking prasugrel experienced significantly fewer thrombotic events, including stent thrombosis. Unfortunately, those taking prasugrel also experienced an increased risk of major bleeding, including fatal bleeding. Prasugrel is under FDA review for approval in the United States.

52.8.3 Glycoprotein IIb/IIIa Receptor Antagonists

52.8.3.1 Group Properties

The GP IIb/IIIa receptor antagonists, sometimes called “super aspirins,” are the most effective antiplatelet drugs on the market. Three agents are available: abciximab, tirofiban, and eptifibatide. All three are administered IV, usually in combination with aspirin and low-dose heparin. Treatment is expensive, costing \$1000 or more for a brief course. Dosages are summarized in [Table 51-7](#).

52.8.3.1.1 Actions.

The GP IIb/IIIa antagonists cause *reversible* blockade of platelet GP IIb/IIIa receptors, and thereby inhibit the final step in aggregation (see [Fig. 51-1](#)). As a result, these drugs can prevent aggregation stimulated by all factors, including collagen, TXA₂, ADP, thrombin, and platelet activation factor.

TABLE 51-7 Dosages for Glycoprotein IIb/IIIa Receptor Antagonists

Application	Tirofiban [Aggrastat]	Eptifibatide [Integrilin]	Abciximab [ReoPro]
Acute coronary syndromes (ACSs)	0.4 mcg/kg/min for 30 min, then 0.1 mcg/kg/min for 48–108 hr	180-mcg/kg bolus, then 2 mcg/kg/min for up to 72 hr	0.25-mg/kg bolus, then 10 mcg/kg/min for 18–24 hr
Percutaneous coronary intervention* (PCI) following treatment for ACSs	Continue 0.1 mcg/kg/min for the procedure and 12–24 hr after	Consider decreasing the infusion rate to 0.5 mcg/kg/min for the procedure and 20–24 hr after	Continue 10 mcg/kg/min for the procedure and 1 hr after
PCI without prior treatment for ACSs	Not FDA approved for this application	135-mcg/kg bolus prior to procedure, then 0.5 mcg/kg/min for 20–24 hr	0.25-mg/kg bolus 10–60 min before the procedure, then 0.125 mcg/kg/min (max 10 mcg/min) for 12 hr
FDA = Food and Drug Administration.			

* Balloon or laser angioplasty, or atherectomy.

52.8.3.1.2 Therapeutic Use.

The GP IIb/IIIa antagonists are used short term to prevent ischemic events in patients with acute coronary syndromes (ACSs) and those undergoing percutaneous coronary intervention (PCI).

52.8.3.1.2.1 Acute Coronary Syndromes.

ACSs have two major manifestations: unstable angina and non–Q-wave MI. In both cases, symptoms result from thrombosis triggered by disruption of atherosclerotic plaque. When added to traditional drugs for ACSs (heparin and aspirin), GP IIb/IIIa antagonists reduce the risk of ischemic complications.

52.8.3.1.2.2 Percutaneous Coronary Intervention.

GP IIb/IIIa antagonists reduce the risk of rapid reocclusion following coronary artery revascularization with PCI (balloon or laser angioplasty, or atherectomy using an intra-arterial rotating blade). Reocclusion is common because PCI damages the arterial wall, and thereby encourages platelet aggregation.

52.8.3.2 Properties of Individual GP IIb/IIIa Antagonists

52.8.3.2.1 Abciximab.

52.8.3.2.1.1 Description and Use.

Abciximab [ReoPro] is a purified Fab fragment of a monoclonal antibody. The drug binds to platelets in the vicinity of GP IIb/IIIa receptors, and thereby prevents the receptors from binding fibrinogen. Abciximab, in conjunction with aspirin and heparin, is approved for IV therapy of ACSs and for patients undergoing PCI. In addition, clinical studies indicate it can accelerate revascularization in patients undergoing thrombolytic therapy for acute MI. Antiplatelet effects persist for 24 to 48 hours after stopping the infusion. The cost of a single course of treatment is about \$1200. Dosages for ACSs and PCI are summarized in [Table 51-7](#).

52.8.3.2.1.2 Adverse Effects and Interactions.

Abciximab doubles the risk of major bleeding, especially at the PCI access site in the femoral artery. The drug may also cause GI, urogenital, and retroperitoneal bleeds. However, it does not increase the risk of fatal hemorrhage or hemorrhagic stroke. In the event of severe bleeding, infusion of abciximab and heparin should be discontinued. Other drugs that impede hemostasis will increase the risk of bleeding.

52.8.3.2.2 Eptifibatide.

Eptifibatide [Integrilin] is a small peptide that causes reversible and highly selective inhibition of GP IIb/IIIa receptors. The drug is approved for patients with ACSs and those undergoing PCI. Antiplatelet effects reverse by 4 hours after stopping the infusion. The most important adverse effect is bleeding, which occurs most often at the site of PCI catheter insertion, and in the GI and urinary tracts. As with other GP IIb/IIIa inhibitors, the risk of bleeding is increased by concurrent use of other drugs that impede hemostasis. Dosages are summarized in [Table 51-7](#).

52.8.3.2.3 Tirofiban.

Tirofiban [Aggrastat] causes selective and reversible inhibition of GP IIb/IIIa receptors. The drug—neither an antibody nor a peptide—was modeled after a platelet inhibitor isolated from the venom of the saw-scaled viper, a snake indigenous to Africa. Like other GP IIb/IIIa inhibitors, tirofiban is used to reduce ischemic events associated with ACSs and PCI. Platelet function returns to baseline within 4 hours of stopping the infusion. Bleeding is the primary adverse effect. The risk of bleeding can be increased by other drugs that suppress hemostasis. Dosages for ACSs and PCI are summarized in [Table 51-7](#).

52.8.4 Other Antiplatelet Drugs

52.8.4.1 Dipyridamole

Dipyridamole [Persantine] suppresses platelet aggregation, perhaps by increasing plasma levels of adenosine. The drug is approved only for prevention of thromboembolism following heart valve replacement. For this application, dipyridamole is always combined with warfarin. The recommended dosage is 75 to 100 mg 4 times a day. A fixed-dose combination of dipyridamole and aspirin is indicated for recurrent stroke (see below).

52.8.4.2 Dipyridamole plus Aspirin

52.8.4.2.1 Actions and Use.

Dipyridamole combined with aspirin is available in a fixed-dose formulation sold as *Aggrenox*. The product is used to prevent recurrent ischemic stroke in patients who have had a previous stroke or TIA. Both drugs—aspirin and dipyridamole—suppress platelet aggregation. However, since they do so by different mechanisms, the combination is more effective than either drug alone.

52.8.4.2.2 Clinical Trial.

The benefit of combining aspirin and dipyridamole was demonstrated in the second *European Stroke Prevention Study* (ESPS-2), a randomized controlled trial that enrolled over 6000 patients who had suffered a prior ischemic stroke or TIA. Some patients took aspirin alone (25 mg twice daily), some took dipyridamole alone (200 mg twice daily), some took both drugs, and some took placebo. The result? After 24 months, the incidence of fatal or nonfatal ischemic stroke was reduced by 16% with dipyridamole alone, 18% with aspirin alone, and 37% with the combination. Unfortunately, ESPS-2 was tainted by scientific scandal (one investigator, who later resigned, was charged with creating and falsifying data). Although all fraudulent data were discarded prior to publication, some authorities remain skeptical of the results.

52.8.4.2.3 Adverse Effects.

The most common adverse effects of the combination are headache, dizziness, and GI disturbances (nausea, vomiting, diarrhea, abdominal pain, dyspepsia). Of course, bleeding is a concern: The product can cause hemorrhage (3.2% vs. 1.5% with placebo), nosebleed (2.4% vs. 1.5%), and purpura (1.4% vs. 0.4%). The aspirin in *Aggrenox* poses a risk of GI bleeding from peptic ulcers.

52.8.4.2.4 Preparations, Dosage, and Administration.

Aggrenox capsules contain 25 mg of aspirin and 200 mg of extended-release dipyridamole. The recommended dosage is 2 capsules a day—one in the morning and one at night. The cost is about \$90 a month, compared with \$3 a month for aspirin alone. It is important to note that the daily dose of aspirin (50 mg) is lower than the dose recommended to prevent MI (at least 80 mg/day). Accordingly, supplemental aspirin may be needed.

611

52.8.4.3 Cilostazol**52.8.4.3.1 Actions and Therapeutic Use.**

Cilostazol [Pletal], a platelet inhibitor and vasodilator, is indicated for *intermittent claudication*. (Intermittent claudication is a syndrome characterized by pain, cramping, and weakness of the calf muscles brought on by walking and relieved by resting a few minutes. The underlying cause is atherosclerosis in the legs.) Cilostazol suppresses platelet aggregation by inhibiting type 3 phosphodiesterase (PDE3) in platelets, and promotes vasodilation by inhibiting PDE3 in blood vessels (primarily in the legs). Inhibition of platelet aggregation is greater than with aspirin, ticlopidine, or dipyridamole. Full effects take up to 12 weeks to develop, but reverse quickly (within 48 hours) following drug withdrawal.

52.8.4.3.2 Adverse Effects.

Cilostazol causes a variety of untoward effects. The most common is headache (34%). Others include diarrhea (19%), abnormal stools (15%), palpitations (10%), dizziness (10%), and peripheral edema (7%).

Other drugs that inhibit PDE3 have increased mortality in patients with heart failure. Whether cilostazol represents a risk is unknown. Nonetheless, heart failure is a contraindication to cilostazol use.

52.8.4.3.3 Drug and Food Interactions.

Cilostazol is metabolized by the 3A4 isozyme of cytochrome P450 (CYP3A4), and hence cilostazol levels can be increased by CYP3A4 inhibitors (eg, ketoconazole, itraconazole, erythromycin, fluoxetine, fluvoxamine, nefazodone, sertraline, and grapefruit juice). Metabolism of cilostazol can also be inhibited by omeprazole.

52.8.4.3.4 Preparations, Dosage, and Administration.

Cilostazol [Pletal] is available in 50- and 100-mg tablets. The usual dosage is 100 mg twice daily, taken 30 minutes before or 2 hours after breakfast and the evening meal. Dosage should be reduced to 50 mg twice daily in patients taking omeprazole and drugs or foods that inhibit CYP3A4.

52.9 THROMBOLYTIC DRUGS

As their name implies, thrombolytic drugs are given to remove thrombi that have already formed. This contrasts with the anticoagulants, which are given to prevent thrombus formation. In the United States, four thrombolytic drugs are currently available: streptokinase, alteplase, reteplase, and tenecteplase. All carry a risk of serious bleeding, and hence should be administered only by clinicians skilled in their use. Thrombolytics are employed acutely and only for severe thrombotic disease. Because of their mechanism of action, these agents are also known as *fibrinolytics* (and informally as *clot busters*). Properties of individual agents are summarized in [Table 51-8](#).

52.9.1 Streptokinase

Streptokinase [Streptase] was the first thrombolytic drug available and will serve as our prototype for the group.

52.9.1.1 Mechanism of Action.

Streptokinase acts by an indirect mechanism. The drug first binds to *plasminogen* to form an active complex. The streptokinase-plasminogen complex then catalyzes the conversion of other plasminogen molecules into plasmin, an enzyme that digests the fibrin meshwork of clots. In addition to digesting fibrin in clots, plasmin degrades fibrinogen and other clotting factors. These actions do not contribute to lysis of thrombi, but they do increase the risk of hemorrhage.

52.9.1.2 Therapeutic Uses.

Streptokinase has three major indications: (1) acute coronary thrombosis (acute MI), (2) DVT, and (3) massive pulmonary emboli. In all three settings, timely intervention is essential. For example, in patients with acute MI, results are best when thrombolytic therapy is started within 4 to 6 hours of symptom onset, and preferably sooner. Thrombolytic therapy of acute MI is discussed further in [Chapter 52](#).

52.9.1.3 Pharmacokinetics.

Streptokinase may be administered by IV infusion or by infusion directly into an occluded coronary artery. Owing to rapid inactivation, the drug's half-life is only 40 to 80 minutes.

52.9.1.4 Adverse Effects.

52.9.1.4.1 Bleeding.

Bleeding is the major complication of treatment. Intracranial hemorrhage (ICH), which occurs in 1% of patients, is by far the most serious concern. Bleeding occurs for two reasons: (1) plasmin can destroy pre-existing clots, and can thereby promote recurrence of bleeding at sites of recently healed injury; and (2) by degrading clotting factors, plasmin can disrupt coagulation, and can thereby interfere with new clot formation in response to vascular injury.

612

613

Likely sites of bleeding include recent wounds, sites of needle puncture, and sites at which invasive procedures have been performed. Anticoagulants (eg, heparin, warfarin) and antiplatelet drugs (eg, aspirin) further increase the risk of hemorrhage. Accordingly, high-dose therapy with these drugs must be avoided until thrombolytic effects of streptokinase have abated.

TABLE 51-8 Properties of Thrombolytic Drugs

	Streptokinase	Alteplase (tPA)	Tenecteplase	Reteplase
Trade name	Streptase	Activase	TNKase	Retavase
Description	A compound that forms an active complex with plasminogen	A compound identical to human tPA	Modified form of tPA with a prolonged half-life	A compound that contains the active sequence of amino acids present in tPA
Source	Streptococcal culture	Recombinant DNA technology	Recombinant DNA technology	Recombinant DNA technology
Mechanism	These drugs promote conversion of plasminogen to plasmin, an enzyme that degrades the fibrin matrix of thrombi			
Adverse effects				
Bleeding	Yes	Yes	Yes	Yes
Allergic reactions	Yes	No	No	No
Half-life (min)	40–80	5	20–24	13–16
Dosage and administration for acute MI	<i>Intravenous:</i> 1.5 million IU infused over 30–60 min <i>Intracoronary:</i> 20,000 IU bolus, then 2000 IU/min for 60 min	<i>Intravenous:</i> 15-mg bolus, then 50 mg infused over 30 min, then 35 mg infused over 60 min	<i>Intravenous:</i> Bolus based on body weight (see text)	<i>Intravenous:</i> 10-IU bolus 2 times, separated by 30 min
Cost	\$540	\$2750	\$3750	\$2750
IU = international unit.				

Management of bleeding depends on severity. Oozing at sites of cutaneous puncture can be controlled with a pressure dressing. If severe bleeding occurs, streptokinase should be discontinued. Patients who require blood replacement can be given whole blood or blood products (packed red blood cells, fresh-frozen plasma). As a rule, blood replacement restores hemostasis. However, if this approach fails, excessive fibrinolysis can be reversed with IV *aminocaproic acid* [Amicar], a compound that prevents activation of plasminogen and directly inhibits plasmin.

The risk of bleeding can be lowered by

- Minimizing physical manipulation of the patient

- Avoiding subQ and IM injections
- Minimizing invasive procedures
- Minimizing concurrent use of anticoagulants (eg, heparin, warfarin)
- Minimizing concurrent use of antiplatelet drugs (eg, aspirin)

Because of the risk of hemorrhage, streptokinase and other thrombolytic drugs must be avoided by patients at high risk for bleeding complications, and must be used with great caution in patients at lower risk of bleeding. A list of absolute and relative contraindications to thrombolytic therapy is presented in [Table 51-9](#).

52.9.1.4.2 Antibody Production.

Streptokinase is a foreign protein extracted from cultures of streptococci. As a result, antibodies may form. Two consequences are possible: *allergic reactions* and *neutralization of streptokinase*. The most common allergic reactions are urticaria, itching, flushing, and headache. These can be treated with antihistamines. Severe anaphylaxis is rare. Because neutralizing antibodies may develop within a few days of streptokinase administration, repeat courses of streptokinase may be ineffective. Hence, if a repeat course is needed, a different thrombolytic agent (eg, alteplase) should be used.

52.9.1.4.3 Hypotension.

Streptokinase may cause significant hypotension soon after dosing. The incidence is between 1% and 10%. Hypotension is not related to bleeding or allergic reactions. Blood pressure should be monitored. If hypotension develops, it may be necessary to slow the streptokinase infusion.

52.9.1.4.4 Fever.

Temperature elevation of 1.5°F or more occurs in one-third of patients. Only 3.5% of patients develop temperatures above 104°F. Acetaminophen—not aspirin—should be used to lower temperature.

52.9.1.5 Preparations, Dosage, and Administration.

Streptokinase [Streptase] is supplied as a powder (250,000, 750,000, and 1,500,000 international units [IU]) for reconstitution with 0.9% saline or 5% dextrose.

For *pulmonary embolism*, *DVT*, and *arterial thrombosis or embolism*, streptokinase is administered by IV infusion. Therapy is usually initiated with an IV loading dose of 250,000 IU infused over 30 minutes. After the loading dose, the infusion is continued for 1 to 3 days at a rate of 100,000 IU/hr.

For an *evolving MI*, streptokinase may be infused through a catheter placed in the occluded coronary artery. This technique offers two benefits: (1) high levels of streptokinase are achieved at the site where the drug is actually needed, and (2) high levels are avoided elsewhere, thereby minimizing generalized bleeding. Timing of therapy is critical: Streptokinase is most effective when therapy is begun within 6 hours of symptom onset, and preferably sooner.

TABLE 51-9 Contraindications and Cautions Regarding Thrombolytic Use for Myocardial Infarction

Absolute Contraindications

- Any prior intracranial hemorrhage
- Known structural cerebral vascular lesion
- Ischemic stroke within last 3 months *except* ischemic stroke within 3 hours
- Known intracranial neoplasm
- Active internal bleeding (other than menses)
- Suspected aortic dissection

Relative Contraindications/Cautions

- Severe, uncontrolled hypertension on presentation (blood pressure above 180/110 mm Hg)
- History of chronic, severe, poorly controlled hypertension
- History of prior ischemic stroke, dementia, or known intracerebral pathology not covered in absolute contraindications
- Current use of anticoagulants in therapeutic doses (INR 2–3 or greater); known bleeding diathesis
- Traumatic or prolonged (more than 10 min) CPR or major surgery (less than 3 weeks ago)
- Recent internal bleeding (within 2–4 weeks)
- Noncompressible vascular punctures
- For streptokinase: prior exposure (more than 5 days ago) or prior allergic reaction
- Pregnancy
- Active peptic ulcer

Adapted from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee to revise the 1999 guidelines for the management of patients with acute myocardial infarction). J Am Coll Cardiol 44:671–719, 2004.

CPR = cardiopulmonary resuscitation; INR = international normalized ratio.

52.9.2 Alteplase (tPA)

Alteplase [Activase, Cathflo Activase], also known as *tissue plasminogen activator* (tPA), is produced commercially by recombinant DNA technology. The commercial preparation is identical to naturally occurring human tPA, an enzyme that promotes conversion of plasminogen to plasmin, an enzyme that digests the fibrin matrix of clots. Low therapeutic doses produce selective activation of plasminogen that is bound to fibrin in thrombi. As a result, activation of plasminogen in the general circulation is minimized. However, despite selective activation of fibrin-bound plasminogen, bleeding tendencies with alteplase are equivalent to those seen with the other thrombolytic drugs. Furthermore, the risk of intracranial bleeding is higher with alteplase than with streptokinase. Since alteplase is devoid of foreign proteins, it does not cause allergic reactions. In contrast to streptokinase, alteplase does not induce hypotension. Alteplase has a short half-life (about 5 minutes) owing to rapid hepatic inactivation.

Like streptokinase, alteplase is indicated for acute MI and pulmonary embolism. In addition, alteplase is approved for ischemic stroke. As discussed below, the GUSTO-I trial has shown that alteplase is slightly better than streptokinase for treating acute MI. Unfortunately, alteplase is also much more expensive: A single course of alteplase costs about \$2750, compared with \$540 for streptokinase.

613

614

Alteplase is now given by an “accelerated” or “front-loaded” schedule. In this schedule, the infusion time is only 90 minutes, compared with the 3-hour infusion employed in the past. For patients who weigh over 67 kg, the total dose for treating acute MI is 100 mg. Administration is divided into three phases: a 15-mg IV bolus, followed by 50 mg infused over 30 minutes, followed in turn by 35 mg infused over 60 minutes. Total doses in excess of 100 mg are associated with an increased risk of intracranial bleeding and should be avoided.

52.9.3 Tenecteplase

Tenecteplase [TNKase], a variant of human tissue plasminogen activator (tPA, alteplase), is approved for patients undergoing acute MI. Except for the substitution of three amino acids, the drug is structurally identical to tPA. However, because of this small structural change, the pharmacokinetics of tenecteplase are much different from those of tPA. Specifically, tenecteplase is 80 times more resistant than tPA to circulating inhibitors and has a much longer half-life (20 to 24 minutes vs. 5 minutes for tPA). Like tPA, tenecteplase acts by converting plasminogen into plasmin, an enzyme that digests fibrin clots. *Tenecteplase is just as safe and effective as tPA, but much easier to use: Whereas tPA must be infused over 90 minutes, tenecteplase is given by bolus*

injection. As a result, thrombolysis develops faster, and emergency personnel are spared the trouble of monitoring a prolonged infusion. Because tenecteplase is so easy to administer, it has the potential to allow dosing before the patient reaches a hospital.

Tenecteplase was compared with tPA in the second Assessment of the Safety and Efficacy of a New Thrombolytic (ASSENT-2) study, which enrolled 16,949 patients. Tenecteplase was given as a 5-second IV bolus; tPA was infused over 90 minutes. The median time between symptom onset and starting treatment was 2.7 hours for tenecteplase and 2.8 hours for tPA. Thirty days after treatment, outcomes were equivalent with respect to mortality (6.2% with each drug), intracranial hemorrhage (0.93% with tenecteplase vs. 0.94% with tPA), and total stroke (1.78% vs. 1.66% with tPA). Of significance, the incidence of major hemorrhage (other than intracranial) was *lower* with tenecteplase (4.7% vs. 5.9%).

Dosage of tenecteplase is based on body weight (BW) as follows:

- BW below 60 kg: dose 30 mg
- BW 60 to 69.9 kg: dose 35 mg
- BW 70 to 79.9 kg: dose 40 mg
- BW 80 to 89.9 kg: dose 45 mg
- BW above 90 kg: dose 50 mg

Note that no one is given more than 50 mg. Interestingly, the price of tenecteplase (\$2750/dose) is identical to that of tPA [Activase] and reteplase [Retavase].

52.9.4 Reteplase and Urokinase

Reteplase and urokinase are similar to streptokinase with regard to mechanism, indications, and ability to promote bleeding. Principal differences between these drugs relate to half-life, source, antigenicity, cost, and indications.

52.9.4.1 Reteplase.

Reteplase [Retavase] is a derivative of tPA produced by recombinant DNA technology. In contrast to tPA itself, which contains 527 amino acids, reteplase is composed of only 355 amino acids. Like tPA, reteplase converts plasminogen to plasmin, which in turn digests the fibrin matrix of the thrombus. Reteplase has a short half-life (13 to 16 minutes) owing to rapid clearance by the liver and kidneys. As with other thrombolytic drugs, bleeding is the major

adverse effect. The risk of bleeding is increased by concurrent use of heparin and aspirin. Allergic reactions have not been reported.

Reteplase is approved only for acute MI. Treatment consists of two 10-unit doses separated by 30 minutes. Each dose is given by IV bolus injected over a 2-minute interval. Reteplase should not be administered through a line that contains heparin. If a heparin-containing line must be used, it should be flushed prior to giving reteplase.

52.9.4.2 Urokinase.

Urokinase [Abbokinase] is an enzyme that occurs naturally in human urine. Commercial urokinase is prepared by extraction from cultures of human fetal kidney cells. Like streptokinase, urokinase promotes the conversion of plasminogen into plasmin, its active form. As with other thrombolytics, bleeding is the principal adverse effect. Since urokinase is human derived, it is not antigenic, and hence allergic reactions do not occur. Urokinase has a short half-life (15 to 20 minutes) owing to rapid inactivation by the liver. The drug is approved for acute MI, DVT, and clearance of IV catheters. For treatment of acute MI, urokinase is infused for 2 hours or less at a rate of 6000 IU/hr. Because of its high cost (see [Table 51-8](#)), urokinase is used much less frequently than streptokinase. Urokinase is no longer available in the United States.

52.9.5 Streptokinase Versus Alteplase: The GUSTO-I Trial

The GUSTO-I (Global Utilization of Streptokinase and tPA for Occluded Coronary Arteries) trial is the largest study ever conducted on the treatment of acute MI. Over 41,000 subjects from 15 countries participated. The results indicate that *mortality* from MI in patients receiving alteplase (tPA) is somewhat lower than in patients receiving streptokinase (SK)—although the risk of *hemorrhagic stroke* with tPA is higher. However, as discussed below, the apparent superiority of tPA as seen in GUSTO may not be relevant to everyday clinical practice.

In GUSTO-I, each participant received one of the following treatments (30-day mortality rates are in parentheses):

- tPA + IV heparin (6.3%)
- SK + IV heparin (7.4%)
- SK + subQ heparin (7.2%)
- SK + tPA + IV heparin (7%)

As the mortality figures indicate, 7.4 of each 100 patients who received streptokinase (plus IV heparin) died within 30 days. In contrast, only 6.3 of each 100 patients who received tPA (plus IV heparin) died within 30 days. Hence, by using tPA instead of streptokinase, we might expect to save one additional life for each 100 patients.

What the above figures don't indicate is the timing of tPA administration with respect to onset of MI symptoms. In GUSTO-I, nearly 90% of patients received treatment within 2 to 4 hours of symptom onset. Among patients who received tPA within 2 hours of symptom onset, the death rate was only 5.4%; among those treated 2 to 4 hours after symptom onset, the rate increased to 6.6%; and among those treated 4 to 6 hours after symptom onset, the rate jumped to 9.4%. Not only do these figures underscore the importance of early treatment, they bring into question the relevance of GUSTO-I to ordinary clinical practice. Why? Because, in usual practice, very few patients are treated as early as those in GUSTO. Furthermore, among patients who are treated *after* 4 hours, GUSTO-I showed no significant difference in mortality between treatment with tPA and treatment with streptokinase. Hence, although tPA may be superior to streptokinase when these drugs are employed under *ideal* conditions, tPA may not be superior in everyday practice. When this observation is coupled with two others—the much higher cost of tPA and the greater incidence of hemorrhagic stroke with tPA—the desirability of tPA over streptokinase is less obvious. Regardless of whether tPA is significantly better than streptokinase, there is no question that treatment with either drug is much better than no treatment at all. Put another way, selecting some thrombolytic drug is much more important than which one is selected.

614

615

52.9.5.1

KEY POINTS

- Hemostasis occurs in two stages: formation of a platelet plug, followed by coagulation (ie, production of fibrin, a protein that reinforces the platelet plug).
- Platelet aggregation depends on activation of GP IIb/IIIa receptors, which bind fibrinogen to form cross-links between platelets.
- Fibrin is produced by two pathways—the contact activation pathway (aka intrinsic pathway) and the tissue factor pathway (aka extrinsic pathway)—which converge at clotting factor Xa, which catalyzes formation of thrombin, which in turn catalyzes formation of fibrin.
- Four factors in the coagulation pathways require an activated form of vitamin K for their synthesis.

- Plasmin, the active form of plasminogen, serves to degrade the fibrin meshwork of clots.
- A thrombus is a blood clot formed within a blood vessel or within the heart.
- Arterial thrombi begin with formation of a platelet plug, which is then reinforced with fibrin.
- Venous thrombi begin with formation of fibrin, which then enmeshes red blood cells and platelets.
- Arterial thrombi are best prevented with antiplatelet drugs (eg, aspirin), whereas venous thrombi are best prevented with anticoagulants (warfarin, heparin).
- Heparin is a large polymer (molecular weight range = 3000 to 30,000) that carries many negative charges.
- Heparin suppresses coagulation by helping antithrombin inactivate thrombin and factor Xa.
- Heparin is administered IV or subQ. Because of its large size and negative charges, heparin is unable to cross membranes, and hence cannot be administered PO.
- Anticoagulant effects of heparin develop within minutes of IV administration.
- The major adverse effect of heparin is bleeding.
- Severe heparin-induced bleeding can be treated with protamine sulfate, a drug that binds heparin and thereby stops it from working.
- Heparin-induced thrombocytopenia is a potentially fatal condition caused by development of antibodies against heparin–platelet protein complexes.
- Heparin is contraindicated for patients with thrombocytopenia or uncontrollable bleeding, and must be used with extreme caution in all patients for whom there is a high likelihood of bleeding.
- Heparin therapy is monitored by measuring the aPTT (activated partial thromboplastin time). The target aPTT is 60 to 80 seconds (ie, 1.5 to 2 times the normal value of 40 seconds).

- Low-molecular-weight (LMW) heparins are produced by breaking molecules of unfractionated heparin into smaller pieces.
- In contrast to unfractionated heparin, which inactivates factor Xa and thrombin equally, LMW heparins preferentially inactivate factor Xa.
- In contrast to unfractionated heparin, LMW heparins do not bind nonspecifically to plasma proteins and tissues. As a result, their bioavailability is high, making their plasma levels predictable.
- Because plasma levels of LMW heparins are predictable, these drugs can be administered on a fixed schedule with no need for routine laboratory monitoring. As a result, LMW heparins can be used at home.
- Warfarin is the only oral anticoagulant currently available in the United States (although two others are nearing approval).
- Warfarin prevents the activation of vitamin K, and thereby blocks the biosynthesis of vitamin K–dependent clotting factors.
- Anticoagulant responses to warfarin develop slowly and persist for several days after warfarin is discontinued.
- Warfarin therapy is monitored by measuring prothrombin time (PT). Results are expressed as an international normalized ratio (INR). An INR of 2 to 3 is the target for most patients.
- Bleeding is the major complication of warfarin therapy.
- Genetic testing for variant genes that code for VKORC1 and CYP2C9 can identify people with increased sensitivity to warfarin, and who therefore may need a dosage reduction.
- Moderate warfarin overdose is treated with vitamin K.
- Warfarin must not be used during pregnancy. The drug can cause fetal malformation, CNS defects, and optic atrophy.
- Warfarin is subject to a large number of clinically significant drug interactions. Drugs can increase anticoagulant effects by displacing warfarin from plasma albumin and by inhibiting hepatic enzymes that degrade warfarin. Drugs can decrease anticoagulant

effects by inducing hepatic drug-metabolizing enzymes, increasing synthesis of clotting factors, and inhibiting warfarin absorption. Drugs that promote bleeding, such as heparin and aspirin, will obviously increase the risk of bleeding in patients taking warfarin. Instruct patients to avoid all drugs—prescription and nonprescription—that have not been specifically approved by the prescriber.

- Aspirin and other antiplatelet drugs suppress thrombus formation in arteries.
- Aspirin inhibits platelet aggregation by causing irreversible inhibition of cyclooxygenase. Since platelets are unable to synthesize new cyclooxygenase, inhibition persists for the life of the platelet (7 to 10 days).
- In its role as an antiplatelet drug, aspirin is given for primary prophylaxis of MI, prevention of MI recurrence, and prevention of stroke in patients with a history of TIAs.
- When used to suppress platelet aggregation, aspirin is administered in low doses—typically 80 to 325 mg/day.
- The GP IIb/IIIa receptor blockers (eg, abciximab) inhibit the final common step in platelet aggregation, and hence are the most effective antiplatelet drugs available.
- Thrombolytic drugs (eg, streptokinase, alteplase [tPA]) are used to dissolve existing thrombi (rather than prevent thrombi from forming).
- Thrombolytic drugs work by converting plasminogen to plasmin, an enzyme that degrades the fibrin matrix of thrombi.
- Thrombolytic therapy is most effective when started early (ie, within 4 to 6 hours of symptom onset, and preferably sooner).
- Thrombolytic drugs carry a significant risk of bleeding. Intracranial hemorrhage is the greatest concern.
- For patients with acute MI, tPA is slightly more effective than streptokinase, but costs much more and causes more intracranial bleeding.

615

616

52.9.5.2 Summary of Major Nursing Implications*

52.9.5.2.1 HEPARIN

52.9.5.2... Preadministration Assessment

52.9.5.2... Therapeutic Goal

The objective is to prevent thrombosis without inducing spontaneous bleeding.

Heparin is the preferred anticoagulant for use during pregnancy and in situations that require rapid onset of effects, including pulmonary embolism, evolving stroke, and massive DVT. Other indications include open heart surgery, renal dialysis, and disseminated intravascular coagulation. Low doses are used to prevent postoperative venous thrombosis and to enhance thrombolytic therapy of MI.

52.9.5.2... Baseline Data

Obtain baseline values for blood pressure, heart rate, complete blood cell counts, platelet counts, hematocrit, and aPTT.

52.9.5.2... Identifying High-Risk Patients

Heparin is *contraindicated* for patients with severe thrombocytopenia or uncontrollable bleeding and for patients undergoing lumbar puncture, regional anesthesia, or surgery of the eye, brain, or spinal cord.

Use with *extreme caution* in patients at high risk of bleeding, including those with hemophilia, increased capillary permeability, dissecting aneurysm, GI ulcers, or severe hypertension. Caution is also needed in patients with severe hepatic or renal dysfunction.

52.9.5.2... Implementation: Administration

52.9.5.2... Routes

Intravenous (continuous infusion or intermittent) and subQ. Avoid IM injections!

52.9.5.2...

Administration

52.9.5.2...

General Considerations.

Dosage is prescribed in units, not milligrams. Heparin preparations vary widely in concentration; read the label carefully to ensure correct dosing.

52.9.5.2...

Intermittent IV Administration.

Administer through a heparin lock every 4 to 6 hours. Determine the aPTT before each dose during the early phase of treatment, and daily thereafter. Rotate the injection site every 2 to 3 days.

52.9.5.2...

Continuous IV Infusion.

Administer with a constant infusion pump or some other approved volume-control unit. Policy may require that dosage be double-checked by a second person. Check the infusion rate every 30 to 60 minutes. During the early phase of treatment, the aPTT should be determined every 4 hours. Check the site of needle insertion periodically for extravasation.

52.9.5.2...

Deep SubQ Injection.

Perform subQ injections into the fatty layer of the abdomen (but not within 2 inches of the umbilicus). Draw up the heparin solution using a 20- to 22-gauge needle, and then discard that needle and replace it with a small needle ($\frac{1}{2}$ to $\frac{5}{8}$ inch, 25 or 26 gauge) to make the injection. Apply firm but gentle pressure to the injection site for 1 to 2 minutes following administration. Rotate and record injection sites.

52.9.5.2...

Ongoing Evaluation and Interventions

52.9.5.2...

Evaluating Treatment

Periodic determinations of the aPTT are used to evaluate treatment. Heparin should increase the aPTT by 1.5- to 2-fold above baseline.

52.9.5.2...	<h2>Minimizing Adverse Effects</h2>	
52.9.5.2...	<h3>Hemorrhage.</h3> <p>Heparin overdose may cause hemorrhage. Monitor closely for signs of bleeding. These include reduced blood pressure, elevated heart rate, discolored urine or stool, bruises, petechiae, hematomas, persistent headache or faintness (suggestive of cerebral hemorrhage), pelvic pain (suggestive of ovarian hemorrhage), and lumbar pain (suggestive of adrenal hemorrhage). Laboratory data suggesting hemorrhage include reductions in the hematocrit and blood cell counts. If bleeding occurs, heparin should be discontinued. Severe overdose can be treated with <i>protamine sulfate</i> administered by slow IV injection. The risk of bleeding can be reduced by ensuring that the aPTT does not exceed 2 times the baseline value.</p>	616
52.9.5.2...	<h3>Heparin-Induced Thrombocytopenia.</h3> <p>HIT, characterized by reduced platelet counts and increased thrombotic events, poses a risk of DVT, pulmonary embolism, cerebral thrombosis, MI, and ischemic injury to the arms and legs. To reduce risk, monitor platelet counts 2 to 3 times a week during the first 3 weeks of heparin use, and monthly thereafter. If severe thrombocytopenia develops (platelet count below 100,000/mm₃), discontinue heparin and, if anticoagulation is still needed, substitute lepirudin or argatroban.</p>	617
52.9.5.2...	<h3>Hypersensitivity Reactions.</h3> <p>Allergy may develop to antigens in heparin preparations. To minimize the risk of severe reactions, administer a small test dose prior to the full therapeutic dose.</p>	
52.9.5.2...	<h2>Minimizing Adverse Interactions</h2>	
52.9.5.2...	<h3>Antiplatelet Drugs.</h3> <p>Concurrent use of aspirin and other antiplatelet drugs increases the risk of bleeding. Use these agents with caution.</p>	

WARFARIN

Preadministration Assessment

Therapeutic Goal

The goal is to prevent thrombosis without inducing spontaneous bleeding. Specific indications include prevention of venous thrombosis and associated pulmonary embolism, prevention of thromboembolism in patients with prosthetic heart valves, and prevention of thrombosis during atrial fibrillation.

Baseline Data

Obtain a thorough medical history. Be sure to identify use of any medications that might interact adversely with warfarin. Obtain baseline values of vital signs and PT. Genetic testing for variants of CYP2C9 and VKORC1 may be done to identify patients in whom anticoagulation may be especially intense.

Identifying High-Risk Patients

Warfarin is *contraindicated* in the presence of vitamin K deficiency, liver disease, alcoholism, thrombocytopenia, uncontrollable bleeding, pregnancy, and lactation, and for patients undergoing lumbar puncture, regional anesthesia, or surgery of the eye, brain, or spinal cord.

Use with *extreme caution* in patients at high risk of bleeding, including those with hemophilia, increased capillary permeability, dissecting aneurysm, GI ulcers, and severe hypertension.

Use with *caution* in patients with variant forms of CYP2C9 or VKORC1.

Implementation: Administration

Route

Oral.

52.9.5.2...

Administration

For most patients, dosage is adjusted to maintain an INR value of 2 to 3. Maintain a flow chart for hospitalized patients indicating INR values and dosage size and timing.

52.9.5.2...

Implementation: Measures to Enhance Therapeutic Effects

52.9.5.2...

Promoting Adherence

Safe and effective therapy requires rigid adherence to the dosing schedule. Achieving adherence requires active and informed participation by the patient. **Provide the patient with detailed written and verbal instructions regarding the purpose of treatment, dosage size and timing, and the importance of strict adherence to the dosing schedule. Also, provide the patient with a chart on which to keep an ongoing record of warfarin use.** If the patient is incompetent (eg, mentally ill, alcoholic, senile), ensure that a responsible individual supervises treatment.

52.9.5.2...

Nondrug Measures

Advise the patient to (1) avoid prolonged immobility, (2) elevate the legs when sitting, (3) avoid garments that can restrict blood flow in the legs, (4) participate in exercise activities, and (5) wear support hose. These measures will reduce venous stasis, and will thereby reduce the risk of thrombosis.

52.9.5.2...

Ongoing Evaluation and Interventions

52.9.5.2...

Evaluating Therapeutic Effects

52.9.5.2...

Monitoring Prothrombin Time.

Evaluate therapy by monitoring PT. Test results are reported as an INR. For most patients, the target INR is 2 to 3. If the INR is below this range, dosage should be increased. Conversely, if the INR is above this range, dosage should be reduced.

PT should be measured frequently: daily during the first 5 days, twice a week for the next 1 to 2 weeks, once a week for the next 1 to 2 months, and every 2 to 4 weeks thereafter. In addition, PT should be determined whenever a drug that interacts with warfarin is added to or deleted from the regimen.

52.9.5.2...	<p>If heparin is being employed concurrently, blood for PT determinations should be drawn no sooner than 5 hours after giving heparin IV, and no sooner than 24 hours giving heparin subQ.</p> <p>If appropriate, teach patients how to monitor their PT and INR at home.</p> <p>Minimizing Adverse Effects</p> <p>Hemorrhage.</p> <p>Hemorrhage is the major complication of warfarin therapy. Warn patients about the danger of hemorrhage, and inform them about signs of bleeding. These include reduced blood pressure, elevated heart rate, discolored urine or stools, bruises, petechiae, hematomas, persistent headache or faintness (suggestive of cerebral hemorrhage), pelvic pain (suggestive of ovarian hemorrhage), and lumbar pain (suggestive of adrenal hemorrhage). Laboratory data suggesting hemorrhage include reductions in the hematocrit and blood cell counts.</p> <p>Instruct the patient to withhold warfarin and notify the prescriber if signs of bleeding are noted. Advise the patient to wear some form of identification (eg, Medic Alert bracelet) indicating warfarin use.</p>	617
52.9.5.2...	<p>To reduce the incidence of bleeding, advise the patient to avoid excessive consumption of alcohol. Suggest use of a soft toothbrush to prevent bleeding from the gums. Advise patients to shave with an electric razor.</p> <p>Warfarin intensifies bleeding during surgical procedures. Instruct the patient to make certain the surgeon is aware of warfarin use. Warfarin should be discontinued several days prior to elective procedures. If emergency surgery must be performed, vitamin K₁ can help reduce bleeding.</p> <p>Warfarin-induced bleeding can be controlled with vitamin K₁. For most patients, oral vitamin K will suffice. For patients with severe bleeding or a very high INR, vitamin K is given by injection (usually IV). The prescriber may advise the patient to keep a supply of vitamin K on hand for use in emergencies, but only after consultation with an informed clinician.</p>	618

52.9.5.2...

Use in Pregnancy and Lactation.

Warfarin can cross the placenta, causing fetal hemorrhage and malformation. **Inform women of child-bearing age about potential risks to the fetus, and warn them against becoming pregnant.** If pregnancy develops, termination should be considered.

Warfarin enters breast milk and may harm the nursing infant. **Warn women against breast-feeding.**

52.9.5.2...

Minimizing Adverse Interactions

Inform patients that warfarin is subject to a large number of potentially dangerous drug interactions. Instruct them to avoid all drugs—prescription and nonprescription—that have not been specifically approved by the prescriber. Prior to treatment, take a complete medication history to identify any drugs that might interact adversely with warfarin.

52.9.5.2.3

THROMBOLYTIC DRUGS

Alteplase (tPA)

Reteplase

Streptokinase

Tenecteplase

52.9.5.2...

Preadministration Assessment

52.9.5.2...

Therapeutic Goal

Thrombolytic drugs are used to treat acute MI, massive pulmonary emboli, ischemic stroke, and DVT.

52.9.5.2...

Baseline Data

Obtain baseline values for blood pressure, heart rate, platelet counts, hematocrit, aPTT, PT, and fibrinogen level.

52.9.5.2...

Identifying High-Risk Patients

Thrombolytic drugs are *contraindicated* for patients with active bleeding, aortic dissection, acute pericarditis, cerebral neoplasm, cerebral vascular disease, or a history of intracranial bleeding.

Use with *great caution* in patients with relative contraindications, including pregnancy, severe hypertension, ischemic stroke within the prior 6 months, and major surgery within the prior 2 to 4 weeks. See [Table 51-9](#) for a complete list of absolute and relative contraindications.

52.9.5.2...

Implementation: Administration

52.9.5.2...

Routes

Intracoronary, intravenous (see [Table 51-8](#)).

52.9.5.2...

Administration

Depending on the drug employed and the specific application, administration may be by IV infusion, slow IV injection, IV bolus, intracoronary infusion, or intracoronary bolus. (See [Table 51-8](#) for administration during acute MI.)

Do not administer heparin and streptokinase through the same IV line.

52.9.5.2...

Ongoing Evaluation and Interventions

52.9.5.2...

Minimizing Adverse Effects

52.9.5.2...

Hemorrhage.

Thrombolytics may cause bleeding; ICH is the greatest concern. To reduce the risk of major bleeding, minimize manipulation of the patient, avoid subQ and IM injections, minimize invasive procedures, and minimize concurrent use of anticoagulants (eg,

heparin, warfarin) and antiplatelet drugs (eg, aspirin). Manage oozing at cutaneous puncture sites with a pressure dressing.

For severe bleeding, discontinue streptokinase and give whole blood or blood products (packed red blood cells, fresh-frozen plasma). If bleeding continues, give IV aminocaproic acid.

52.9.5.2...

Minimizing Adverse Interactions

52.9.5.2...

Anticoagulants and Antiplatelet Drugs.

Anticoagulants (eg, heparin, warfarin) and antiplatelet drugs (eg, aspirin) increase the risk of bleeding from antithrombotics. Avoid high-dose therapy with these drugs until thrombolytic effects have subsided.

* Patient education information is highlighted as **blue text**.

⁵³CHAPTER 52 Management of ST-Elevation Myocardial Infarction

Myocardial infarction (MI), also known as heart attack, is defined as necrosis of the myocardium (heart muscle) resulting from local ischemia (deficient blood flow). The underlying cause is partial or complete blockage of a coronary artery. When blockage is complete, the area of infarction is much larger than when the blockage is partial. In this chapter, discussion is limited to acute MI caused by *complete* interruption of regional myocardial blood flow. This class of MI is called *ST-elevation MI* (STEMI), because it causes elevation of the ST segment on the electrocardiogram (ECG).

Management of STEMI differs from management of non-ST-elevation MI, which occurs when blockage of blood flow is only partial.

In the United States, STEMI strikes about 500,000 people each year and is the most common cause of death. Between 20% and 30% of STEMI victims die before reaching the hospital, another 9.9% die in the hospital, and 7.1% die within a year of hospital discharge. Risk factors for STEMI include advanced age, a family history of MI, sedentary lifestyle, obesity, high serum cholesterol, hypertension, smoking, and diabetes. The objectives of this chapter are to describe the pathophysiology of STEMI and to discuss interventions that can help reduce morbidity and mortality.

^{53.1} PATHOPHYSIOLOGY OF STEMI

Acute MI occurs when blood flow to a region of the myocardium is stopped owing to platelet plugging and thrombus formation in a coronary artery—almost always at the site of a fissured or ruptured atherosclerotic plaque. Myocardial injury is ultimately the result of an imbalance between oxygen demand and oxygen supply.

In response to local ischemia, a dramatic redistribution of ions takes place. Hydrogen ions accumulate in the myocardium and calcium ions become sequestered in mitochondria. The resultant acidosis and functional calcium deficiency alter the distensibility of cardiac muscle. Sodium ions accumulate in myocardial cells and promote edema. Potassium ions are lost from myocardial cells, thereby setting the stage for dysrhythmias.

Local metabolic changes begin rapidly following coronary arterial occlusion. Within seconds, metabolism shifts from aerobic to anaerobic. High-energy stores of ATP and creatine phosphate become depleted. As a result, contraction ceases in the affected region.

If blood flow is not restored, cell death begins within 20 minutes. Clear indices of cell death—myocyte disruption, coagulative necrosis, elevation of cardiac proteins in serum—are present by 24 hours. By 4 days, monocyte infiltration and removal of dead myocytes weaken the infarcted area,

making it vulnerable to expansion and rupture. Structural integrity is partially restored with deposition of collagen, which begins in 10 to 12 days, and ends with dense scar formation by 4 to 6 weeks.

Myocardial injury also triggers ventricular remodeling, a process in which ventricular mass increases and the chambers change in volume and shape. Remodeling is driven in part by local production of angiotensin II. Ventricular remodeling increases the risk of heart failure and death.

The degree of residual cardiac impairment depends on how much of the myocardium was damaged. With infarction of 10% of left ventricular (LV) mass, the ejection fraction is reduced. With 25% LV infarction, cardiac dilation and heart failure (HF) occur. With 40% LV infarction, cardiogenic shock and death are likely.

53.2 DIAGNOSIS OF STEMI

Acute STEMI is diagnosed by the presence of chest pain, characteristic ECG changes, and elevated serum levels of myocardial cellular components (troponin, creatine kinase). Other symptoms include sweating, weakness, and a sense of impending doom. About 20% of people with STEMI experience no symptoms.

53.2.1 Chest Pain.

Patients undergoing STEMI typically experience severe substernal pressure that they characterize as unbearable crushing or constricting pain. The pain often radiates down the arms and up to the jaw. STEMI can be differentiated from angina pectoris in that pain caused by STEMI lasts longer (20 to 30 minutes) and is not relieved by nitroglycerin. Some patients confuse the pain of STEMI with indigestion.

53.2.2 ECG Changes.

Acute STEMI produces changes in the ECG. Why? Because conduction of electrical impulses through the heart becomes altered in the region of injury. Elevation of the ST segment, which defines STEMI, occurs almost immediately in response to acute ischemia ([Fig. 52-1](#)).

619

620

Figure 52-1 ECG changes associated with ST-elevation myocardial infarction.

Following a period of ST-segment elevation, a prominent Q wave (more than 0.04-second duration) develops in the majority of patients. (Q waves are small or absent in the normal ECG.) Over time, the ST segment returns to baseline, after which a symmetric inverted T wave appears. This T wave inversion may resolve within weeks to months. Q waves may resolve over a period of years.

53.2.3 Biochemical Markers for MI.

When myocardial cells undergo necrosis, they release intracellular proteins (eg, cardiac troponins, creatine kinase). Hence, elevations in these proteins in blood can be diagnostic of STEMI.

Today, cardiac-derived troponins—*cardiac troponin I* and *cardiac troponin T*—are considered the best serum markers for STEMI. These proteins are components of the sarcomere, and are distinct from their counterparts in skeletal muscle. Under normal conditions, troponin I and troponin T are undetectable in blood. However, when STEMI occurs, their levels rise dramatically, often to 100-fold or more above the lower limits of detection. Cardiac troponins become detectable 2 to 4 hours after symptom onset, peak in 10 to 24 hours, and return to undetectable in 5 to 14 days.

Measurements of troponin I and troponin T are more sensitive than measurements of other biochemical markers for STEMI, and produce fewer false-positive or false-negative results.

Before cardiac troponins became the preferred biomarkers for STEMI, clinicians relied on measurement of the MB isozyme of creatine kinase (CK-MB). Since CK-MB is found primarily in cardiac muscle rather than skeletal muscle, an increase in serum CK-MB is highly suggestive of cardiac injury. Following MI, serum levels of CK-MB begin to rise in 4 to 8 hours, peak in 24 hours, and return to baseline in 36 to 72 hours. In some patients, the increase in CK-MB may be too small to allow a definitive diagnosis, even though significant myocardial injury has occurred.

53.3 MANAGEMENT OF STEMI

The acute phase of management refers to the interval between the onset of symptoms and discharge from the hospital (usually 6 to 10 days). The goal is to bring cardiac oxygen supply back in balance with oxygen demand. This can be accomplished by reperfusion therapy, which restores blood flow to the myocardium, and by reducing myocardial oxygen demand. The first few hours of treatment are most critical. The major threats to life during acute STEMI are ventricular dysrhythmias, cardiogenic shock, and HF.

In 2004 and again in 2007, the American College of Cardiology (ACC), in conjunction with the American Heart Association (AHA), issued revised guidelines for the management of acute MI. These guidelines—*ACC/AHA Guidelines for the Management of Patients with ST-Elevation*

Pharmacology for Nursing Care, 7th Edition

Myocardial Infarction and *2007 Focused Update of ACC/AHA 2004 Guidelines for the Management of Patients With ST-Elevation Myocardial Infarction*—are available online at www.acc.org and www.americanheart.org. The discussion below reflects recommendations in these documents.

53.3.1 Routine Drug Therapy

When a patient presents with suspected STEMI, several interventions should be started immediately. The objective is to minimize possible myocardial necrosis while waiting for a clear diagnosis. Once STEMI has been diagnosed, more definitive therapy—reperfusion—can be implemented (see below).

53.3.1.1 Oxygen

Supplemental oxygen, administered by nasal cannula, can increase arterial oxygen saturation, and thereby increase oxygen delivery to the ischemic myocardium. Accordingly, oxygen should be given to all patients with reduced arterial oxygen saturation (below 90%), and may be given to all other patients with suspected STEMI as well.

53.3.1.2 Aspirin

Aspirin suppresses platelet aggregation, producing an immediate antithrombotic effect. In the Second International Study of Infarct Survival (ISIS-2), aspirin caused a substantial reduction in mortality. Moreover, benefits were synergistic with fibrinolytic drugs: mortality was 13.2% with thrombolytics alone, and dropped to 8% with the addition of aspirin. Because of these benefits, virtually all patients with evolving STEMI should get aspirin. Therapy should begin immediately after onset of symptoms, and should continue indefinitely. The first dose (162 to 325 mg) should be chewed to allow rapid absorption across the buccal mucosa. Prolonged therapy (with 81 to 162 mg/day) reduces the risk of reinfarction, stroke, and death.

53.3.1.3 Nonaspirin NSAIDs

According to the 2007 guideline updates, routine use of nonsteroidal drugs (NSAIDs) other than aspirin should be *discontinued*. Why? Because, unlike aspirin, these agents increase the risk of mortality, reinfarction, hypertension, HF, and myocardial rupture.

620

53.3.1.4 Morphine

Intravenous morphine is the treatment of choice for STEMI-associated pain. In addition, morphine can improve hemodynamics. By promoting venodilation, the drug reduces cardiac preload. By promoting modest arterial dilation, morphine may cause some reduction in

621

afterload. The combined reductions in preload and afterload lower cardiac oxygen demand, thereby helping preserve the ischemic myocardium.

53.3.1.5 Beta Blockers

When given to patients undergoing acute STEMI, beta blockers (eg, atenolol, metoprolol) reduce cardiac pain, infarct size, and short-term mortality. Recurrent ischemia and reinfarction are also decreased. Reduction in myocardial wall tension may decrease the risk of myocardial rupture. Continued use of an oral beta blocker increases long-term survival. Unfortunately, although nearly all patients can benefit from beta blockers, many don't get them.

Benefits result from several mechanisms. As STEMI evolves, traffic along sympathetic nerves to the heart increases greatly, as does the number of beta receptors in the heart. As a result, heart rate and force of contraction rise substantially, thereby increasing cardiac oxygen demand. By preventing beta receptor activation, beta blockers reduce heart rate and contractility, and thereby reduce oxygen demand. They reduce oxygen demand further by lowering blood pressure. By prolonging diastolic filling time, beta blockers increase coronary blood flow and myocardial oxygen supply. Additional benefits derive from antidysrhythmic actions.

Beta blockers should be used routinely in the absence of specific contraindications (eg, asthma, bradycardia, significant LV dysfunction). The initial dose may be oral or IV; oral dosing is used thereafter. Treatment with an oral beta blocker should begin within 24 hours and should continue for at least 2 to 3 years, and perhaps longer. Beta blockers are especially good for patients with reflex tachycardia, systolic hypertension, atrial fibrillation, and atrioventricular conduction abnormalities. Contraindications include overt severe HF, pronounced bradycardia, persistent hypotension, advanced heart block, and cardiogenic shock. The basic pharmacology of the beta blockers is presented in [Chapter 18](#).

53.3.1.6 Nitroglycerin

In patients with STEMI, nitroglycerin has several beneficial effects: It can (1) reduce preload, and thereby reduce oxygen demand; (2) increase collateral blood flow in the ischemic region of the heart; (3) control hypertension caused by STEMI-associated anxiety; and (4) limit infarct size and improve LV function. However, despite these useful effects, nitroglycerin does not reduce mortality. Nonetheless, since the drug is easily administered, offers hemodynamic benefits, and helps relieve ischemic chest pain, it continues to be used. According to the current guidelines, patients with ongoing ischemic discomfort should be given sublingual nitroglycerin (0.4 mg) every 5 minutes for a total of three doses, and then be assessed to determine whether

IV nitroglycerin should be given. Indications for IV therapy include persisting ischemic discomfort, hypertension, and pulmonary congestion. Nitroglycerin should be avoided in patients with hypotension (systolic pressure below 90 mm Hg), severe bradycardia (heart rate below 50 bpm), marked tachycardia (heart rate above 100 bpm), or suspected right ventricular infarction. In addition, nitroglycerin should be avoided in men who have taken sildenafil or vardenafil for erectile dysfunction within the last 24 hours, or tadalafil within the last 48 hours.

53.3.2 Reperfusion Therapy

The goal of reperfusion therapy is to restore blood flow through the blocked coronary artery. Reperfusion is the most effective way to preserve myocardial function and limit infarct size. How do we accomplish reperfusion? Either with fibrinolytic drugs (also known as thrombolytic drugs) or with percutaneous coronary intervention (PCI), usually balloon angioplasty. Both options are very effective. However, PCI is generally preferred. The relative advantages of fibrinolytic therapy and primary PCI are summarized in [Table 52-1](#). With either intervention, rapid implementation is essential.

53.3.2.1 Primary Percutaneous Coronary Intervention

The term *primary PCI* refers to the use of angioplasty, rather than fibrinolytic therapy, to recanalize an occluded coronary artery. In the most common type of angioplasty, a catheter containing a deflated balloon is worked into the affected coronary artery, and then the balloon is inflated. This opens the vessel, allowing blood to flow. Placement of a stent (a small mesh tube) in the artery helps prevent reocclusion. Under current guidelines, the institutional goal is to implement PCI within 90 minutes of initial patient contact. As discussed below, all patients undergoing PCI should receive an anticoagulant (IV heparin) and antiplatelet drugs (aspirin plus clopidogrel, and probably a glycoprotein IIb/IIIa inhibitor).

The success rate with primary PCI is somewhat higher than with fibrinolytic therapy. Moreover, studies indicate that the benefits of PCI last longer. After 30 days, the rate of death, reinfarction, or disabling stroke following PCI is 9.6%, versus 13.6% following fibrinolytic therapy with tissue plasminogen activator (tPA). After 5 years, the rate of all-cause mortality following PCI is 13%, versus 24% with streptokinase—the difference being due entirely to lower cardiovascular mortality in PCI-treated patients. Benefits of primary PCI over fibrinolytic therapy are greatest in high-risk patients.

TABLE 52-1 Comparison of Fibrinolytic Therapy with Primary PCI

Advantages of Fibrinolytic Therapy <ul style="list-style-type: none">• More universal access• Shorter time to treatment• Results less dependent on physician experience• Lower system cost
Advantages of Primary PCI <ul style="list-style-type: none">• Higher initial reperfusion rates• Less residual stenosis• Lower recurrence rates of ischemia/infarction• Does not promote intracranial bleeding• Defines coronary anatomy and LV function• Can be used when fibrinolytic therapy is contraindicated
LV = left ventricular, PCI = percutaneous coronary intervention.

621

TABLE 52-2 Contraindications and Cautions Regarding Fibrinolytic Use for Myocardial Infarction

Absolute Contraindications

- Any prior intracranial hemorrhage
- Known structural cerebral vascular lesion
- Ischemic stroke within last 3 months *except* ischemic stroke within 3 hours
- Known intracranial neoplasm
- Active internal bleeding (other than menses)
- Suspected aortic dissection

Relative Contraindications/Cautions

- Severe, uncontrolled hypertension on presentation (blood pressure above 180/110 mm Hg)
- History of chronic, severe, poorly controlled hypertension
- History of prior ischemic stroke, dementia, or known intracerebral pathology not covered in contraindications
- Current use of anticoagulants in therapeutic doses (INR 2–3 or greater); known bleeding diathesis
- Traumatic or prolonged (more than 10 minutes) CPR or major surgery (less than 3 weeks ago)
- Recent internal bleeding (within 2–4 weeks)
- Noncompressible vascular punctures
- For streptokinase: prior exposure (more than 5 days ago) or prior allergic reaction
- Pregnancy
- Active peptic ulcer

Adapted from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA Guidelines for the Management of Patients with ST-Elevation Myocardial Infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to revise the 1999 guidelines for the management of patients with acute myocardial infarction). J Am Coll Cardiol 44:671–719, 2004.

CPR = cardiopulmonary resuscitation, INR = international normalized ratio.

53.3.2.2 Fibrinolytic Therapy

Fibrinolytic drugs dissolve clots. How? By converting plasminogen into plasmin, a proteolytic enzyme that digests the fibrin meshwork that holds clots together. Five fibrinolytic drugs are available: *alteplase (tPA)*, *reteplase*, *streptokinase*, *tenecteplase*, and *urokinase*. The basic pharmacology of these drugs is presented in [Chapter 51](#). Discussion here is limited to their use in STEMI.

Fibrinolytic therapy is most effective when presentation is early. When thrombolytics are given soon enough, the occluded artery can be opened in 80% of patients. Current guidelines suggest a target of 30 minutes or less for the elapsed time between entering the emergency department and starting fibrinolysis. Clinical trials have shown that timely therapy improves ventricular function, limits infarct size, and reduces mortality. Restoration of blood flow reduces or eliminates chest pain, and often reduces ST elevation. Current guidelines restrict fibrinolytic therapy to patients with ischemic pain that has been present no more than 12 hours. Patients for whom fibrinolytic therapy is contraindicated are listed in [Table 52-2](#).

Under *typical* conditions, all of the available fibrinolytics are equally beneficial. However, under ideal conditions (ie, treatment within 4 to 6 hours of pain onset), alteplase is most effective, especially in patients under age 75 (see discussion of the GUSTO-I trial in [Chapter 51](#)). Unfortunately, alteplase is also very expensive. With streptokinase, neutralizing antibodies may develop within 5 days of initial use. These antibodies prevent streptokinase from acting, and hence a different agent must be used if fibrinolytic therapy must be repeated.

The major complication of fibrinolytic therapy is bleeding, which occurs in 1% to 5% of patients. Intracranial hemorrhage (ICH) is the greatest concern. ICH has an incidence of 0.5% to 1%, and is most likely in the elderly. Nonetheless, the benefits of fibrinolysis generally outweigh the risks. ICH is slightly more common with alteplase than with streptokinase.

As discussed below, all patients undergoing fibrinolytic therapy should receive an anticoagulant (IV heparin) plus antiplatelet drugs (aspirin plus clopidogrel—but not a glycoprotein IIb/IIIa inhibitor [eg, abciximab]).

53.3.3 Adjuncts to Reperfusion Therapy

53.3.3.1 Heparin

Heparin is a parenteral anticoagulant that was used widely to treat MI before fibrinolytics and primary PCI became available. The drug was shown to decrease mortality, reinfarction, stroke,

pulmonary embolism, and deep vein thrombosis. Today, heparin is used in conjunction with fibrinolytics and PCI to reduce the risk of thrombosis. The main complication of heparin is bleeding.

Heparin is recommended for all STEMI patients undergoing fibrinolytic therapy or PCI. For those receiving fibrinolytic drugs, treatment should begin prior to giving the fibrinolytic, and should continue for at least 48 to 72 hours after. For patients undergoing PCI, heparin is given once, immediately before the procedure.

As discussed in [Chapter 51](#), heparin is available as the intact (unfractionated) drug and in low-molecular-weight (LMW) forms. When heparin is used as an adjunct to fibrinolytic therapy, selection of a heparin product depends on duration of its use. For treatment lasting less than 48 hours, *unfractionated* heparin can be employed. However, for treatment lasting more than 48 hours, an *LMW* heparin should be chosen. Why? Because prolonged use of unfractionated heparin poses a risk of heparin-induced thrombocytopenia.

53.3.3.2 Antiplatelet Drugs

53.3.3.2.1 Clopidogrel.

Clopidogrel [Plavix] is an antiplatelet drug that works by blocking receptors for adenosine diphosphate (see [Chapter 51](#)). The drug is recommended for all MI patients undergoing reperfusion therapy, and even for those who do not undergo reperfusion. In all cases, clopidogrel should be *combined* with aspirin. In patients undergoing PCI, dosing should continue for 1 to 12 months, and in patients undergoing fibrinolytic therapy, dosing should continue at least 14 days.

53.3.3.2.2 Glycoprotein (GP) IIb/IIIa Inhibitors.

As discussed in [Chapter 51](#), the GP IIb/IIIa inhibitors (eg, abciximab [Reo-Pro]) are powerful, intravenous antiplatelet drugs that inhibit the final step in platelet aggregation. These drugs are recommended for patients undergoing PCI, but not for those undergoing fibrinolytic therapy. Of the three GP IIb/IIIa inhibitors available, abciximab is preferred. Treatment should begin as soon as possible before PCI and should continue for 12 hours after.

622

53.3.3.2.3 Aspirin.

623

As discussed above, *low-dose* aspirin (81 to 162 mg/day) should be taken indefinitely by all people who have had an MI. In addition, *higher-dose* aspirin (162 to 325 mg/day) is

recommended for patients who have undergone PCI combined with stent implantation. How long should the higher dose be taken? For at least 1 month by those with a *bare-metal* stent, at least 3 months by those with a *sirolimus-eluting* stent, and at least 6 months by those with a *paclitaxel-eluting* stent—after which all patients should switch to low-dose aspirin and take it indefinitely.

53.3.3.3 Angiotensin-Converting Enzyme Inhibitors and Angiotensin II Receptor Blockers

When used following acute STEMI, angiotensin-converting enzyme (ACE) inhibitors (eg, captopril, lisinopril) decrease short-term mortality in all patients, and long-term mortality in patients with reduced LV function. Benefits derive from reducing preload and afterload, promoting water loss, and favorably altering ventricular remodeling. Because of their benefits, ACE inhibitors are recommended for all STEMI patients in the absence of specific contraindications. Treatment should start within 24 hours of symptom onset and should continue for 6 weeks in all patients, and indefinitely in patients with LV dysfunction. The possibility that long-term therapy may also benefit patients who do not have LV dysfunction is being evaluated in large-scale trials. The major adverse effects of ACE inhibitors are hypotension and cough. Contraindications to ACE inhibitors are hypotension, bilateral renal artery stenosis, renal failure, and a history of ACE inhibitor-induced cough or angioedema. The basic pharmacology of the ACE inhibitors is presented in [Chapter 43](#).

Therapy with angiotensin II receptor blockers (ARBs) in STEMI patients has not been studied as extensively as has therapy with ACE inhibitors. However, one major trial—Valsartan in Acute Myocardial Infarction Trial (VALIANT)—demonstrated that, in patients with post-MI HF or LV dysfunction, valsartan (an ARB) was as effective as captopril (an ACE inhibitor) at reducing short-term and long-term mortality. In the current guidelines, ARBs are recommended for STEMI patients who are intolerant of ACE inhibitors and have HF or reduced LV function.

53.3.3.4 Calcium Channel Blockers

Because of their antianginal, vasodilatory, and antihypertensive actions, calcium channel blockers (CCBs) were presumed beneficial for patients with acute STEMI, and hence were once used widely. However, in large-scale controlled trials, these drugs failed to decrease mortality either during or after acute STEMI. Accordingly, CCBs are not recommended for routine use. However, since the effects of CCBs on the heart are nearly identical to those of beta blockers, current guidelines state that it is reasonable to use two CCBs—verapamil or diltiazem—when beta blockers are either ineffective or contraindicated to relieve ongoing ischemia or control a

rapid ventricular rate caused by atrial fibrillation or atrial flutter. These drugs should not be used if the patient has HF, LV dysfunction, or atrioventricular block.

53.3.3.5 Magnesium

Magnesium has several potential cardioprotective effects. The drug decreases platelet aggregation, increases coronary blood flow, reduces cardiac afterload, and lowers the risk of serious ventricular dysrhythmias. In several small trials, magnesium infusion decreased mortality from MI. However, in ISIS-4, a trial involving over 58,000 patients, adding magnesium to fibrinolytic therapy failed to reduce mortality—and actually *increased* the incidence of bradycardia, HF, and death from cardiogenic shock. Accordingly, magnesium is not recommended for routine use. However, if magnesium deficiency is present, it should be corrected.

53.4 COMPLICATIONS OF STEMI

Myocardial infarction predisposes the heart and vascular system to serious complications. Among the most severe are ventricular dysrhythmias, cardiogenic shock, and HF.

53.4.1 Ventricular Dysrhythmias.

These develop frequently and are the major cause of death following MI. Sudden death from dysrhythmias occurs in 15% of patients during the first hour. Ultimately, ventricular dysrhythmias cause 60% of infarction-related deaths. Acute management of ventricular fibrillation consists of defibrillation followed by IV lidocaine for 24 to 48 hours. Programmed ventricular stimulation with guided antidysrhythmic therapy may be lifesaving for some patients.

Attempts to prevent dysrhythmias by giving antidysrhythmic drugs *prophylactically* have failed to reduce mortality. Worse yet, attempted prophylaxis of ventricular dysrhythmias with two drugs—encainide and flecainide—actually increased mortality. Similarly, when quinidine was employed to prevent supraventricular dysrhythmias, it too increased mortality. Therefore, since prophylaxis with antidysrhythmic drugs does not reduce mortality—and may in fact increase mortality—antidysrhythmic drugs should be withheld until a dysrhythmia actually occurs.

53.4.2 Cardiogenic Shock.

Shock results from greatly reduced tissue perfusion secondary to impaired cardiac function. Shock develops in 7% to 15% of patients during the first few days after MI and has a mortality rate of up to 90%. Patients at highest risk are those with large infarcts, a previous infarct, a low ejection

fraction (less than 35%), diabetes, and advanced age. Drug therapy includes inotropic agents (eg, dopamine, dobutamine) to increase cardiac output and vasodilators (nitroglycerin, nitroprusside) to improve tissue perfusion and reduce cardiac work and oxygen demand. Unfortunately, although these drugs can improve hemodynamic status, they do not seem to reduce mortality. Restoration of cardiac perfusion with PCI or coronary artery bypass grafting may be of value.

53.4.3 Heart Failure.

HF secondary to acute MI can be treated with a combination of drugs. A diuretic (eg, furosemide) is given to decrease preload and pulmonary congestion. Inotropic agents (eg, digoxin) increase cardiac output by enhancing contractility. Vasodilators (eg, nitroglycerin, nitroprusside) improve hemodynamic status by reducing preload, afterload, or both. ACE inhibitors (or ARBs), which reduce both preload and afterload, can be especially helpful. Beta blockers may also improve outcome. Drug therapy of heart failure is discussed at length in [Chapter 47](#).

53.4.4 Cardiac Rupture.

Weakening of the myocardium predisposes the heart wall to rupture. Following rupture, shock and circulatory collapse develop rapidly. Death is often immediate. Fortunately, cardiac rupture is relatively rare (less than 2% incidence). Patients at highest risk are those with a large anterior infarction. Cardiac rupture is most likely within the first days after MI. Early treatment with vasodilators and beta blockers may reduce the risk of wall rupture.

53.5 SECONDARY PREVENTION OF STEMI

As a rule, patients who survive the acute phase of STEMI can be discharged from the hospital after 6 to 10 days. However, they are still at risk of reinfarction (5% to 15% incidence within the first year) and other complications (eg, dysrhythmias, heart failure). Outcome can be improved with risk factor reduction, exercise, and long-term therapy with drugs.

Reduction of risk factors for MI can increase long-term survival. Patients who smoke must be encouraged to quit; the goal is total cessation. Patients with high serum cholesterol should be given an appropriate dietary plan and, if necessary, treated with a cholesterol-lowering drug (usually one of the statins); the goal is an LDL cholesterol level substantially below 100 mg/dL. Patients with high triglyceride levels (200 mg/dL or higher) should be given niacin or a “fibrate” (eg, gemfibrozil). Overweight patients should reduce; the goal is a body mass index of 18.5 to 29.4 kg/m² (see [Chapter 81](#)) and a waist circumference under 35 inches (for women) or under 40 inches (for men). Hypertension and diabetes increase the risk of mortality and must be controlled. For patients with hypertension, blood pressure should be decreased to below 140/90 mm Hg (or below 130/80

mm Hg for those with chronic kidney disease or diabetes). For patients with diabetes, the goal is a level of hemoglobin A_{1c} below 7%.

Exercise training can be valuable for two reasons: (1) it reduces complications associated with prolonged bed rest and (2) it accelerates return to an optimal level of functioning. The goal is 30 minutes of exercise at least 3 to 4 days a week, and preferably 7. Although exercise is safe for most patients, there is concern about cardiac risk and impairment of infarct healing in patients whose infarct is large.

All post-MI patients should take three drugs: (1) a beta blocker, (2) an ACE inhibitor or an ARB, and (3) an antiplatelet drug (aspirin or clopidogrel) or an anticoagulant (warfarin). All three should be taken indefinitely.

Estrogen therapy for postmenopausal women is not effective as secondary prevention, and hence should not be initiated post-MI.

53.5.1

KEY POINTS

- Myocardial infarction (MI) is defined as necrosis of the myocardium secondary to acute occlusion of a coronary artery. The usual cause is platelet plugging and thrombus formation at the site of a ruptured atherosclerotic plaque.
- ST-elevation MI (STEMI) is diagnosed by the presence of chest pain, characteristic ECG changes, and elevated serum levels of cardiac troponins.
- Aspirin suppresses platelet aggregation, and thereby decreases mortality, reinfarction, and stroke. All patients should chew a 162- to 325-mg dose upon hospital admission, and should take 81 to 162 mg/day indefinitely after discharge. A higher dose (162 to 325 mg/day) should be used short term (1 to 6 months) by patients who received a stent during PCI.
- In patients undergoing acute STEMI, beta blockers reduce cardiac pain, infarct size, short-term mortality, recurrent ischemia, and reinfarction. Continued use increases long-term survival. All patients should receive a beta blocker in the absence of specific contraindications.
- In addition to aspirin and a beta blocker, three other drugs—oxygen, morphine, and nitroglycerin—are considered routine therapy for suspected STEMI. They should be started, as appropriate, soon after symptom onset.

- Reperfusion therapy, which restores blood flow through blocked coronary arteries, is the most beneficial treatment for STEMI.
- Reperfusion can be accomplished with PCI or with fibrinolytic drugs. Both approaches are highly effective—but PCI is now generally preferred.
- The most common PCI procedure is balloon angioplasty, with or without stent implantation.
- Fibrinolytic drugs dissolve clots by converting plasminogen into plasmin, an enzyme that digests the fibrin meshwork that holds clots together.
- Under typical conditions, all fibrinolytic drugs are equally effective. However, when treatment is initiated within 4 to 6 hours of pain onset, alteplase is most effective (but also very expensive).
- The major complication of fibrinolytic therapy is bleeding. Intracranial hemorrhage is the greatest concern.
- Heparin (an anticoagulant) is recommended for all patients undergoing fibrinolytic therapy or PCI.
- Clopidogrel (an antiplatelet drug) *combined* with aspirin (also an antiplatelet drug) is recommended for all patients undergoing reperfusion therapy, either with PCI or with a fibrinolytic drug.
- Glycoprotein IIb/IIIa inhibitors (eg, abciximab) are powerful IV antiplatelet drugs that can enhance the benefits of primary PCI.
- In patients with acute MI, ACE inhibitors decrease mortality, severe heart failure, and recurrent MI. All patients should receive an ACE inhibitor in the absence of specific contraindications. For patients who cannot tolerate ACE inhibitors, an ARB may be used instead.
- To lower the risk of a second MI, all patients should decrease cardiovascular risk factors (eg, smoking, hypercholesterolemia, hypertension, obesity, diabetes); exercise for 30 minutes at least 3 or 4 days a week; and undergo long-term therapy with three drugs: (1) a beta blocker, (2) an ACE inhibitor or an ARB, and (3) an antiplatelet drug (aspirin or clopidogrel) or warfarin (an anticoagulant).

⁵⁴CHAPTER 53 Drugs for Hemophilia

Hemophilia is a genetically based bleeding disorder seen almost exclusively in males. About 70% of cases result from inheriting a defective gene from the mother; the other 30% result from a spontaneous gene mutation.

Hemophilia has two forms: hemophilia A and hemophilia B. In hemophilia A, there is a deficiency of clotting factor VIII (aka antihemophilic factor). In hemophilia B, there is a deficiency of clotting factor IX (aka Christmas factor, named for Stephen Christmas, the first boy diagnosed with the disease). Hemophilia A is about 6 times more prevalent than hemophilia B, occurring in 1 of every 5000 males, compared with 1 of every 30,000 for hemophilia B.

When hemophilia is managed well, the prognosis is good. Patients starting treatment today can live healthy, near-normal lives. The foundation of treatment is clotting factor replacement, which may be given on a regular schedule (to prevent bleeds from occurring) or “on demand” (to stop an ongoing bleed). Unfortunately, although treatment is highly effective, it is also very expensive: For patients undergoing prophylactic treatment, the cost for clotting factors alone is about \$300,000 a year.

^{54.1}BASIC CONSIDERATIONS

^{54.1.1} Pathophysiology

In people with hemophilia, there is a failure of hemostasis, the process by which bleeding is normally stopped. As discussed in [Chapter 51](#), hemostasis occurs in two stages: (1) formation of a platelet plug followed by (2) production of fibrin, a protein that reinforces the platelet plug. In patients with hemophilia, platelet aggregation proceeds normally, but fibrin production does not. The underlying problem is a deficiency of clotting factors—specifically, factor VIII (in hemophilia A)

Figure 53-1 Outline of the coagulation cascade showing clotting factors used to treat hemophilia. TF = tissue factor. Common names for factors shown in roman numerals: II = prothrombin, IIa = thrombin, VII = proconvertin, VIII = antihemophilic factor, IX = Christmas factor, X = Stuart factor, XI = plasma thromboplastin antecedent, and XII = Hageman factor. The letter “a” after a factor's name (eg, factor VIIIa) indicates the active form of the factor. Note that factors VIII and IX, which are deficient in hemophilia A and B respectively, are part of the contact-activation (intrinsic) coagulation pathway. The symbol  indicates acceleration of the reaction.

and factor IX (in hemophilia B). As indicated in [Figure 53-1](#), both factors are part of the contact-activation (intrinsic) coagulation pathway, and both—in their activated forms—are needed to catalyze the conversion of factor X to its active form (factor Xa), which in turn catalyzes the conversion of prothrombin to thrombin, which catalyzes the formation of fibrin. If either factor VIII or factor IX is deficient, the contact-activation pathway will not work properly, causing clot formation to be delayed. As a result, bleeding will continue longer than in the population at large.

It should be noted that the degree of factor deficiency—and hence the tendency for bleeding to be prolonged—depends on the nature of the underlying gene mutation. In some patients, the mutation produces a severe deficiency, resulting in a high probability of prolonged bleeding; in others, the mutation causes mild deficiency, and hence the tendency to bleed is low.

625

626

54.1.2 Inheritance Pattern

The genes for factors VIII and IX are *recessive*, and both are carried on the X chromosome. Because males have only one X chromosome, a male with a defective gene will have hemophilia. In contrast, a female with a defective gene on one X chromosome will usually be an asymptomatic carrier, since she still has a functioning gene on her other X chromosome. Please be aware, however, that although females are usually asymptomatic carriers, there are two situations in which females *can* have hemophilia: (1) a female could be born with defective genes on *both* X chromosomes, which is rare; and (2) a female who was born with one defective gene could experience *inactivation* of the good gene. Boys whose mothers are carriers have a 1 in 2 chance of inheriting the disease. Girls whose mothers are carriers have a 1 in 2 chance of being carriers themselves. Males with hemophilia cannot pass the disease on to their sons, but all of their daughters will be carriers. The risk of acquiring hemophilia is shared by all races and ethnic groups.

54.1.3 Clinical Features

Hemophilia may be severe, moderate, or mild, depending on the degree of clotting factor deficiency. Patients with severe hemophilia may experience life-threatening hemorrhage in response to minor trauma, whereas those with mild hemophilia may experience little or no excessive bleeding. The defining characteristics of severe, moderate, and mild hemophilia are summarized in [Table 53-1](#).

54.1.3.1 Severe Hemophilia.

In patients with severe hemophilia, the concentration of clotting factor VIII or IX is very low—less than 1% of normal. As a result, these patients experience frequent bleeds within joints and soft tissues, especially muscle. Trauma or surgery can cause profuse hemorrhage. Joint bleeding

occurs most often in the knee, followed in turn by the elbow, ankle, shoulder, and hip. Bleeding in these joints causes swelling and intense pain. With recurrent episodes, permanent injury to the joint develops. In addition to joints, bleeding may occur in muscles, mucous membranes (eg, nosebleeds), the GI and urinary tracts, near the pharynx (which can cause life-threatening restriction of airflow), and within the skull (which carries a 30% risk of death). Among patients with hemophilia A, about 60% have severe disease. In contrast, among patients with hemophilia B, only 20% to 45% have severe disease. Although severe hemophilia can be devastating, most patients can live normal and productive lives, thanks to the availability of safe factor concentrates for replacement therapy.

54.1.3.2 Moderate Hemophilia.

In patients with moderate hemophilia, the concentration of factor VIII or factor IX is between 1% and 5% of normal. Excessive bleeding in response to minor trauma is unlikely. However, it can be induced by significant trauma, tooth extractions, and surgery. Joint bleeding may occur, but the frequency is much lower than with severe hemophilia.

54.1.3.3 Mild Hemophilia.

In patients with mild hemophilia, the concentration of clotting factors is between 6% and 24% of normal. Joint bleeding is uncommon, but can be induced by severe injury or surgery.

54.1.4 Overview of Therapy

Whenever possible, treatment should be guided by a team of specialists at a hemophilia treatment center. Typically, the team consists of a hematologist, orthopedist, dietitian, psychologist, physical therapist, occupational therapist, genetics counselor, infectious disease specialist, social worker, and nurse coordinator.

The cornerstone of treatment is *replacement therapy* with factor VIII (hemophilia A) or factor IX (hemophilia B). Traditionally, factor replacement was performed only to terminate an ongoing bleeding episode. Today, however, there is increasing emphasis on primary prophylaxis, especially for young children. Why? Because, by minimizing bleeding episodes, prophylaxis can minimize long-term damage to joints.

For some patients with mild *hemophilia A*, bleeding can be stopped with *desmopressin*, a drug that promotes release of factor VIII from the vascular endothelium. Desmopressin has the advantage of being much cheaper than factor VIII, and can be administered by nasal spray as well as by IV infusion. Keep in mind, however, that repeated use of desmopressin can deplete stored factor VIII, making the drug ineffective until more factor VIII is made.

TABLE 53-1 Clinical Classification of Hemophilia Severity

Disease Parameter	Disease Severity		
	Severe	Moderate	Mild
Clotting factor level (VIII or IX)	Less than 1% of normal	Between 1% and 5% of normal	Between 6% and 24% of normal
Bleeding tendency	Can bleed with very mild injury	Can bleed with moderate injury	Can bleed with severe injury, surgery, or invasive procedures
Bleeding frequency	May bleed once or twice a week	May bleed once a month	May never have a bleeding episode
Occurrence of joint bleeding	Frequent	Less frequent	Infrequent, but can occur in response to severe injury

626
627

Antifibrinolytic drugs (ie, drugs that prevent the breakdown of fibrin) can be used as adjuncts to factors VIII and IX in special situations, such as tooth extractions. Two antifibrinolytic drugs are currently available: aminocaproic acid and tranexamic acid.

In some patients receiving factor VIII or factor IX, antibodies against the factor develop. These antibodies, referred to as inhibitors, prevent the factor from working. When inhibitors are present, bleeding can be stopped by infusing *activated factor VII*. Other treatments are also available, as discussed below under *Managing Patients with Inhibitors*.

54.1.5 **Pain Management**

How should we manage bleeding-related pain? For mild pain, *acetaminophen* [Tylenol, others] is the drug of choice. For severe pain, an *opioid analgesic* may be needed. Regardless of pain severity, *aspirin should be avoided!* Why? First, aspirin causes irreversible inhibition of platelet aggregation, and can thereby increase bleeding risk. Second, aspirin can induce GI ulceration and bleeding, an obvious problem.

Can we use nonsteroidal anti-inflammatory drugs (NSAIDs) other than aspirin? As a rule, these agents should also be avoided. Why? First, like aspirin, most NSAIDs inhibit platelet aggregation (although the inhibition is reversible rather than irreversible). Second, like aspirin, most NSAIDs can promote GI ulceration and bleeding (although the risk is somewhat lower than with aspirin).

What about the second-generation NSAIDs, known as cyclooxygenase-2 (COX-2) inhibitors? As discussed in [Chapter 70](#), the COX-2 inhibitors (eg, celecoxib) do not suppress platelet

aggregation, and they cause less GI ulceration and bleeding than traditional NSAIDs. Accordingly, these agents are clearly preferred to traditional NSAIDs, although their safety in hemophilia has not been proved.

54.1.6 Immunization

Children with hemophilia should undergo the normal immunization schedule (see [Chapter 67](#)). Some clinicians inject vaccines subQ (rather than IM) to avoid muscle hemorrhage. However, since the efficacy of subQ vaccination is not certain, and since most patients tolerate IM injections without bleeding, IM vaccination is generally preferred. The risk of bleeding after IM injection can be reduced by prolonged application of pressure.

To minimize the risk of hepatitis (see below), all patients with newly diagnosed hemophilia should be vaccinated for hepatitis A and hepatitis B, as should all other patients with hemophilia who are not seropositive for hepatitis A or B. Family members who administer clotting factors at home should also be immunized, provided they test negative for hepatitis.

54.2 PREPARATIONS USED TO TREAT HEMOPHILIA

54.2.1 Factor VIII Concentrates

Factor VIII concentrates are the mainstay of hemophilia A treatment. What's a concentrate? It's simply a powdered formulation in which the amount of factor VIII is very high. When treatment is needed, the powder is dissolved in a sterile solution and administered IV.

All factor VIII concentrates available today are very safe. They carry essentially no risk of HIV/AIDS, and little or no risk of hepatitis.

54.2.1.1 Production Methods and Product Safety

Factor VIII concentrates are made in two basic ways: (1) purification from human plasma and (2) production in cell culture using recombinant DNA technology. Recombinant factor VIII is somewhat safer than plasma-derived factor VIII, but is also more expensive. All factor VIII products, whether recombinant or plasma derived, are equally effective. Currently available products are listed in [Table 53-2](#).

54.2.1.1.1 Plasma-Derived Factor VIII.

Prior to 1985, factor VIII produced from donor plasma often contained viral contaminants. As a result, nearly all people with hemophilia developed hepatitis and/or HIV/AIDS. Today, however, the risk of viral contamination is exceedingly low. Why? First, donated plasma is

now screened for viral pathogens—specifically, human immunodeficiency virus (HIV), hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), and parvovirus B19. Second, techniques for inactivating *lipid-coated* viruses (HIV, HBV, and HCV) are now employed. Unfortunately, viruses that lack a lipid coat, such as HAV and parvovirus B19, are not eliminated. Nonetheless, no case of virus transmission has been reported with any of the products now used in the United States.

There is one additional concern: prions. These strange proteins, which are responsible for Creutzfeldt-Jakob disease (CJD, the human form of “mad cow disease”), are not susceptible to any known inactivation technique. Hence, the possibility of transmitting CJD remains.

As indicated in [Table 53-2](#), plasma-derived factor VIII is available in varying degrees of purity. The ultrapure products (eg, Hemofil-M) are prepared using monoclonal antibodies.

54.2.1.1.2 Recombinant Factor VIII.

Recombinant factor VIII is produced in culture, using hamster cells that have been genetically transformed. All recombinant factor VIII products are very safe, and hence are considered the agents of choice for treating hemophilia A.

TABLE 53-2 Some Factor VIII and Factor IX Concentrates

Type of Preparation	Factor VIII	Factor IX
Recombinant		
Third generation	Advate	BeneFix
	Xyntha	
Second generation	Helixate FS	
	Kogenate FS	
	ReFacto	
First generation	Recombinate	
	Bioclate	
Plasma-Derived		
Ultrapure	Hemofil-M	AlphaNine SD
	Monoclate-P	Mononine Profilnine SD
Intermediate and high purity	Alphanate	
	Koate-DVI	
	Humate-P [*]	

* Factor VIII complexed with von Willebrand factor.

During the manufacturing process, most recombinant factor VIII products are exposed to bovine serum albumin (BSA), human serum albumin (HSA), or both. Because BSA or HSA could, in theory, be a source of viruses or prions, manufacturing processes that reduce the use of BSA and HSA have been developed. As a result, we now have three “generations” of recombinant products:

- *First-generation products*—Bioclote and Recombinate—are made using BSA in the cell culture, and they contain HSA as a stabilizer in the vial.
- *Second-generation products*—Helixate FS, Kogenate FS, and ReFacto—are made using HSA in the cell culture, but they contain neither BSA nor HSA in the vial.
- *Third-generation products*—Advate and Xyntha—are not exposed to BSA or HSA during cell culture, and they contain neither BSA nor HSA in the vial.

Theoretically, the third-generation products—Advate and Xyntha—which are never exposed to any proteins of animal or human origin, are safer than the first- or second-generation products. However, there are no published data showing this is the case. With all three generations, the risk of human viral contamination is essentially zero. Transmission of HIV, HBV, or HCV has not been reported.

54.2.1.2 Adverse Effects: Allergic Reactions

Factor VIII concentrates can cause allergic reactions, which can range from mild to severe. Symptoms of a mild reaction include hives, rash, urticaria, stuffy nose, and fever. These can be managed with an antihistamine (eg, diphenhydramine [Benadryl]). Rarely, anaphylaxis may develop. Symptoms of this potentially fatal reaction include wheezing, tightness in the throat, shortness of breath, and swelling in the face. The treatment of choice is epinephrine, injected subQ.

54.2.1.3 Dosage and Administration

54.2.1.3.1 On-Demand Therapy.

On-demand therapy is indicated for patients who are bleeding or about to undergo surgery. As a rule, administration is by slow IV push over a period of 5 to 10 minutes. Continuous infusion may also be done, but only by a clinician with special training.

Dosage depends primarily on the site and severity of the bleed. [Table 53-3](#) indicates approximate dosages for a variety of bleeding situations. The dosing target is expressed as a percentage of normal factor VIII activity. For example, when treating a joint bleed, the dosing target is 40% of the normal activity level.

How can we calculate dosage? By knowing that, *for each unit of factor VIII we give per kilogram of body weight, we will raise factor VIII activity in plasma by 2%*. Hence, to calculate dosage, we simply multiply the patient's weight by the target activity level for factor VIII and then divide by 2, as in this example:

$$\frac{50(\text{kg body weight}) \times 40(\text{target \%})}{2} = 1000(\text{units of factor VIII})$$

To help guide dosing, factor VIII activity can be measured before and after treatment. However, although knowledge of factor VIII activity is helpful, dosage is ultimately determined by the clinical response.

54.2.1.3.2 Prophylactic Therapy.

For prophylaxis, factor VIII is administered on a regular schedule. The goal is to *prevent* bleeding, and thereby prevent life-threatening hemorrhage and long-term injury to joints. Children with severe hemophilia are the primary candidates for prophylaxis. Treatment is often done at home. The goal is to maintain factor VIII activity above 1% of normal. As a rule, this can be achieved by infusing factor VIII concentrate 3 times a week. However, dosing just once or twice a week may work for some patients. Recombinant factor VIII products are generally preferred, although plasma-derived products, which are just as effective and much less expensive, may also be used.

To facilitate frequent IV administration, a central venous access device can be installed. Options include an external catheter (eg, Hickman catheter) or an implanted venous port (eg, Port-A-Cath). Both types of device are intended for long-term use, and can remain in place several years. It should be noted, however, that although these devices make prophylaxis much easier, they do carry risks, infection and thrombosis being the greatest concerns.

54.2.2 Factor IX Concentrates

54.2.2.1 Therapeutic Use, Production, and Safety

Factor IX concentrates are the mainstay of treatment for hemophilia B. The pharmacology of these concentrates is nearly identical to that of the factor VIII concentrates. Like the factor VIII concentrates, the factor IX concentrates are made either by extraction from donor plasma or by

recombinant DNA technology (see [Table 53-2](#)). None of the products in current use poses a risk of HIV/AIDS. However, the plasma-derived products may carry a very small risk of hepatitis A, parvovirus B19, or CJD—although there have been no reports of transmitting any of these infections with current products. Because recombinant factor IX [BeneFix] is, in theory, safer than plasma-derived factor IX [AlphaNine SD, Mononine, Profilnine SD], recombinant factor IX is considered the preparation of choice. Like factor VIII, factor IX can cause allergic reactions.

54.2.2.2 Dosage and Administration

54.2.2.2.1 On-Demand Therapy.

On-demand therapy, administered by IV push, should be initiated at the earliest sign of bleeding. As with factor VIII, dosage is determined primarily by the site and severity of bleeding (see [Table 53-3](#)). However, factors VIII and IX differ in that, on a unit-per-kilogram (unit/kg) basis, we need twice as much factor IX to achieve an equivalent increase in plasma factor level. Hence, with factor IX, *for each unit we give per kilogram of body weight, we will raise the plasma activity level by 1%* (compared with 2% for each unit/kg of factor VIII). To calculate dosage, we simply multiply the patient's weight by the target factor IX activity level (expressed as a percentage of normal factor IX activity level), as in this example:

$$50(\text{kg body weight}) \times 40(\text{target \%}) = 2000(\text{units of factor IX})$$

As with factor VIII therapy, plasma levels of factor IX activity can be measured to guide treatment—although the dose depends ultimately on the clinical response.

54.2.2.2.2 Prophylactic Therapy.

As with factor VIII, prophylaxis is done to prevent bleeding, and thereby prevent injury to joints. The dosing goal is to maintain factor IX levels above 1% of normal. Because factor IX has a longer half-life than factor VIII (18 to 24 hours vs. 8 to 12 hours), prophylaxis can be done less often (twice a week rather than 3 times a week). The usual dose is 20 to 40 units/kg.

628

629

TABLE 53-3 Estimated Dosages for Factor VIII and Factor IX

Type of Hemorrhage	Factor VIII (Hemophilia A)		Factor IX (Hemophilia B)	
	Target Activity Level [*]	Dose (units/kg)	Target Activity Level [*]	Dose (units/kg)
Joint	40%	20	40%	40

CNS = central nervous system.				

* Target activity levels are expressed as a percentage of the normal activity level.

† The iliopsoas is a compound muscle consisting of the iliacus and psoas major muscles, located in the groin region.

54.2.3 Desmopressin

54.2.3.1 Therapeutic Use.

Desmopressin [DDAVP, Stimate], an analog of antidiuretic hormone, can stop or prevent bleeding in patients with *mild* hemophilia A. The drug works by releasing stored factor VIII from the vascular endothelium. Levels of factor VIII begin to rise within 30 minutes of drug administration, and peak within 90 to 120 minutes. Desmopressin can be used to stop episodes of trauma-induced bleeding, and can be given preoperatively to maintain hemostasis during surgery. Desmopressin does not release factor IX, and hence cannot be used to treat hemophilia B. Principal adverse effects are fluid retention and hyponatremia. The basic pharmacology of desmopressin, along with its use in hypothalamic diabetes insipidus, is discussed in [Chapter 58](#) (Drugs Related to Hypothalamic and Pituitary Function).

54.2.3.2 Preparations, Dosage, and Administration.

For treatment of hemophilia A, desmopressin may be administered IV or by intranasal spray. An oral formulation is available, but is not indicated for hemophilia.

For *intravenous therapy*, desmopressin [DDAVP] is formulated in a concentrated solution (4 mcg/mL) that must be diluted in physiologic saline. The usual dosage is 0.3 mcg/kg infused over 15 to 30 minutes.

For *intranasal therapy*, desmopressin is available under two trade names: *DDAVP*, which delivers 10 mcg/spray, and *Stimate*, which delivers 150 mcg/spray. Only *Stimate* is used for hemophilia. For patients who weigh 50 kg or more, the dosage is 150 mcg/nostril, for a total of 300 mcg; for patients who weigh less than 50 kg, the dosage is one spray (150 mcg) in just one nostril.

54.2.4 Antifibrinolytic Agents

Antifibrinolytic agents inhibit the normal process of fibrin breakdown. As discussed in [Chapter 51](#), when a clot is no longer needed, an enzyme called *plasmin* dissolves the fibrin meshwork that holds the clot together, and thereby promotes clot removal. Unfortunately, in people with hemophilia, fibrin breakdown can lead to a resumption of bleeding. Accordingly, by preserving fibrin with an antifibrinolytic drug, we can help keep bleeding under control. Because of their mechanism, antifibrinolytic drugs are most useful for *preventing recurrent* bleeding; they are less useful for stopping an ongoing bleed.

Two antifibrinolytic drugs are currently available: *aminocaproic acid* [Amicar] and *tranexamic acid* [Cyklokapron]. Both agents act primarily by preventing the formation of plasmin from its precursor (plasminogen). These drugs are most useful for controlling bleeding in mucous membranes (of the nose, mouth, and throat) as well as bleeding caused by dental extractions—presumably because fibrinolytic activity at all of these sites is especially high.

629

630

Aminocaproic acid is available in solution (250 mg/mL) for IV use, and in tablets (500 and 1000 mg) and a syrup (250 mg/mL) for oral use. Dosages to prevent or treat serious bleeding are as follows:

- *Oral therapy, adults*—give 5 gm for the first hour, then 1 or 1.25 gm every hour
- *IV therapy, adults*—infuse 4 to 5 gm over the first hour, then infuse at a rate of 1 gm/hr
- *Oral therapy, children*—give 100 mg/kg for the first hour, then 33.3 mg/kg every hour
- *IV therapy, children*—infuse 100 mg/kg over the first hour, then infuse at a rate of 33.3 mg/kg/hr

In all cases, continue dosing for 8 hours or until bleeding stops.

Tranexamic acid is available in tablets (500 mg) for oral use and in solution (100 mg/mL) for IV use. To control bleeding associated with dental extractions, the recommended dosage is 10 mg/kg IV immediately before the extraction, followed by 25 mg/kg PO every 6 to 8 hours for 2 to 8 days. Dosage should be decreased in patients with renal impairment.

54.2.5 Managing Patients with Inhibitors

Patients receiving factor VIII or factor IX can develop antibodies against the factor. These antibodies, referred to as inhibitors, neutralize the clotting factor, and thereby render factor replacement ineffective. In most cases, the antibodies develop early, typically after only 9 to 12 courses of treatment.

Some patients are more likely to develop inhibitors than others. Among patients with *severe* hemophilia A, between 20% and 30% develop antibodies to factor VIII, compared with 3% to 13% of those with *mild* hemophilia A. Among patients with severe hemophilia B, between 2% and 12% develop antibodies to factor IX. The risk of inhibitor development among African American and Hispanic patients is unusually high (up to 50%).

The titer of inhibitors to factor VIII is measured using the Bethesda assay. In this procedure, serial dilutions of patient plasma are mixed with an equal volume of normal plasma, after which factor

VIII activity in the mixture is measured. The dilution that inhibits 50% of factor VIII activity defines the inhibitor titer. For example, if the 1:40 dilution inhibits 50% of the factor VIII activity, the patient is said to have a titer of 40 *Bethesda units* (BU) of factor VIII inhibitor.

For some patients, *immune tolerance therapy* (ITT) can eliminate inhibitor production. The procedure involves repeated administration of factor replacement products over an extended time. The success rate is high (63% to 83%) for patients with hemophilia A, and very low for those with hemophilia B. A low antibody titer (less than 5 BU) increases the chances of success. If ITT fails to stop antibody production, then hemostasis must be achieved with drugs, as discussed immediately below.

54.2.5.1 Drugs for Patients with Factor VIII Inhibitors

To control bleeding in patients with inhibitors to factor VIII, the preferred treatments are (1) activated factor VII and (2) anti-inhibitor coagulant complex. Neither option is clearly superior to the other. Accordingly, selection between them is based on previous response and physician preference.

54.2.5.1.1 Activated Factor VII (Factor VIIa).

Factor VIIa [NovoSeven RT], manufactured by recombinant DNA technology, can control bleeding in patients with inhibitors to factor VIII or factor IX. As indicated in [Figure 53-1](#), factor VIIa has the same action as factors VIII and IX. That is, it catalyzes the conversion of factor X to its active form. Hence, by giving factor VIIa, we can bypass neutralization of factors VIII and IX, and thereby allow clotting to proceed normally.

Factor VIIa is generally well tolerated. No human proteins are used in making this agent, and hence there is no risk of transmitting a human virus. Rarely, thrombotic events have occurred, including venous thrombosis, cerebral sinus thrombosis, and myocardial infarction (MI). In most cases, these events were seen when NovoSeven was used off-label to stop bleeding in nonhemophiliacs, including patients with acute intracerebral hemorrhage.

Factor VIIa is supplied as a powder in single-use vials (1.2, 2.4, and 4.8 mg) and must be reconstituted in sterile water prior to use. Administration is by IV bolus. The usual dosage is 90 mcg/kg, repeated every 2 hours until bleeding is stopped. However, some patients require much higher doses (eg, 300 mcg/kg). Treatment is very expensive: A single 90-mcg/kg dose for a 70-kg patient costs about \$10,000. The drug should be stored under refrigeration.

54.2.5.1.2 Anti-inhibitor Coagulant Complex (AICC).

AICC [Autoplex T, Feiba VH Immuno^{*}], made from pooled human plasma, contains variable amounts of clotting factors II, VII, IX, and X—in both their activated and nonactivated forms. AICC is indicated for patients with inhibitors to factor VIII or factor IX who are bleeding or about to undergo surgery. Benefits are believed to derive from factors VIIa and Xa, which bypass factors VIII and IX in the coagulation cascade (see [Fig. 53-1](#)).

Because AICC is made from human plasma, there is a theoretical risk of transmitting viral or prion disease. However, there have been no reports of transmitting CJD, HIV, or hepatitis A, B, or C with these products as currently formulated.

Because AICC contains multiple coagulation factors, it poses a risk of thrombotic complications, specifically, MI and disseminated intravascular coagulation (DIC). Fortunately, these events are very rare. The risk of MI or DIC is increased with repeated dosing and by liver disease.

Preparations of Feiba VH Immuno are standardized in *Immuno units*. The usual dosage is 50 to 100 Immuno units/kg, infused IV at a rate no faster than 2 Immuno units/kg/min. Dosing can be repeated every 6 hours, but the total daily dose must not exceed 200 Immuno units/kg.

Preparations of Autoplex T are standardized in *Hyland factor VII correctional units*. The usual dosage is 25 to 100 Hyland correctional units/kg, infused IV. Dosing may be repeated in 6 hours.

* FYI: *Feiba* stands for *factor VIII inhibitor bypassing activity*.

54.2.5.1.3 Factor VIII Concentrate.

If the inhibitor titer is very low (less than 5 BU), we may be able to overcome inhibition with high doses of factor VIII itself. However, if the inhibitor titer is high, then factor VIII will not work, and the agents discussed above must be employed.

54.2.5.1.4 Porcine Factor VIII.

Porcine factor VIII [Hyate: C] can establish hemostasis in patients with hemophilia A who have developed antibodies to human factor VIII. The product, a highly purified form of factor VIII, is extracted from the blood of pigs. The donor animals live in a carefully maintained environment and undergo frequent screening for several viruses. Transmission of porcine viruses to humans receiving the product has never been documented. However, allergic reactions, including anaphylaxis, have occurred, especially with recurrent use. The incidence

630

631

is about 5%. Rarely, patients develop acute thrombocytopenia. Like all other factor VIII preparations, porcine factor VIII is administered IV. The recommended initial dosage is 100 to 150 factor VIII units/kg. The product should be stored at -15°C to -20°C (5°F to -4°F).

Antibodies to human factor VIII can cross-react with porcine factor VIII. However, the degree of cross-reactivity is low. Accordingly, if the antibody titer is not too high (less than 50 BU/mL), porcine factor VIII is likely to work. If the titer exceeds 50 BU/mL, significant neutralization of the porcine factor can occur. To determine if Hyate: C will work in a patient with a high titer, we need to directly measure the ability of a plasma sample to neutralize the drug.

54.2.5.2 Drugs for Patients with Factor IX Inhibitors

Treatment options for patients with factor IX inhibitors are limited. In contrast to factor VIII inhibitors, which may be overcome with large doses of human factor VIII or porcine factor VIII, factor IX inhibitors are difficult to overcome with any preparation of factor IX available. Furthermore, elimination of factor IX inhibitors with ITT often fails. Currently, factor VIIa and AICC are the treatments of choice. Both options are effective because they bypass the blockade caused by the inhibitor.

54.2.5.2.1

KEY POINTS

- Hemophilia is a bleeding disorder seen almost exclusively in males. The underlying cause is a genetically based deficiency of clotting factors.
- Hemophilia has two forms: hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency).
- Hemophilia may be severe, moderate, or mild, depending on the degree of clotting factor deficiency.
- Patients with severe hemophilia may experience life-threatening hemorrhage in response to minor trauma, whereas those with mild hemophilia may experience little or no excessive bleeding.
- Repeated bleeding in the knee and other joints can cause permanent joint damage.
- The cornerstone of hemophilia treatment is replacement therapy with factor VIII (hemophilia A) or factor IX (hemophilia B).

- Replacement therapy may be done prophylactically (to prevent bleeding and thereby prevent joint injury) or on demand (to stop an ongoing bleed or prevent excessive bleeding during surgery).
- Clotting factor products are made in two basic ways: extraction from donor plasma and production in cell culture using recombinant DNA technology.
- All clotting factor concentrates, whether plasma derived or recombinant, are equally effective.
- All clotting factor concentrates in use today are very safe: They carry no risk of transmitting HIV/AIDS, and little or no risk of transmitting hepatitis or CJD. However, because recombinant factors are, in theory, slightly safer than plasma-derived factors, recombinant factors are considered the treatment of choice.
- As a rule, clotting factors are given by slow IV push. Continuous infusion may also be done, but only by a clinician with special training.
- Clotting factor dosage depends primarily on the site and severity of the bleed.
- A dose of 1 unit of factor VIII/kg will raise the plasma level of factor VIII activity by 2%, whereas 1 unit of factor IX/kg will raise the plasma level of factor IX activity by only 1%.
- Although we can monitor the activity of clotting factors in blood to help guide treatment, dosage is ultimately determined by the clinical response.
- For prophylaxis, clotting factor concentrates are administered on a regular schedule, usually 3 times a week for factor VIII and twice a week for factor IX. With both factors, the goal is to maintain plasma levels above 1% of normal.
- To facilitate frequent IV administration during prophylaxis, a central venous access device can be installed.
- Clotting factor concentrates can cause allergic reactions. Mild reactions can be managed with an antihistamine (eg, diphenhydramine [Benadryl]). The most severe reaction—anaphylaxis—is treated with subQ epinephrine.
- For some patients with mild hemophilia A, bleeding can be stopped with desmopressin, a drug that promotes release of stored factor VIII. Desmopressin does not release factor IX, and hence cannot treat hemophilia B.

- Two drugs—aminocaproic acid and tranexamic acid—can suppress fibrinolysis (by blocking production of plasmin) and can thereby promote hemostasis in hemophilia A and hemophilia B. These antifibrinolytic agents are more effective for preventing recurrent bleeding than for stopping an ongoing bleed.
- Development of inhibitors (antibodies that neutralize factor VIII or factor IX) is a serious complication of hemophilia therapy.
- Activated factor VII (factor VIIa) and AICC are preferred agents for controlling bleeding when inhibitors of factor VIII or factor IX are present.
- People with hemophilia should avoid aspirin and other traditional NSAIDs because these agents suppress platelet aggregation and promote GI ulceration and bleeding. Second-generation NSAIDs (COX-2 inhibitors) are *probably* safe.

631

632

54.2.5.2.2

Summary of Major Nursing Implications*

54.2.5.2.2.1

FACTOR VIII AND FACTOR IX CONCENTRATES

54.2.5.2.2....

Preadministration Assessment

54.2.5.2.2....

Therapeutic Goal

Factor VIII is indicated for replacement therapy in patients with hemophilia A, and factor IX is indicated for replacement therapy in patients with hemophilia B.

Both factors may be given prophylactically (to prevent bleeding and subsequent joint injury) or “on demand” (to stop ongoing bleeding or prevent excessive bleeding during anticipated surgery).

54.2.5.2.2....

Baseline Data

Obtain a baseline level for activity of factor VIII or factor IX.

54.2.5.2.2....

Identifying High-Risk Patients

Use with *caution* in patients with a history of allergic reactions to the factor concentrate.

54.2.5.2.2....

Implementation: Administration

54.2.5.2.2....

Route

Intravenous.

54.2.5.2.2....

Administration

Administer by slow IV push or continuous infusion.

Record the following each time you give a factor concentrate:

- Time and date
- Infusion site and rate
- Total dose
- Manufacturer, trade name, lot number, and expiration date of the factor concentrate

Teach home caregivers about

- **The importance of having an assistant, who can give aid or call for help if complications arise**
- **The importance and proper method of hand washing**
- **Making dosage calculations**
- **Reconstituting the powdered factor concentrate**
- **Infusion technique**
- **Cleanup and waste disposal**
- **Recording the time, date, and other information listed above**

54.2.5.2.2....

Ongoing Evaluation and Interventions

54.2.5.2.2....

Evaluating Therapeutic Effects

Success is indicated by preventing bleeding (during prophylactic therapy) or controlling bleeding (during ondemand therapy). With both forms of therapy, monitoring activity levels of factor VIII or factor IX can help guide treatment.

54.2.5.2.2....

Minimizing Adverse Effects

54.2.5.2.2....

Allergic Reactions.

Clotting factor concentrates can cause allergic reactions, ranging from mild to severe. **Inform patients about symptoms of mild reactions (eg, hives, rash, urticaria, stuffy nose, fever), and advise them to take an antihistamine (eg, diphenhydramine) if these occur. Inform patients about symptoms of anaphylaxis (wheezing, tightness in the throat, shortness of breath, swelling in the face), and instruct them to seek immediate emergency care if these develop.** The treatment of choice is epinephrine, injected subQ.

54.2.5.2.2....

Minimizing Adverse Interactions

54.2.5.2.2....

Aspirin.

Warn patients not to use aspirin, a drug that inhibits platelet aggregation and can cause GI ulceration and bleeding.

54.2.5.2.2....

NSAIDs Other Than Aspirin.

Advise patients that first-generation NSAIDs (eg, ibuprofen, naproxen) have actions similar to those of aspirin, and hence should be avoided.

Advise patients that second-generation NSAIDs (eg, celecoxib), which do not inhibit platelets and cause minimal GI effects, are *probably* safe.

* Patient education information is highlighted as **blue text**.

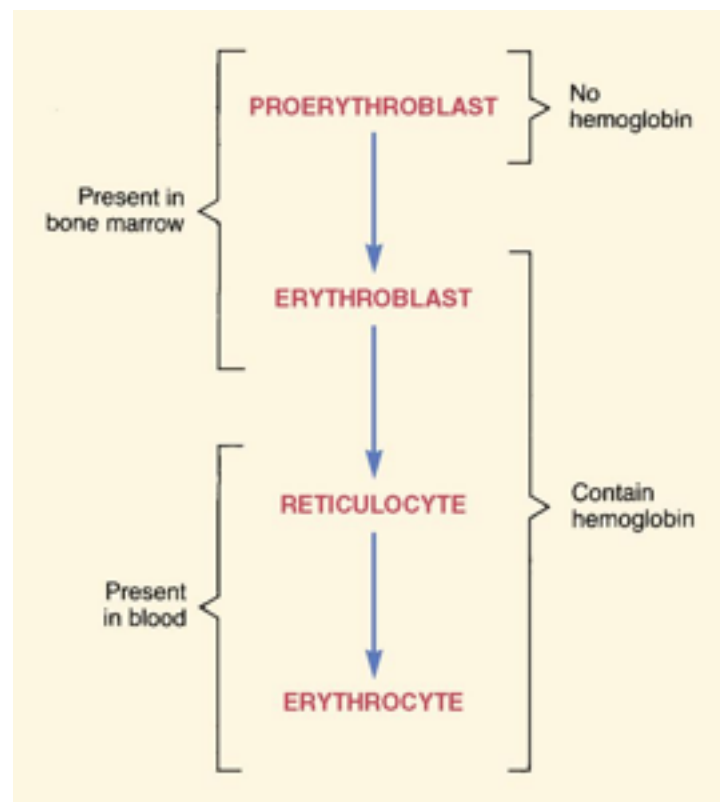

⁵⁵CHAPTER 54 Drugs for Deficiency Anemias

Anemia is defined as a decrease in the number, size, or hemoglobin content of erythrocytes (red blood cells [RBCs]). Causes include blood loss, hemolysis, bone marrow dysfunction, and deficiencies of substances essential for RBC formation and maturation. Most deficiency anemias result from deficiency of iron, vitamin B₁₂, or folic acid. Accordingly, this chapter focuses on anemias caused by these three deficiencies. To facilitate discussion, we begin by reviewing RBC development.

^{55.1} RED BLOOD CELL DEVELOPMENT

RBCs begin developing in the bone marrow and then mature in the blood. As developing RBCs grow and divide, they evolve through four stages ([Fig. 54-1](#)). In their earliest stage, RBCs lack hemoglobin and are known as *proerythroblasts*. In the next stage, they gain hemoglobin and are called *erythroblasts*. Both the erythroblasts and the proerythroblasts reside in bone marrow. After the erythroblast stage, RBCs evolve into *reticulocytes* (immature erythrocytes) and enter the systemic circulation. Following the reticulocyte stage, circulating RBCs reach full maturity and are referred to as *erythrocytes*.

Figure 54-1 Stages of red blood cell development.

Development of RBCs requires the cooperative interaction of several factors: the bone marrow must be healthy; erythropoietin (a stimulant of RBC maturation) must be present; iron must be available for hemoglobin synthesis; and other factors, including vitamin B₁₂ and folic acid, must be available to support synthesis of DNA. If any of these is absent or amiss, anemia will result.

55.2 IRON DEFICIENCY

Iron deficiency is the most common nutritional deficiency, and the most common cause of nutrition-related anemia. Worldwide, people with iron deficiency number in the hundreds of millions. In the United States, about 5% of the population is iron deficient.

55.2.1 Biochemistry and Physiology of Iron

In order to understand the consequences of iron deficiency as well as the rationale behind iron therapy, we must first understand the biochemistry and physiology of iron. This information is reviewed below.

633

55.2.1.1 Metabolic Functions

634

Iron is essential to the function of hemoglobin, myoglobin (the oxygen-storing molecule of muscle), and a variety of iron-containing enzymes. Most (70% to 80%) of the body's iron is present in hemoglobin. A much smaller amount (10%) is present in myoglobin and iron-containing enzymes.

55.2.1.2 Fate in the Body

The major pathways for iron movement and utilization are shown in [Figure 54-2](#). In the discussion below, the numbers in parentheses refer to the circled numbers in the figure.

55.2.1.2.1 Uptake and Distribution.

The life cycle of iron begins with (1) uptake of iron into mucosal cells of the small intestine. These cells absorb between 5% and 20% of dietary iron. Their maximum absorptive capacity is 3 to 4 mg/day. Iron in the ferrous form (Fe⁺⁺) is absorbed more readily than iron in the ferric form (Fe⁺⁺⁺). Food greatly reduces absorption.

Following uptake, iron can either (2a) undergo storage within mucosal cells in the form of *ferritin* (a complex consisting of iron plus a protein used to store iron) or (2b) undergo binding to *transferrin* (the iron transport protein) for distribution throughout the body.

55.2.1.2.2 Utilization and Storage.

Iron that is bound to transferrin can undergo one of three fates. The majority of transferrin-bound iron (3a) is taken up by cells of the bone marrow for incorporation into hemoglobin. Small amounts (3b) are taken up by the liver and other tissues for storage as ferritin. Lastly (3c), some of the iron in plasma is taken up by muscle (for production of myoglobin) and some is taken up by all tissues (for production of iron-containing enzymes).

55.2.1.2.3 Recycling.

As [Figure 54-2](#) depicts, iron associated with hemoglobin undergoes continuous recycling. After hemoglobin is made in bone marrow, iron re-enters the circulation (4) as a component of hemoglobin in erythrocytes. (The iron in circulating erythrocytes accounts for about 70% of total body iron.) After 120 days of useful life, RBCs are catabolized (5). Iron released by this process re-enters the plasma bound to transferrin (6), and then the cycle begins anew.

Figure 54-2 Fate of iron in the body. Pathways labeled with circled numbers are explained in the text. Values in parentheses indicate percentage of total body stores. Elimination of iron is not shown, because most iron is rigidly conserved. (Fe = iron, RBC = red blood cell.)

55.2.1.2.4 Elimination.

Excretion of iron is minimal. Under normal circumstances, only 1 mg of iron is excreted each day. At this rate, if none of the lost iron were replaced, body stores would decline by only 10% a year.

Iron leaves the body by several routes. Most excretion occurs via the bowel. Iron in ferritin is lost as mucosal cells slough off, and iron also enters the bowel in bile. Small amounts are excreted in urine and sweat.

It should be noted that, although very little iron leaves the body as a result of excretion (ie, normal physiologic loss), substantial amounts can leave because of blood loss. Hence, menorrhagia (excessive menstrual flow), hemorrhage, and blood donations can all cause iron deficiency.

55.2.1.2.5 Regulation of Body Iron Content.

The amount of iron in the body is regulated through control of intestinal absorption. As noted, most of the iron that enters the body stays in the body. Hence, if all dietary iron were readily absorbed, body iron content would rapidly accumulate to toxic levels. However, *excessive buildup is prevented through control of iron uptake: As body stores rise, uptake of iron declines; conversely, as body stores become depleted, uptake increases.* For example, when body stores of iron are high, only 2% to 3% of dietary iron is absorbed. In contrast, when body stores are depleted, as much as 20% may be absorbed.

55.2.1.3 Daily Requirements

Requirements for iron are determined largely by the rate of erythrocyte production. When RBC production is low, iron needs are low too. Conversely, when RBC production is high, iron needs rise. Accordingly, among infants and children—individuals whose rapid growth rate requires massive RBC synthesis—iron requirements are high (relative to body weight). In contrast, the daily iron needs of adults are relatively low. Adult males need only 10 mg of dietary iron each day. Adult females need somewhat more, so as to replace iron lost through menstruation.

During pregnancy, requirements for iron increase dramatically, owing to (1) expansion of maternal blood volume and (2) production of RBCs by the fetus. In most cases, the iron needs of pregnant women are too great to be met by diet alone. Consequently, iron supplements (about 30 mg/day) are recommended during pregnancy and for 2 to 3 months after parturition.

[Table 54-1](#) summarizes the recommended dietary allowances (RDAs) of iron as a function of age. For each age, the table presents two iron values. The first is the actual physiologic need for iron; the second is the RDA. Note that RDA values are about 10 times greater than the values for physiologic need. Why? Because, on average, only 10% of dietary iron is absorbed. Hence, if physiologic requirements are to be met, the diet must contain 10 times more iron than we actually need.

55.2.1.4 Dietary Sources

Iron is available in foods of plant and animal origin. Foods especially rich in iron include liver, egg yolk, brewer's yeast, and wheat germ. Other foods with a high iron content include muscle meats, fish, fowl, cereal grains, beans, and green leafy vegetables. Foods that do not provide much iron include milk and most nongreen vegetables. Since iron can be extracted from cooking utensils, using iron pots and pans can augment dietary iron. Except for individuals who have very high iron requirements (infants, pregnant women, those undergoing chronic blood loss), the average diet is sufficient to meet iron needs.

55.2.2 Iron Deficiency: Causes, Consequences, and Diagnosis

55.2.2.1 Causes

Iron deficiency results when there is an imbalance between iron uptake and iron demand. As a rule, the imbalance results from increased demand—not from reduced uptake. The most common causes of increased iron demand (and resulting iron deficiency) are (1) blood volume expansion during pregnancy coupled with RBC synthesis by the growing fetus; (2) blood volume expansion during infancy and early childhood; and (3) chronic blood loss, usually of GI or uterine origin. Rarely, iron deficiency results from reduced iron uptake; potential causes include gastrectomy and sprue.

55.2.2.2 Consequences

Iron deficiency has multiple effects, the most conspicuous being *iron deficiency anemia*. In the absence of iron for hemoglobin synthesis, red blood cells become *microcytic* (small) and *hypochromic* (pale). The reduced oxygen-carrying capacity of blood results in listlessness, fatigue, and pallor of the skin and mucous membranes. If tissue oxygenation is severely compromised, tachycardia, dyspnea, and angina may result. In addition to causing anemia, iron deficiency impairs myoglobin production and synthesis of iron-containing enzymes. In young children, iron deficiency can cause developmental problems, and in school-age children, iron deficiency may impair cognition.

635

636

TABLE 54-1 Recommended Dietary Allowances (RDAs) for Iron

	Age (yr)	Physiologic Requirement for Iron (mg/day)	RDA* for Iron (mg/ day)
Infants	0–0.5	0.6	6
	0.5–1	1	10
Children	1–10	1	10
Males	11–18	1.2	12
	18†	1	10
Females	11–50	1.5	15
	50†	1	10
Pregnant and 2–3 mo postpartum	—	5	30†

* Because only a small fraction of dietary iron is absorbed, the RDA is higher than the actual physiologic need.

† Iron requirements during pregnancy cannot be met through dietary sources alone; supplements are recommended.

55.2.2.3 Diagnosis

The hallmarks of iron deficiency anemia are (1) the presence of microcytic, hypochromic erythrocytes, and (2) the absence of hemosiderin (aggregated ferritin) in bone marrow. Additional laboratory data that can help confirm a diagnosis include reduced RBC count, reduced reticulocyte hemoglobin content, reduced hemoglobin and hematocrit values, reduced serum iron content, and increased serum iron-binding capacity (IBC).^{*}

When a diagnosis of iron deficiency anemia is made, it is imperative that the underlying cause be determined. This is especially true when the suspected cause is GI-related blood loss. Why? Because GI blood loss may be indicative of peptic ulcer disease or GI cancer, conditions that demand immediate treatment.

* Serum IBC measures iron binding by transferrin. An *increase* in IBC indicates an increase in the amount of transferrin that is *not* carrying any iron, and hence signals reduced iron availability.

55.2.3 Oral Iron Preparations I: Iron Salts

Three oral iron salts are available: ferrous sulfate, ferrous gluconate, and ferrous fumarate. All three are equally effective, and with all three, GI disturbances are the major adverse effect.

55.2.3.1 Ferrous Sulfate

Ferrous sulfate is the least expensive oral iron preparation and the standard against which the others are measured. Accordingly, ferrous sulfate will be our prototype for the group.

55.2.3.1.1 Indications.

Ferrous sulfate is the drug of choice for treating iron deficiency anemia. It is also the preferred drug for *preventing* deficiency when iron needs cannot be met by diet alone (eg, during pregnancy or chronic blood loss).

55.2.3.1.2 Adverse Effects.

55.2.3.1.2.1 GI Disturbances.

The most significant adverse effects involve the GI tract. These effects, which are dose dependent, include nausea, pyrosis (heartburn), bloating, constipation, and diarrhea. Gastrointestinal reactions are most intense during initial therapy, and become less disturbing with continued drug use. Because of their GI effects, oral iron preparations can aggravate peptic ulcers, regional enteritis, and ulcerative colitis. Accordingly, patients with these disorders should not take iron by mouth. In addition to its other GI effects, oral iron may impart a dark green or black color to stools. This effect is harmless and should not be interpreted as a sign of bleeding.

55.2.3.1.2.2 Staining of Teeth

Liquid iron preparations can stain the teeth. This can be prevented by (1) diluting liquid preparations with juice or water, (2) administering the iron through a straw or with a dropper, and (3) rinsing the mouth after administration.

55.2.3.1.3 Toxicity.

Iron in large amounts is toxic. Poisoning is almost always the result of accidental or intentional overdose, not from therapeutic doses. Death from iron ingestion is rare in adults. By contrast, in young children, iron-containing products are a leading cause of poisoning

fatalities. For children, the lethal dose of elemental iron is 2 to 10 gm. To reduce the risk of pediatric poisoning, iron should be stored in childproof containers and kept out of reach.

55.2.3.1.3.1 Symptoms.

The effects of iron poisoning are complex. Early reactions include nausea, vomiting, diarrhea, and shock. These are followed by acidosis, gastric necrosis, hepatic failure, pulmonary edema, and vasomotor collapse.

55.2.3.1.3.2 Diagnosis and Treatment.

With rapid diagnosis and treatment, mortality from iron poisoning is low (about 1%). Serum iron should be measured and the intestine x-rayed to determine if unabsorbed tablets are present. Gastric lavage will remove iron from the stomach. Acidosis and shock should be treated as required.

If the plasma level of iron is high (above 350 to 500 mcg/dL), it should be lowered with parenteral *deferoxamine* [Desferal]. A new oral drug—*deferasirox* [Exjade]—is indicated for patients with chronic iron overload caused by blood transfusions. Both agents—deferoxamine and deferasirox—adsorb iron and thereby prevent toxic effects. The pharmacology of these drugs is discussed in [Chapter 108](#) (Management of Poisoning).

55.2.3.1.4 Drug Interactions.

Interaction of iron with other drugs can alter the absorption of iron, the other drug, or both. *Antacids* reduce the absorption of iron. Coadministration of iron with tetracyclines decreases absorption of both. *Ascorbic acid* (vitamin C) promotes iron absorption but also increases its adverse effects. Accordingly, attempts to enhance iron uptake by combining iron with ascorbic acid offer no advantage over a simple increase in iron dosage.

55.2.3.1.5 Formulations.

Ferrous sulfate is available in several formulations. Sustained-release products (eg, Slow FE) are designed to reduce gastric disturbances. Unfortunately, although side effects may be lowered, these formulations have disadvantages. First, iron may be released at variable rates, causing variable and unpredictable absorption. Second, these preparations are expensive. Ordinary tablets do not share these drawbacks.

55.2.3.1.6 Dosage and Administration.

55.2.3.1.6.1 General Considerations.

Dosing with oral iron can be complicated in that oral iron salts differ from one another with regard to percentage of elemental iron (Table 54-2). Ferrous *sulfate*, for example, contains 20% iron by weight. In contrast, ferrous **gluconate** contains only 11.6% iron by weight. Consequently, in order to provide equivalent amounts of elemental iron, we must use different doses of these iron preparations. For example, if we want to provide 100 mg of elemental iron using ferrous *sulfate*, we need to administer a 500-mg dose. To provide this same amount of elemental iron using ferrous *fumarate*, the dose would be only 300 mg. In the discussion below, dosage values refer to milligrams of *elemental iron*, and not to milligrams of any particular iron preparation needed to provide that amount of elemental iron.

Food affects therapy in two ways. First, food helps protect against iron-induced GI distress. Second, food decreases iron absorption by 50% to 70%. Hence, we have a dilemma: *Absorption is best* when iron is taken *between meals*, but *side effects are lowest* when iron is taken *with meals*. As a rule, iron should be administered between meals, thereby maximizing absorption. If necessary, the dosage can be lowered to render GI effects more acceptable.

For two reasons, it may be desirable to take iron *with* food during *initial* therapy. First, since the GI effects of iron are most intense when treatment commences, the salving effects of food can be especially beneficial. Second, by reducing GI discomfort during the early phase of therapy, administration with food can help promote adherence.

TABLE 54-2 Oral Iron Preparations

Iron Preparation	% Iron (by weight)	Dose Providing 100 mg Iron
Iron Salts		
Ferrous sulfate	20	500 mg
Ferrous sulfate (dried)	~30	330 mg
Ferrous fumarate	33	300 mg
Ferrous gluconate	11.6	860 mg
Elemental Iron		
Carbonyl iron	100	100 mg

55.2.3.1.6.2 Use in Iron Deficiency Anemia

Dosing with oral iron represents a compromise between a desire to replenish lost iron rapidly and a desire to keep GI effects to a minimum. For most adults, this compromise can best be achieved by giving 65 mg 3 times a day, yielding a total daily dose of about 200 mg. Since there is a ceiling to intestinal absorption of iron, doses above this amount provide only a modest increase in therapeutic effect. On the other hand, at dosages greater than 200 mg/day, GI disturbances become disproportionately high. Hence, elevation of the daily dosage above 200 mg would augment adverse effects without offering a significant increase in benefits. When treating iron deficiency in infants and children, a typical dosage is 5 mg/kg/day administered in three or four divided doses.

Timing of administration is important: Doses should be spaced evenly throughout the day. This schedule provides the bone marrow with a continuous iron supply, thereby maximizing RBC production.

Duration of therapy is determined by the therapeutic objective. If correction of anemia is the sole objective, a few months of therapy is sufficient. However, if the objective also includes replenishing ferritin, treatment must continue 4 to 6 months longer. It should be noted, however, that drugs are usually unnecessary for ferritin replenishment; in most cases, diet alone can do the job. Accordingly, once anemia has been corrected, pharmaceutical iron can usually be discontinued.

55.2.3.1.6.3 Prophylactic Use

Pregnant women are the principal candidates for prophylactic therapy. A total daily dose of 30 mg, taken between meals, is recommended. Other candidates include infants, children, and women experiencing menorrhagia.

55.2.3.2 Ferrous Gluconate and Ferrous Fumarate

In addition to ferrous sulfate, two other oral iron salts are available: ferrous gluconate [Fergon] and ferrous fumarate [Ferro-Sequels, others]. Except for differences in percentage of iron content (see [Table 54-2](#)), all of these preparations are equivalent. Hence, when dosage is adjusted to provide equal amounts of elemental iron, ferrous gluconate and ferrous fumarate produce pharmacologic effects identical to those of ferrous sulfate. All three agents produce equivalent therapeutic responses, and all three cause the same degree of GI distress. Patients who fail to respond to one will not respond to the others. Patients who cannot tolerate the GI effects of one agent will find the others intolerable too.

55.2.4 Oral Iron Preparations II: Carbonyl Iron

Carbonyl iron is pure, elemental iron in the form of microparticles. Because of these microparticles, the iron has good bioavailability. Therapeutic efficacy of carbonyl iron equals that of the iron salts. Carbonyl iron is reputed to be less toxic than the iron salts, and hence should pose less risk to children in the event of poisoning. Four formulations are available: (1) 45-mg tablets, marketed as *Feosol*; (2) 65-mg tablets, marketed as *Ircon*; (3) 15-mg chewable tablets, marketed as *Icar*; and (4) a suspension (15 mg/1.25 mL), also marketed as *Icar*. Because these products contain 100% iron, rather than an iron salt, there should be no confusion about dosage: 100 mg of either product provides 100 mg of elemental iron. The usual dosage is 50 mg 3 times a day.

55.2.5 Parenteral Iron I: Iron Dextran

Iron dextran [INFeD, DexFerrum] is the most frequently used parenteral iron preparation. The drug is a complex consisting of ferric hydroxide and dextrans (polymers of glucose). The rate of response to parenteral iron is equal to that of oral iron. Iron dextran is dangerous—fatal anaphylactic reactions have occurred—and hence should be used only when circumstances demand.

55.2.5.1 Indications

Iron dextran is reserved for patients with a clear diagnosis of iron deficiency and for whom oral iron is either ineffective or intolerable. Primary candidates for parenteral iron are patients who, because of intestinal disease, are unable to absorb iron taken orally. Iron dextran is also indicated when blood loss is so great (500 to 1000 mL/wk) that oral iron cannot be absorbed fast enough to meet hematopoietic needs. Parenteral iron may also be employed when there is concern that oral iron might exacerbate pre-existing disease of the stomach or bowel. Lastly, parenteral iron can be given to the rare patient for whom the GI effects of oral iron are intolerable.

55.2.5.2 Adverse Effects

55.2.5.2.1 Anaphylactic Reactions.

Potentially fatal anaphylaxis is the most serious adverse effect. These reactions are triggered by dextran in the product, not by the iron. Although anaphylactic reactions are rare, their possibility demands that iron dextran be used only when clearly required. Whenever iron

dextran is administered, injectable epinephrine and facilities for resuscitation should be at hand. Furthermore, each full dose should be preceded by a small test dose.

55.2.5.2.2 Other Adverse Effects.

Hypotension is common in patients receiving parenteral iron. In addition, iron dextran can cause headache, fever, urticaria, and arthralgia. More serious reactions—circulatory failure and cardiac arrest—may also occur. When administered IM, iron dextran can cause persistent pain and prolonged, localized discoloration. Very rarely, tumors develop at sites of IM injection. Intravenous administration may result in lymphadenopathy and phlebitis.

55.2.5.3 Preparations, Dosage, and Administration

55.2.5.3.1 Preparations.

Iron dextran [INFeD, DexFerrum] is available in single-dose vials (1 and 2 mL) that contain 50 mg/mL of elemental iron.

55.2.5.3.2 Dosage.

Dosage determination is complex. Dosage depends on the degree of anemia, the weight of the patient, and the presence of persistent bleeding. For patients with iron deficiency anemia who are not losing blood, the equation in [Figure 54-3](#) provides a guideline for estimating total iron dosage.

55.2.5.3.3 Administration.

Iron dextran may be administered IM or IV. Intravenous administration is preferred. This route is just as effective as IM administration but causes fewer anaphylactic reactions and other adverse effects.

55.2.5.3.3.1 Intravenous.

To minimize anaphylactic reactions, intravenous iron dextran should be administered by the following protocol: (1) administer a

637

638

Figure 54-3 Formula for estimating total dosage of parenteral iron dextran.

$$\text{mg iron} = 0.66 \times \text{kg body weight} \times \left(100 - \frac{\text{hemoglobin value in g/dL}}{14.8} \right)$$

small test dose (25 mg over 5 minutes) and observe the patient for at least 15 minutes; (2) if the test dose appears safe, slowly administer a larger dose (500 mg over a 10- to 15-minute interval); and (3) if the 500-mg dose is uneventful, additional doses may be given as needed.

55.2.5.3.3.2 Intramuscular.

Intramuscular iron dextran has significant drawbacks and should be avoided. Disadvantages include persistent pain and discoloration at the injection site, possible development of tumors, and a greater risk of anaphylaxis. When IM administration must be performed, iron dextran should be injected deep into each buttock using the Z-track technique. (Z-track injection keeps the iron dextran deep in the muscle, thereby minimizing leakage and surface discoloration.) As with IV iron dextran, a small test dose should precede the full therapeutic dose.

55.2.6 Parenteral Iron II: Sodium–Ferric Gluconate Complex and Iron Sucrose

Iron sucrose and sodium–ferric gluconate complex (SFGC) represent alternatives to iron dextran for parenteral iron therapy. With both drugs, the risk of anaphylaxis is very low, and hence there is much less need for giving test doses. As a result, both drugs are more convenient than iron dextran. Indications for these drugs are limited to treatment of iron deficiency anemia in patients with chronic kidney disease (CKD).

55.2.6.1 Sodium–Ferric Gluconate Complex

SFGC, sold under the trade name *Ferrlecit*, is a parenteral iron product indicated for iron deficiency anemia in patients with CKD who are undergoing chronic hemodialysis. The drug is always used in conjunction with erythropoietin, an agent that stimulates RBC production (see [Chapter 55](#)). SFGC can cause transient flushing and hypotension, associated with lightheadedness, malaise, fatigue, weakness, and severe pain in the chest, back, flanks, or groin. This reaction can be minimized by infusing the drug slowly. In contrast to iron dextran, SFGC poses little risk of anaphylaxis. Accordingly, *repeated* test doses are unnecessary—although a test dose *is* required the first time the drug is used. SFGC is supplied in 5-mL ampules that contain 62.5 mg of elemental iron. Dilution is not required (but may be done) before the infusion. For most patients, a single dose consists of 125 mg (contents of 2 ampules) infused slowly (over 10 minutes or more). The typical patient requires a cumulative dose of 1 gm (eight 125-mg infusions on separate days). A small test dose (25 mg infused over 60 minutes) should precede the first full dose. Every time the drug is administered, facilities for cardiopulmonary resuscitation should be immediately available.

55.2.6.2 Iron Sucrose

Like SFGC, iron sucrose [Venofer] is a parenteral form of iron indicated for iron deficiency anemia in patients with CKD. However, in contrast to SFGC, whose indications are limited to CKD patients undergoing hemodialysis in conjunction with erythropoietin therapy, iron sucrose is indicated for a broader range of CKD patients, specifically

- Non–dialysis-dependent (NDD) patients receiving erythropoietin
- NDD patients *not* receiving erythropoietin
- Hemodialysis-dependent (HDD) patients receiving erythropoietin
- Peritoneal dialysis–dependent (PDD) patients receiving erythropoietin

The most common adverse effects of iron sucrose are hypotension (36%) and cramps (23%). The drug has also been associated with heart failure, sepsis, and taste perversion. Life-threatening hypersensitivity reactions are very rare: No cases were observed during clinical trials, and only 27 cases (out of 450,000 patients) were reported during postmarketing surveillance. Nonetheless, facilities for cardiopulmonary resuscitation should be available during administration. However, in contrast to iron dextran, test doses are not needed.

Iron sucrose is supplied in 5-mL single-dose vials that contain 100 mg of elemental iron. Administration is IV, either by (1) slow injection (1 mL/min) or (2) infusion (dilute iron sucrose in up to 100 mL of 0.9% saline and infuse over 15 minutes or longer). Iron sucrose should not be mixed with other drugs or with peripheral nutrition solutions. All patients should receive a *total* dose of 1000 mg, but the dosing schedule and administration technique depend on the patient as follows:

- HDD patients—Give ten 100-mg doses during each of 10 consecutive dialysis sessions. Administer by slow IV injection or IV infusion.
- NDD patients—Give five 200-mg doses on separate occasions over a 14-day span. Administer by slow IV injection.
- PDD patients—Give two 300-mg doses 14 days apart, then one 400-mg dose 14 days later. Administer by slow IV infusion.

55.2.7 Guidelines for Treating Iron Deficiency

55.2.7.1 Assessment.

Prior to starting therapy, the cause of iron deficiency must be determined. Without this information, appropriate treatment is not possible. Potential causes of deficiency include pregnancy, bleeding, inadequate diet, and, rarely, reduced intestinal absorption.

The objective is to increase production of hemoglobin and erythrocytes. When therapy is successful, reticulocytes will increase within 4 to 7 days; within 1 week, increases in hemoglobin and the hematocrit will be apparent; and within 1 month, hemoglobin levels will rise by at least 2 gm/dL. If these responses fail to occur, the patient should be evaluated for (1) compliance, (2) continued bleeding, (3) inflammatory disease (which can interfere with hemoglobin production), and (4) malabsorption of oral iron.

55.2.7.2 Routes of Administration.

Iron preparations are available for oral, IV, and IM administration. Oral iron is preferred. Why? Because oral iron is safer than parenteral iron and just as effective. Parenteral iron should be used only when oral iron is ineffective or intolerable. Of the two parenteral routes, IV is safer and preferred.

55.2.7.3 Duration of Therapy.

Therapy with oral iron should be continued until hemoglobin levels become normal (about 15 gm/dL). This phase of treatment may require 1 to 2 months. After this, continued treatment can help replenish stores of ferritin. However, for most patients, dietary iron alone is sufficient.

55.2.7.4 Therapeutic Combinations.

As a rule, combinations of antianemic agents should be avoided. Combining oral iron with parenteral iron can lead to iron toxicity. Accordingly, use of oral iron should cease prior to giving iron injections. Combinations of iron with vitamin B₁₂ or folic acid should be avoided; as discussed in the following sections, these combinations can confuse interpretation of hematologic responses.

^{55.3} VITAMIN B₁₂ DEFICIENCY

The term *vitamin B₁₂* refers to a group of compounds that have similar structures. These compounds are large molecules that contain an atom of cobalt. Because of the cobalt atom, members of the vitamin B₁₂ family are known as *cobalamins*.

The most prominent consequences of vitamin B₁₂ deficiency are *anemia* and *injury to the nervous system*. Anemia reverses rapidly following vitamin B₁₂ administration. Neurologic damage takes longer to repair and, in some cases, may

638

639

Figure 54-4 Relationship of folic acid and vitamin B₁₂ to DNA synthesis and cell maturation. Folic acid requires activation to be of use. Normally, activation occurs via a vitamin B₁₂–dependent pathway. However, when folic acid is present in large amounts, activation can occur via an alternate pathway, thereby bypassing the need for B₁₂.

never fully resolve. Additional effects of B₁₂ deficiency include GI disturbances and impaired production of white blood cells and platelets.

55.3.1 Biochemistry and Physiology of Vitamin B₁₂

In order to understand the consequences of vitamin B₁₂ deficiency and the rationale behind therapy, we must first understand the normal biochemistry and physiology of B₁₂. This information is reviewed below.

55.3.1.1 Metabolic Function

Vitamin B₁₂ is essential for synthesis of DNA, and hence is required for the growth and division of virtually all cells. The mechanism by which the vitamin influences DNA synthesis is depicted in [Figure 54-4](#). As indicated, vitamin B₁₂ helps catalyze the conversion of folic acid to its active form. Active folic acid then participates in several reactions essential for DNA synthesis. Hence, *it is by permitting utilization of folic acid that vitamin B₁₂ influences cell growth and division*—and it is the absence of usable folic acid that underlies the blood cell abnormalities seen during B₁₂ deficiency.

55.3.1.2 Fate in the Body

55.3.1.2.1 Absorption.

Efficient absorption of B₁₂ requires *intrinsic factor*, a compound secreted by parietal cells of the stomach. Following ingestion, vitamin B₁₂ forms a complex with intrinsic factor. Upon reaching the ileum, the B₁₂–intrinsic factor complex interacts with specific receptors on the intestinal wall, causing the complex to be absorbed. In the absence of intrinsic factor, absorption of vitamin B₁₂ is greatly reduced. However, about 1% of the amount present can still be absorbed by passive diffusion; no intrinsic factor is required.

55.3.1.2.2 Distribution and Storage.

Following absorption, the vitamin B₁₂–intrinsic factor complex dissociates. Free B₁₂ then binds to *transcobalamin II* for transport to tissues. Most vitamin B₁₂ goes to the liver and is stored. Total body stores of B₁₂ are minute, ranging from 2 to 3 mg by most estimates.

55.3.1.2.3 Elimination.

Excretion of vitamin B₁₂ takes place very slowly: Daily losses are about 0.1% of total body stores. Because B₁₂ is excreted so slowly, years are required for B₁₂ deficiency to develop—even with no replenishment of lost B₁₂ taking place.

55.3.1.3 Daily Requirements

Because very little vitamin B₁₂ is excreted, and because body stores are small to begin with, daily requirements for this vitamin are minuscule. The average adult needs about 2.4 mcg of B₁₂ per day. Children need even less.

55.3.1.4 Dietary Sources

The ability to biosynthesize vitamin B₁₂ is limited to microorganisms; higher plants and animals can't make it. The microorganisms that make B₁₂ reside in the soil, sewage, and the intestines of humans and other animals. Unfortunately, vitamin B₁₂ produced in the human GI tract is unavailable for absorption. Consequently, humans must obtain the majority of their B₁₂ by consuming animal products. Liver and dairy products are especially good sources. Between 10% and 30% of adults over age 50 are unable to absorb vitamin B₁₂ found naturally in foods. Accordingly, these people should meet their requirements by consuming B₁₂-fortified foods or a B₁₂-containing vitamin supplement.

55.3.2 Vitamin B₁₂ Deficiency: Causes, Consequences, and Diagnosis

55.3.2.1 Causes

In the majority of cases, vitamin B₁₂ deficiency is the result of *impaired absorption*. Insufficient B₁₂ in the diet is rarely a cause of deficiency. Potential causes of poor absorption include (1) regional enteritis, (2) celiac disease (a malabsorption syndrome involving abnormalities in the intestinal villi), and (3) development of antibodies directed against the vitamin B₁₂–intrinsic factor complex. In addition, because stomach acid is required to release vitamin B₁₂ from foods, it cannot be absorbed if acid secretion is significantly reduced, as often happens in the elderly and in those taking acid-suppressing drugs.

Most frequently, impaired absorption of vitamin B₁₂ occurs secondary to a lack of intrinsic factor. The usual causes are atrophy of gastric parietal cells and surgery of the stomach (total gastric resection).

When vitamin B₁₂ deficiency is caused by an absence of intrinsic factor, the resulting syndrome is called *pernicious anemia*—a term suggesting a highly destructive or fatal condition. 639
640

Pernicious anemia is an old term that refers back to the days when, for most patients, vitamin B₁₂ deficiency had no effective therapy. Hence, the condition was uniformly fatal. Today,

vitamin B₁₂ deficiency secondary to lack of intrinsic factor can be managed successfully. Hence, the label *pernicious* no longer bears its original ominous connotation.

55.3.2.2 Consequences

Many of the consequences of B₁₂ deficiency result from disruption of DNA synthesis. The tissues affected most are those with a high proportion of cells undergoing growth and division. Accordingly, B₁₂ deficiency has profound effects on the bone marrow (the site where blood cells are produced) and the epithelial cells lining the mouth and GI tract.

55.3.2.2.1 Megaloblastic Anemia.

The most conspicuous consequence of B₁₂ deficiency is an anemia in which large numbers of *megaloblasts* (oversized erythroblasts) appear in the bone marrow, and in which *macrocytes* (oversized erythrocytes) appear in the blood. These strange cells are produced because of impaired DNA synthesis: lacking sufficient DNA, growing cells are unable to divide; hence, as erythroblasts mature and their division is prevented, oversized cells result. Most megaloblasts die within the bone marrow; only a few evolve into the macrocytes that can be seen in the blood. Because of these unusual cells, the anemia associated with vitamin B₁₂ deficiency is often referred to as either *megaloblastic* or *macrocytic* anemia.

Severe anemia is the principal cause of mortality from B₁₂ deficiency. Anemia produces peripheral and cerebral hypoxia. Heart failure and dysrhythmias are the most frequent cause of death.

It is important to note that the hematologic effects of vitamin B₁₂ deficiency can be reversed with large doses of *folic acid*. As indicated in [Figure 54-4](#), when folic acid is present in large amounts, some of it can be activated by an alternate pathway that is independent of vitamin B₁₂. This pathway bypasses the metabolic block caused by B₁₂ deficiency, thereby permitting DNA synthesis to proceed.

55.3.2.2.2 Neurologic Damage.

Deficiency of vitamin B₁₂ causes demyelination of neurons, primarily in the spinal cord and brain. A variety of signs and symptoms can result. Early manifestations include paresthesias (tingling, numbness) of the hands and feet and a reduction in deep tendon reflexes. Late-developing responses include loss of memory, mood changes, hallucinations, and psychosis. If vitamin B₁₂ deficiency is prolonged, neurologic damage can become permanent.

The precise mechanism by which B₁₂ deficiency results in neuronal damage is unknown. We do know, however, that *neuronal damage is not related to effects on folic acid or DNA*. That is, the mechanism that underlies neuronal damage is different from the mechanism that underlies disruption of hematopoiesis. Consequently, although administering large doses of folic acid can correct the hematologic consequences of B₁₂ deficiency, folic acid will not affect the neurologic picture.

55.3.2.2.3 Other Effects.

As noted, vitamin B₁₂ deficiency can adversely affect virtually all tissues in which a high proportion of cells are undergoing growth and division. Hence, in addition to disrupting the production of erythrocytes, lack of B₁₂ also prevents the bone marrow from making leukocytes (white blood cells) and thrombocytes (platelets). Loss of these blood elements can lead to infection and spontaneous bleeding. Disruption of DNA synthesis can also suppress division of the cells that form the epithelial lining of the mouth, stomach, and intestine, thereby causing oral ulceration and a variety of GI disturbances.

55.3.2.3 Diagnosis

When megaloblastic anemia occurs, it may be due to vitamin B₁₂ deficiency or other causes, especially a lack of folic acid. Hence, if therapy is to be appropriate, a definitive diagnosis must be made. Two tests are particularly helpful. The first is obvious: measurement of plasma B₁₂ content. The second procedure, known as the Schilling test, measures vitamin B₁₂ absorption. The combination of megaloblastic anemia plus low plasma vitamin B₁₂ plus evidence of B₁₂ malabsorption permits a clear diagnosis of vitamin B₁₂ deficiency.

55.3.3 Vitamin B₁₂ Preparations: Cyanocobalamin

Cyanocobalamin is a purified, crystalline form of vitamin B₁₂. This compound is the drug of choice for all forms of B₁₂ deficiency.

55.3.3.1 Adverse Effects

Cyanocobalamin is generally devoid of serious adverse effects. One potential response, *hypokalemia*, may occur as a natural consequence of increased erythrocyte production. Erythrocytes incorporate significant amounts of potassium. Hence, as large numbers of new erythrocytes are produced, levels of free potassium may fall.

55.3.3.2 Preparations, Dosage, and Administration

Cyanocobalamin can be given orally, intranasally, and by IM or subQ injection. Most pharmacology texts, including prior editions of this one, will tell you that oral therapy is appropriate only for people who absorb B₁₂ well; all others (ie, those with impaired absorption) should use intranasal or parenteral therapy. However, this statement is not correct. Although it is true that various conditions—including lack of intrinsic factor, low gastric acidity, and regional enteritis—severely impair B₁₂ absorption, these conditions do not prevent absorption entirely. Hence, even people with impaired absorption can still be treated orally; the only catch is that doses must be very high. Is there any advantage to oral therapy compared with parenteral therapy? Yes. First, oral therapy is more comfortable (injections sometimes hurt). Second, oral therapy is more convenient (because it avoids regular trips to the physician for shots).

55.3.3.2.1 Oral.

Oral cyanocobalamin is appropriate for most people with mild to moderate B₁₂ deficiency, regardless of the cause. (The principal exception is patients with severe neurologic involvement.) If the B₁₂ deficiency is due to malabsorption, dosages must be high—ranging between 1000 and 10,000 mcg/day. To ensure that absorption has been adequate, B₁₂ levels should be measured periodically.

In addition to treating patients with B₁₂ deficiency, oral cyanocobalamin can be used as a dietary supplement. The usual dosage is 6 mcg/day.

Three oral formulations are available: standard tablets (100, 500, 1000, and 5000 mg), sold as *Big Shot B-12*; sublingual tablets (1000 mg); and lozenges (50, 100, 250, and 500 mg).

55.3.3.2.2 Parenteral.

Parenteral cyanocobalamin [Crystamine, Cyanoject, others] can be administered by *IM or deep subQ injection. Cyanocobalamin must NOT be given IV.* Intramuscular and subQ injections are generally well tolerated, although they occasionally cause pain and other local reactions.

Parenteral administration is indicated for patients with impaired B₁₂ absorption—although most of these people can be treated with oral cyanocobalamin instead. If the cause of malabsorption is irreversible (eg, parietal cell atrophy, total gastrectomy), therapy must continue lifelong. A typical dosing schedule for megaloblastic anemia is 30 mcg/day for 5 to

640

641

10 days followed by 100 to 200 mcg monthly until remission is complete. After anemia has been corrected, doses of 100 mcg are administered monthly for life.

55.3.3.2.3 Intranasal.

Intranasal cyanocobalamin [Nascobal, CaloMist] represents a convenient alternative to IM or subQ injection for people who cannot take cyanocobalamin by mouth. Efficacy of intranasal cyanocobalamin has not been determined for patients with nasal congestion, allergic rhinitis, or upper respiratory infections. Accordingly, until more is known, patients with these disorders should not use this formulation until symptoms subside. Hot foods or liquids can increase nasal secretions, which might flush cyanocobalamin gel from the nose. Accordingly, hot foods should not be eaten within 1 hour before or 1 hour after administering the drug.

Intranasal cyanocobalamin is available in two metered-dose formulations: Nascobal and CaloMist. Nascobal delivers 500 mg/actuation; CaloMist delivers only 25 mcg/actuation. The dosing schedule with Nascobal is 500 mcg in one nostril once a week. The dosing schedule with CaloMist is 25 mcg in each nostril once a day.

55.3.4 Guidelines for Treating Vitamin B₁₂ Deficiency

55.3.4.1 Route of B₁₂ Administration.

As discussed above, oral therapy can be used for most patients, including those with conditions that impair B₁₂ absorption. The major exception is patients with severe neurologic deficits caused by B₁₂ deficiency. For these people, parenteral cyanocobalamin is indicated.

55.3.4.2 Treatment of Moderate B₁₂ Deficiency.

The primary manifestations of moderate B₁₂ deficiency are megaloblasts in the bone marrow and macrocytes in peripheral blood. Moderate deficiency does not cause leukopenia, thrombocytopenia, or neurologic complications. Moderate deficiency can be managed with vitamin B₁₂ alone; no other measures are required.

55.3.4.3 Treatment of Severe B₁₂ Deficiency.

Severe deficiency produces multiple effects, all of which must be attended to. Unlike mild deficiency, in which erythrocytes are the only blood cells affected, severe deficiency disrupts production of all blood cells. Loss of erythrocytes leads to hypoxia, cerebrovascular insufficiency, and heart failure. Loss of leukocytes encourages infection, and loss of

thrombocytes promotes bleeding. In addition to causing serious hematologic deficits, severe B₁₂ deficiency has adverse effects on the nervous system and GI tract.

Treatment of severe deficiency involves the following: (1) IM injection of vitamin B₁₂ and folic acid (the folic acid accelerates recovery of hematologic deficits); (2) administration of 2 to 3 units of packed RBCs (to correct anemia quickly); (3) transfusion of platelets (to suppress bleeding); and (4) therapy with antibiotics if infection has developed.

Following treatment with vitamin B₁₂ plus folic acid, recovery from anemia occurs quickly. Within 1 to 2 days, megaloblasts disappear from the bone marrow; within 3 to 5 days, reticulocyte counts become elevated; by day 10, the hematocrit begins to rise; and within 14 to 21 days, the hematocrit becomes normal.

Recovery from neurologic damage is slow and depends on how long the damage had been present. When deficits have been present for only 2 to 3 months, recovery is relatively fast. When deficits have been present for many months or for years, recovery is slow: Months may pass before any improvement is apparent, and complete recovery may never occur.

55.3.4.4 Long-Term Treatment.

For patients who lack intrinsic factor or who suffer from some other permanent cause of vitamin B₁₂ malabsorption, lifelong treatment is required. Traditional therapy consists of monthly IM or subQ injections. However, *large* daily oral doses can be just as effective, as can intranasal doses (weekly with Nascobal or daily with CaloMist). During prolonged therapy, treatment should be periodically assessed: plasma levels of vitamin B₁₂ should be measured every 3 to 6 months, blood samples should be examined for the return of macrocytes, and blood counts should be performed.

55.3.4.5 Potential Hazard of Folic Acid.

Treatment with folic acid can exacerbate the neurologic consequences of B₁₂ deficiency. Recall that folic acid, by itself, can reverse the *hematologic* effects of B₁₂ deficiency—but will not alleviate *neurologic* deficits. Hence, by correcting the most obvious manifestation of B₁₂ deficiency (anemia), folic acid can mask the fact that deficiency of B₁₂ still exists. As a result, *use of folic acid can lead to undertreatment with B₁₂ itself*, and can thereby permit neurologic damage to progress. Clearly, folic acid is not a substitute for vitamin B₁₂, and vitamin B₁₂ deficiency should never be treated with folic acid alone. Whenever folic acid is employed during treatment of vitamin B₁₂ deficiency, extra care must be taken to ensure that B₁₂ dosage is adequate.

55.4 FOLIC ACID DEFICIENCY

In one respect, folic acid deficiency is identical to vitamin B₁₂ deficiency: In both states, *megaloblastic anemia* is the most conspicuous pathology. However, in other important ways, folic acid deficiency and vitamin B₁₂ deficiency are dissimilar ([Table 54-3](#) provides a summary). Consequently, when a patient presents with megaloblastic anemia, it is essential to determine whether the cause is deficiency of folic acid, vitamin B₁₂, or both.

55.4.1 Physiology and Biochemistry of Folic Acid

55.4.1.1 Metabolic Function

As noted when we discussed vitamin B₁₂, folic acid (also known as *folate*) is an essential factor for DNA synthesis. Without folic acid, DNA replication and cell division cannot proceed.

In order to be usable, dietary folic acid must first be converted to an active form. Under normal conditions, activation occurs through a pathway employing vitamin B₁₂ (see [Fig. 54-4](#)). However, when large amounts of folate are ingested, some can be activated through an alternate pathway—one that does not employ vitamin B₁₂. Hence, even in the absence of vitamin B₁₂, if sufficient amounts of folic acid are consumed, active folate will be available for DNA synthesis.

641
642

TABLE 54-3 Vitamin B₁₂ Deficiency Versus Folic Acid Deficiency

	Vitamin B ₁₂ Deficiency	Folic Acid Deficiency
Usual cause	Vitamin B ₁₂ malabsorption from lack of intrinsic factor	Low dietary folic acid
Primary hematologic effect	Megaloblastic anemia	Megaloblastic anemia
Neurologic effect	Damage to brain and spinal cord	None*
Diagnosis	Low plasma vitamin B ₁₂ ; low B ₁₂ absorption (Schilling test)	Low plasma folic acid
Treatment (usual route)	Cyanocobalamin (IM)	Folic acid (PO)
Usual duration of therapy	Lifelong	Short term

* Folic acid deficiency in pregnancy can cause neural tube defects in the fetus.

55.4.1.2 Fate in the Body

Folic acid is absorbed in the early segment of the small intestine, and then is transported to the liver and other tissues, where it is either used or stored.

Folic acid in the liver undergoes extensive enterohepatic recirculation. That is, folate from the liver is excreted into the intestine, after which it is reabsorbed and then returned to the liver through the hepatic-portal circulation. This enterohepatic recirculation helps salvage up to 200 mcg of folate per day. Accordingly, the process is an important way to maintain folic acid stores.

In contrast to vitamin B₁₂, folic acid is not conserved rigidly: every day, significant amounts are excreted. As a result, if intake of folic acid were to cease, signs of deficiency would develop rapidly (within weeks if body stores were already low).

55.4.1.3 Daily Requirements

The RDA of folic acid is now 400 mcg for adult males and females. RDAs during pregnancy and lactation are 600 mcg and 500 mcg, respectively. Individuals with malabsorption syndromes (eg, tropical sprue) may require as much as 2000 mcg (2 mg) per day; at these high doses, folate will be taken up in sufficient quantity despite impaired absorption.

55.4.1.4 Dietary Sources

Folic acid is present in all foods. Good sources include liver, peas, lentils, oranges, whole-wheat products, asparagus, beets, broccoli, and spinach. Also, many grain products (eg, cereals, bread, pasta, rice, flour) are now fortified with folic acid.

55.4.2 Folic Acid Deficiency: Causes, Consequences, and Diagnosis

55.4.2.1 Causes

Folic acid deficiency has two principal causes: (1) poor diet (especially as seen in alcoholics), and (2) malabsorption secondary to intestinal disease. Rarely, certain drugs may cause folate deficiency.

55.4.2.1.1 Alcoholism.

Alcoholism, either acute or chronic, may be the most common cause of folate deficiency. Deficiency results for two reasons: (1) insufficient folic acid in the diet and (2) derangement of enterohepatic recirculation secondary to alcohol-induced injury to the liver. Fortunately, with improved diet and reduced alcohol consumption, alcohol-related folate deficiency can often be reversed.

55.4.2.1.2 Sprue.

Sprue is an intestinal malabsorption syndrome that decreases folic acid uptake. Since sprue does not block folate absorption entirely, deficiency can be corrected by giving large doses of folic acid orally.

55.4.2.2 Consequences

55.4.2.2.1 All People.

With the important exception that folic acid deficiency does not injure the nervous system, the effects of folate deficiency are identical to those of vitamin B₁₂ deficiency. Hence, as with B₁₂ deficiency, the most prominent consequence of folate deficiency is *megaloblastic anemia*. In addition, like B₁₂ deficiency, lack of folic acid may result in leukopenia, thrombocytopenia, and injury to the oral and GI mucosa. Since we already noted that many of the consequences of vitamin B₁₂ deficiency result from depriving cells of active folic acid, the similarities between folate deficiency and vitamin B₁₂ deficiency should be no surprise.

55.4.2.2.2 The Developing Fetus.

Folic acid deficiency *very early* in pregnancy can cause neural tube defects (eg, spina bifida, anencephaly). Accordingly, it is imperative that all women of reproductive age ensure adequate folate levels *before* pregnancy occurs. Because folate present naturally in foods has relatively low bioavailability, women capable of becoming pregnant should consume 400 mcg/day of *synthetic* folate (either from fortified foods, supplements, or both). If pregnancy occurs, folate intake should increase to 600 mcg/day.

55.4.2.2.3 Other Consequences.

As discussed in [Chapter 80](#) (Vitamins), folic acid deficiency may increase the risk of colorectal cancer and atherosclerosis.

55.4.2.3 Diagnosis

When patients present with megaloblastic anemia, it is essential to distinguish between folic acid deficiency and vitamin B₁₂ deficiency as the cause. How? By comparing plasma levels of folate and vitamin B₁₂. If folic acid levels are low and vitamin B₁₂ levels are normal, a diagnosis of folic acid deficiency is suggested. Conversely, if folate levels are normal and B₁₂ is

low, B₁₂ deficiency would be the likely diagnosis. A decision against folic acid deficiency would be strengthened if neurologic deficits were observed.

55.4.3 Folic Acid Preparations

55.4.3.1 Nomenclature

Nomenclature regarding folic acid preparations can be confusing and deserves comment. Two forms of folic acid are available. One form is inactive as administered (but undergoes activation after being absorbed). The second form is active to start with. Both forms have several generic names: the *inactive* form is referred to as *folacin*, *folate*, *pteroylglutamic acid*, or *folic acid*; the *active* form is referred to as *leucovorin*, *calcium*, *folinic acid*, or *citrovorum factor*. The inactive form is by far the most commonly used preparation.

642

643

55.4.3.2 Folic Acid (Pteroylglutamic Acid)

55.4.3.2.1 Chemistry.

Folic acid is inactive as administered and cannot support DNA synthesis. Activation takes place rapidly following absorption.

55.4.3.2.2 Indications.

Folic acid has three uses: (1) treatment of megaloblastic anemia resulting from folic acid deficiency; (2) prophylaxis of folate deficiency, especially during pregnancy and lactation; and (3) initial treatment of severe megaloblastic anemia resulting from vitamin B₁₂ deficiency.

55.4.3.2.3 Adverse Effects.

Oral folic acid is nontoxic. Massive dosages (eg, as much as 15 mg/day) have been taken with no ill effects.

55.4.3.2.4 Warning.

If taken in sufficiently large doses, folic acid can correct the hematologic consequences of vitamin B₁₂ deficiency, thereby masking the fact that a deficiency in vitamin B₁₂ still exists. Since folic acid will not prevent the neurologic consequences of B₁₂ deficiency (despite correcting the hematologic picture), this masking effect may allow the development of irreversible damage to the nervous system. To reduce the chances of this problem, folate should not be used indiscriminately: Unless specifically indicated, consumption of folic acid

should not exceed 1000 mcg/day. Furthermore, whenever folic acid is given to patients known to have a deficiency in vitamin B₁₂, special care must be taken to ensure that the vitamin B₁₂ dosage is adequate.

55.4.3.2.5 Formulations and Routes of Administration.

Folic acid is available in tablets (0.4, 0.8, and 1 mg) for oral use and in a 5-mg/mL solution [Folvite] for IM, IV, or subQ injection. As a rule, injections are reserved for patients with severely impaired GI absorption.

55.4.3.2.6 Dosage.

For treatment of folate-deficient megaloblastic anemia in adults, the usual oral dosage is 1000 to 2000 mcg/day. Once symptoms have resolved, the maintenance dosage is 400 mcg/day. For prophylaxis during pregnancy and lactation, doses up to 1000 mcg/day may be used.

55.4.3.3 Leucovorin Calcium (Folinic Acid)

Leucovorin calcium is an active form of folic acid used primarily as an adjunct to cancer chemotherapy (see [Chapter 101](#)). Leucovorin is not used routinely to correct folic acid deficiency. Why? Because folic acid is just as effective and cheaper.

55.4.4 Guidelines for Treating Folic Acid Deficiency

55.4.4.1 Choice of Treatment Modality.

The modality for treating folic acid deficiency should be matched with the cause. If folic acid deficiency is due to poor diet, the deficiency should be corrected by dietary measures—not with drugs (except for women who may become pregnant). Ingestion of one serving of a fresh vegetable or one glass of fruit juice a day will often suffice. In contrast, when folate deficiency is the result of malabsorption, diet alone cannot correct the deficiency, and hence pharmaceutical folate will be needed.

55.4.4.2 Route of Administration.

Oral administration is preferred for most patients. Unlike vitamin B₁₂, folic acid is rarely administered by injection. Even in the presence of intestinal disease, oral folic acid can be effective, providing the dosage is big enough.

55.4.4.3 Prophylactic Use of Folic Acid.

Folic acid should be taken prophylactically only when clearly appropriate. The principal indications are pregnancy and lactation. Since folic acid may mask vitamin B₁₂ deficiency, indiscriminate use of folate should be avoided.

55.4.4.4 Treatment of Severe Deficiency.

Folic acid deficiency can produce severe megaloblastic anemia. To ensure a rapid response, therapy should be initiated with an IM injection of folic acid and vitamin B₁₂. (Because of the metabolic interrelationship between folic acid and vitamin B₁₂, combining these agents accelerates recovery.) After the initial injection, treatment should be continued with folic acid alone. Folic acid should be given orally in a dosage of 1000 to 2000 mcg/day for 1 to 2 weeks. After this, maintenance doses of 400 mcg/day may be required.

Therapy is evaluated by monitoring the hematologic picture. When treatment has been effective, megaloblasts will disappear from the bone marrow within 48 hours; the reticulocyte count will increase measurably within 2 to 3 days; and the hematocrit will begin to rise in the second week.

55.4.4.4.1

KEY POINTS

- The principal cause of iron deficiency is increased iron demand secondary to (1) maternal and fetal blood volume expansion during pregnancy; (2) blood volume expansion during infancy and early childhood; or (3) chronic blood loss, usually of GI or uterine origin.
- The major consequence of iron deficiency is microcytic, hypochromic anemia.
- Ferrous sulfate, given PO, is the drug of choice for iron deficiency.
- Iron-deficient patients who cannot tolerate or absorb oral ferrous salts are treated with parenteral iron—usually iron dextran administered IV.
- The major adverse effects of ferrous sulfate are GI disturbances. These are best managed by reducing the dosage (rather than by administering the drug with food, which would greatly reduce absorption).
- Parenteral iron dextran carries a significant risk of fatal anaphylactic reactions. The risk is much lower with other parenteral iron products (eg, iron sucrose).

- The principal cause of vitamin B₁₂ deficiency is impaired absorption secondary to lack of intrinsic factor.
- The principal consequences of B₁₂ deficiency are megaloblastic (macrocytic) anemia and neurologic injury.
- Vitamin B₁₂ deficiency caused by malabsorption is treated lifelong with cyanocobalamin. Traditional treatment consists of IM injections administered monthly. However, large oral doses administered daily are also effective, as are intranasal doses (administered weekly with Nascobal or daily with CaloMist).
- For initial therapy of severe vitamin B₁₂ deficiency, parenteral folic acid is given along with cyanocobalamin.
- When folic acid is combined with vitamin B₁₂ to treat B₁₂ deficiency, it is essential that the dosage of B₁₂ be adequate. Why? Because folic acid can mask continued B₁₂ deficiency (by improving the hematologic picture), while allowing the neurologic consequences of B₁₂ deficiency to progress.

643

644

- The principal causes of folic acid deficiency are poor diet (usually in alcoholics) and malabsorption secondary to intestinal disease.
- The principal consequences of folic acid deficiency are megaloblastic anemia and neural tube defects in the developing fetus.
- To prevent neural tube defects, all women who may become pregnant should ingest 400 mcg of folate daily, in the form of folate supplements or folate-fortified foods.

55.4.4.4.2

Summary of Major Nursing Implications*

55.4.4.4.2.1

IRON PREPARATIONS

Carbonyl iron

Ferrous fumarate

Ferrous gluconate

Ferrous sulfate

Iron dextran

Iron sucrose

Sodium–ferric gluconate complex (SFGC)

Except where indicated, the implications summarized below apply to all iron preparations.

55.4.4.4.2....

Preadministration Assessment

55.4.4.4.2....

Therapeutic Goal

Prevention or treatment of iron deficiency anemias.

55.4.4.4.2....

Baseline Data

Prior to treatment, assess the degree of anemia. Fatigue, listlessness, and pallor indicate mild anemia; dyspnea, tachycardia, and angina suggest severe anemia. Laboratory findings indicative of anemia are subnormal hemoglobin levels, subnormal hematocrit, subnormal hemosiderin in bone marrow, and the presence of microcytic, hypochromic erythrocytes.

The cause of iron deficiency (eg, pregnancy, occult bleeding, menorrhagia, inadequate diet, malabsorption) must be determined.

55.4.4.4.2....

Identifying High-Risk Patients

All iron preparations are *contraindicated* for patients with anemias other than iron deficiency anemia.

Parenteral preparations are *contraindicated* for patients who have had a severe allergic reaction to them in the past.

Use *oral* preparations with *caution* in patients with peptic ulcer disease, regional enteritis, and ulcerative colitis.

55.4.4.4.2....

Implementation: Administration

55.4.4.4.2....

Routes

55.4.4.4.2....

Oral.

Ferrous sulfate, ferrous fumarate, ferrous gluconate, carbonyl iron.

55.4.4.4.2....

Parenteral.

Iron dextran, SFGC, iron sucrose.

55.4.4.4.2....

Oral Administration

Food reduces GI distress from oral iron but also greatly reduces absorption. **Instruct patients to administer oral iron between meals to maximize uptake.** If GI distress is intolerable, the dosage may be reduced. If absolutely necessary, oral iron may be administered with meals.

Liquid preparations can stain the teeth. **Instruct patients to dilute liquid preparations with juice or water, administer them through a straw, and rinse the mouth after.**

Warn patients not to crush or chew sustained-release preparations.

Warn patients against ingesting iron salts together with antacids or tetracyclines.

Inform patients that oral iron preparations differ and warn them against switching from one to another.

55.4.4.4.2....

Parenteral Administration: Iron Dextran

Iron dextran may be given IV or IM. Intravenous administration is safer and preferred.

55.4.4.4.2....

Intravenous.

To minimize anaphylactic reactions, follow this protocol: (1) Infuse 25 mg as a test dose and observe the patient for at least 15 minutes. (2) If the test dose appears safe, infuse 500 mg over 10 to 15 minutes. (3) If the 500-mg dose proves uneventful, give additional doses as needed.

55.4.4.4.2....	<p>Intramuscular.</p> <p>Intramuscular injection can cause significant adverse reactions (anaphylaxis, persistent pain, localized discoloration, promotion of tumors) and is generally avoided. Make injections deep into each buttock using the Z-track technique. Give a 25-mg test dose and wait 1 hour before giving the full therapeutic dose.</p>	
55.4.4.4.2....	<p>Parenteral Administration: SFGC</p> <p>To minimize adverse reactions, precede the first full dose with a test dose (25 mg infused IV over 60 minutes). Administer therapeutic doses by slow IV infusion (no faster than 12.5 mg/min).</p>	
55.4.4.4.2....	<p>Parenteral Administration: Iron Sucrose</p>	
55.4.4.4.2....	<p>Hemodialysis-Dependent Patients.</p> <p>Administer iron sucrose directly into the dialysis line. Do not mix with other drugs or with parenteral nutrition solutions. Administer by either (1) slow injection (1 mL/min) or (2) infusion (dilute iron sucrose in up to 100 mL of 0.9% saline and infuse over 15 minutes or longer).</p>	
55.4.4.4.2....	<p>Peritoneal Dialysis-Dependent Patients.</p> <p>Administer by slow infusion.</p>	644
55.4.4.4.2....	<p>Non-Dialysis-Dependent Patients.</p> <p>Administer by slow injection.</p>	645
55.4.4.4.2....	<p>Implementation: Measures to Enhance Therapeutic Effects</p> <p>If the diet is poor in iron, advise the patient to increase consumption of iron-rich foods (eg, liver, egg yolks, brewer's yeast, wheat germ, muscle meats, fish, fowl).</p>	
55.4.4.4.2....	<p>Ongoing Evaluation and Interventions</p>	
55.4.4.4.2....	<p>Evaluating Therapeutic Responses</p> <p>Evaluate treatment by monitoring hematologic status. Reticulocyte counts should increase within 4 to 7 days, hemoglobin content and the hematocrit should begin to rise within 1 week, and hemoglobin levels should rise by at least 2 gm/dL within 1</p>	

month. If these responses do not occur, evaluate the patient for adherence, persistent bleeding, inflammatory disease, and malabsorption.

55.4.4.4.2....

Minimizing Adverse Effects

55.4.4.4.2....

GI Disturbances.

Forewarn patients about possible GI reactions (nausea, vomiting, constipation, diarrhea) and inform them these will diminish over time. If GI distress is severe, the dosage may be reduced, or, if absolutely necessary, iron may be administered with food.

Inform patients that iron will impart a harmless dark green or black color to stools.

55.4.4.4.2....

Anaphylactic Reactions.

Parenteral iron dextran (and, rarely, SFGC and iron sucrose) can cause potentially fatal anaphylaxis. Before giving parenteral iron, ensure that injectable epinephrine and facilities for resuscitation are immediately available. After administration, observe the patient for 60 minutes. Give test doses as described above. Precede all doses of iron dextran and the first dose of SFGC with a test dose; test doses are unnecessary with iron sucrose.

55.4.4.4.2....

Managing Acute Toxicity.

Iron poisoning can be fatal to young children. **Instruct parents to store iron out of reach and in childproof containers.** If poisoning occurs, rapid treatment is imperative. Use gastric lavage to remove iron from the stomach. Administer deferoxamine if plasma levels of iron exceed 500 mcg/mL. Manage acidosis and shock as required.

55.4.4.4.2.2

CYANOCOBALAMIN (VITAMIN B₁₂)

55.4.4.4.2....

Preadministration Assessment

55.4.4.4.2....

Therapeutic Goal

Correction of megaloblastic anemia and other sequelae of vitamin B₁₂ deficiency.

55.4.4.4.2....

Baseline Data

Assess the extent of vitamin B₁₂ deficiency. Record signs and symptoms of anemia (eg, pallor, dyspnea, palpitations, fatigue). Determine the extent of neurologic damage. Assess GI involvement.

Baseline laboratory data include plasma vitamin B₁₂ levels, erythrocyte and reticulocyte counts, and hemoglobin and hematocrit values. Bone marrow may be examined for megaloblasts. A Schilling test may be ordered to assess vitamin B₁₂ absorption.

55.4.4.4.2....

Identifying High-Risk Patients

Use with *caution* in patients receiving folic acid.

55.4.4.4.2....

Implementation: Administration

55.4.4.4.2....

Routes and Administration

Administration may be IM, subQ, oral, or intranasal. For most patients, lifelong treatment is required. Traditional therapy consists of IM or subQ injections administered monthly. However, treatment can be just as effective with large daily oral doses or with intranasal doses (administered weekly with Nascobal or daily with CaloMist). **Inform patients that intranasal doses should not be administered within 1 hour before or 1 hour after consuming hot foods or hot liquids.**

55.4.4.4.2....

Implementation: Measures to Enhance Therapeutic Effects

55.4.4.4.2....

Promoting Adherence

Patients with permanent impairment of B₁₂ absorption require lifelong B₁₂ therapy. To promote adherence, **educate patients about the nature of their condition and impress upon them the need for monthly injections, daily oral therapy, or daily or weekly intranasal therapy.** Schedule appointments for injections at convenient times.

55.4.4.4.2....

Improving Diet

When B₁₂ deficiency is not due to impaired absorption, a change in diet may accelerate recovery. **Advise the patient to increase consumption of B₁₂-rich foods (eg, muscle meats, dairy products).**

55.4.4.4.2....

Ongoing Evaluation and Interventions

55.4.4.4.2....

Evaluating Therapeutic Effects

Assess for improvements in hematologic and neurologic status. Over a period of 2 to 3 weeks, megaloblasts should disappear, reticulocyte counts should rise, and the hematocrit should normalize. Neurologic damage may take months to improve; in some cases, full recovery may never occur.

For patients receiving long-term therapy, vitamin B₁₂ levels should be measured every 3 to 6 months, and blood counts should be performed.

55.4.4.4.2....

Minimizing Adverse Effects

Hypokalemia may develop during the first days of therapy. Monitor serum potassium levels and observe the patient for signs of potassium insufficiency. **Teach patients the signs and symptoms of hypokalemia (eg, muscle weakness, irregular heartbeat) and instruct them to report these immediately.**

55.4.4.4.2....

Minimizing Adverse Interactions

Folic acid can mask hematologic symptoms of vitamin B₁₂ deficiency, resulting in undertreatment and progression of neurologic injury caused by low B₁₂. When folic acid and cyanocobalamin are used concurrently, special care must be taken to ensure that the cyanocobalamin dosage is adequate.

645

646

55.4.4.4.2.3

FOLIC ACID (FOLACIN, FOLATE, PTEROYLGLUTAMIC ACID)

55.4.4.4.2....

Preadministration Assessment

55.4.4.4.2....

Therapeutic Goal

Folic acid is used for (1) treatment of megaloblastic anemia resulting from folic acid deficiency, (2) initial treatment of severe megaloblastic anemia resulting from

vitamin B₁₂ deficiency, and (3) prevention of folic acid deficiency (especially during pregnancy).

55.4.4.4.2....

Baseline Data

Assess the extent of folate deficiency. Record signs and symptoms of anemia (eg, pallor, dyspnea, palpitations, fatigue). Determine the extent of GI damage.

Baseline laboratory data include serum folate levels, erythrocyte and reticulocyte counts, and hemoglobin and hematocrit values. In addition, bone marrow may be evaluated for megaloblasts. To rule out vitamin B₁₂ deficiency, vitamin B₁₂ determinations and a Schilling test may be ordered.

55.4.4.4.2....

Identifying High-Risk Patients

Folic acid is *contraindicated* for patients with pernicious anemia (except during the acute phase of treatment). Inappropriate use of folic acid by these patients can mask signs of vitamin B₁₂ deficiency, thereby allowing further neurologic deterioration.

55.4.4.4.2....

Implementation: Administration

55.4.4.4.2....

Routes

55.4.4.4.2....

Oral, subQ, IV, and IM.

Oral administration is most common and preferred. Injections are employed only when intestinal absorption is severely impaired.

55.4.4.4.2....

Implementation: Measures to Enhance Therapeutic Effects

55.4.4.4.2....

Improving Diet

If the diet is deficient in folic acid, advise the patient to increase consumption of folate-rich foods (eg, green vegetables, liver). If alcoholism underlies dietary deficiency, counseling should be offered.

55.4.4.4.2....

Ongoing Evaluation and Interventions

55.4.4.4.2....

Evaluating Therapeutic Effects

Monitor hematologic status. Within 2 weeks, megaloblasts should disappear, reticulocyte counts should increase, and the hematocrit should begin to rise.

* Patient education information is highlighted as **blue text**.

⁵⁶CHAPTER 55 Hematopoietic Growth Factors

Hematopoiesis is the process by which the body makes red blood cells, white blood cells, and platelets. The process is regulated in part by hematopoietic growth factors—naturally occurring hormones that stimulate the proliferation and differentiation of hematopoietic stem cells, and enhance function in the mature forms of those cells. In a laboratory setting, hematopoietic growth factors can cause stem cells to form colonies of mature blood cells. Because of this action, some hematopoietic growth factors are also known as *colony-stimulating factors*. Therapeutic applications of hematopoietic growth factors include (1) acceleration of neutrophil and platelet repopulation after cancer chemotherapy, (2) acceleration of bone marrow recovery after an autologous bone marrow transplantation (BMT), and (3) stimulation of erythrocyte production in patients with chronic renal failure (CRF).

The names used for the hematopoietic growth factors are a potential source of confusion. Why? Because each product has a biologic name, a generic name, and one or more proprietary (trade) names. The biologic, generic, and proprietary names for available products are listed in [Table 55-1](#).

^{56.1} ERYTHROPOIETIC GROWTH FACTORS

Erythropoietic growth factors—also known as *erythropoiesis stimulating agents* or ESAs—stimulate production of erythrocytes (red blood cells, RBCs). Because they increase RBC production, ESAs represent an alternative to infusions for patients with low RBC counts, including patients with CRF and cancer patients undergoing chemotherapy or radiation treatment.

Unfortunately, data gathered in recent years have shown that, for many cancer patients, ESAs can shorten time to tumor progression and reduce overall survival. Also, these drugs can increase the risk of deep vein thrombosis when used prior to elective surgery. Currently, three ESA preparations are available: epoetin alfa (erythropoietin), darbepoetin alfa (a long-acting form of erythropoietin), and methoxy polyethylene glycol–epoetin beta (a very-long-acting form of erythropoietin).

^{56.1.1} Epoetin Alfa (Erythropoietin)

Epoetin alfa [Epogen, Procrit] is a growth factor produced by recombinant DNA technology.

Chemically, the compound is a glycoprotein containing 165 amino acids. The protein portion of epoetin alfa is identical to that of human erythropoietin, a naturally occurring hormone. Epoetin alfa is used to maintain erythrocyte counts in (1) patients with CRF, (2) HIV-infected patients taking zidovudine, and (3) patients with nonmyeloid malignancies who have anemia secondary to chemotherapy. In addition, the drug can be used to elevate erythrocyte counts in anemic patients prior to elective surgery.

647

648

TABLE 55-1 Nomenclature for Hematopoietic Growth Factors

Biologic Name	Pharmacologic Names	
	Generic Name	Trade Name
Erythropoietic Growth Factors		
Erythropoietin	Darbepoetin alfa	Aranesp
	Epoetin alfa	Epogen, Procrit
	MPEG–epoetin beta*	Mircera
Leukopoietic Growth Factors		
Granulocyte colony-stimulating factor (G-CSF)	Filgrastim	Neupogen
	Pegfilgrastim	Neulasta
Granulocyte-macrophage colony-stimulating factor (GM-CSF)	Sargramostim	Leukine
Thrombopoietic Growth Factor		
Interleukin-11	Oprelvekin	Neumega

* MPEG–epoetin beta = methoxy polyethylene glycol–epoetin beta.

56.1.1.1 Physiology

Erythropoietin is a glycoprotein hormone that stimulates production of red blood cells in the bone marrow. The hormone is produced by peritubular cells in the proximal tubules of the kidney. In response to anemia or hypoxia, circulating levels of erythropoietin rise dramatically, triggering an increase in erythrocyte synthesis. However, because production of erythrocytes requires iron, folic acid, and vitamin B₁₂, the response to erythropoietin is minimal if any of these is deficient.

Evidence gathered over the last decade shows that erythropoietin has significant physiologic effects outside the hematopoietic system. Animal studies indicate that erythropoietin is secreted by cells of many organs, including the brain, bone marrow, liver, heart, kidney, uterus, testes, and blood vessels—and that receptors for erythropoietin are present at most of these sites. Actions of the hormone include modulation of angiogenesis (blood vessel formation) and maintenance of cellular integrity (by inhibiting apoptotic mechanisms of cell injury). In the future, these actions may be exploited to treat a variety of disorders, including stroke, diabetic nephropathy, multiple sclerosis, myocardial infarction (MI), and heart failure (HF).

56.1.1.2 Therapeutic Uses

56.1.1.2.1 Anemia of Chronic Renal Failure.

Epoetin alfa can reverse anemia associated with CRF. The drug can benefit patients on dialysis as well as those who do not yet require dialysis. Effective treatment virtually eliminates the need for transfusions. Initial effects can be seen within 1 to 2 weeks. Hemoglobin reaches target levels (10 to 12 gm/dL) in 2 to 3 months. Patients experience an improved quality of life and increased energy levels. Unfortunately, treatment does not prevent progressive renal deterioration.

For therapy to be effective, iron stores must be adequate. Transferrin saturation should be at least 20%, and ferritin concentration should be at least 100 ng/mL. If pretreatment assessment indicates these values are low, they must be restored with iron supplements.

56.1.1.2.2 HIV-Infected Patients Taking Zidovudine.

Epoetin alfa is approved for treating anemia caused by therapy with zidovudine (AZT) in patients with AIDS. For these patients, treatment can maintain or elevate erythrocyte counts and reduce the need for transfusions. However, if endogenous levels of erythropoietin are at or above 500 milliunits/mL, raising them further with epoetin is unlikely to help.

56.1.1.2.3 Chemotherapy-Induced Anemia.

Epoetin alfa is used to treat chemotherapy-induced anemia in patients with *nonmyeloid malignancies*, thereby reducing or eliminating the need for periodic transfusions. Since transfusions require hospitalization, whereas epoetin can be self-administered at home, epoetin therapy can spare patients considerable inconvenience. Because epoetin works slowly (the hematocrit may take 2 to 4 weeks to recover), transfusions are still indicated when rapid replenishment of red blood cells is required. Please note that epoetin is not approved for patients with *leukemias* and *other myeloid malignancies*. Why? Because the drug may stimulate proliferation of these cancers.

56.1.1.2.4 Anemia in Patients Facing Surgery.

Epoetin may be given to increase erythrocyte levels in anemic patients scheduled for elective surgery. The drug should be used only when significant blood loss is anticipated—but should not be used prior to cardiac or vascular surgery. For surgical patients, epoetin offers two benefits: (1) it decreases the need for transfusions, and (2) by increasing erythrocyte synthesis, it allows patients to predeposit more blood in anticipation of transfusion needs.

56.1.1.3 Pharmacokinetics

Epoetin alfa is administered parenterally (IV or subQ). The drug cannot be given orally because, being a glycoprotein, it would be degraded in the GI tract. The plasma half-life is highly variable and unchanged by dialysis.

56.1.1.4 Adverse Effects and Interactions

Epoetin alfa is generally well tolerated. Although the drug is a protein, no serious allergic reactions have been reported. The most significant adverse effect is hypertension. There are no significant drug interactions. As discussed below under *Warnings*, improper use of epoetin alfa has been associated with serious cardiovascular events, tumor progression, and deaths.

56.1.1.4.1 Hypertension.

In patients with CRF, epoetin is frequently associated with an increase in blood pressure. The extent of hypertension is directly related to the rate of rise in the hematocrit. To minimize risk, blood pressure should be monitored and, if necessary, controlled with antihypertensive drugs. If hypertension cannot be controlled, epoetin dosage should be reduced. In patients with pre-existing hypertension (a common complication of CRF), it is imperative that blood pressure be under control prior to epoetin use. About 30% of dialysis patients receiving epoetin require an adjustment in their antihypertensive therapy once the hematocrit has been normalized.

56.1.1.4.2 Cardiovascular Events.

Epoetin has been associated with an increase in cardiovascular events. Among these are cardiac arrest, hypertension, HF, and thrombotic events, including stroke and MI. Risk is greatest when (1) the hemoglobin level exceeds 12 gm/dL or (2) the rate of rise in hemoglobin exceeds 1 gm/dL in any 2-week interval. Accordingly, dosage should be reduced when hemoglobin approaches 12 gm/dL or when the rate of rise exceeds 1 gm/dL in 2 weeks—and dosing should be temporarily stopped if hemoglobin rises to 13 gm/dL or more. To prevent clotting in the artificial kidney, CRF patients on dialysis may need increased anticoagulation with heparin.

56.1.1.4.3 Autoimmune Pure Red-Cell Aplasia.

Very, very rarely, treatment with epoetin leads to pure red-cell aplasia (PRCA), a condition characterized by severe anemia and a complete absence of erythrocyte precursor cells in bone marrow. The cause is production of neutralizing antibodies directed against epoetin itself as well as any native erythropoietin the body is still able to produce. In the absence of epoetin

and erythropoietin, production of red blood cells ceases. Because patients can no longer make erythrocytes, transfusions are required for survival. If evidence of PRCA develops, epoetin should be discontinued and blood should be assessed for neutralizing antibodies.

56.1.1.5 Warnings

56.1.1.5.1 Excessive Dosage.

To minimize the risk of serious adverse events, the dosage of epoetin alfa and all other ESAs should be the lowest needed to gradually raise hemoglobin content to the lowest level

648

sufficient to eliminate the need for RBC transfusions. In all cases, hemoglobin level should not exceed 12 gm/dL. Why? Because when ESAs are administered in doses sufficient to raise hemoglobin above this level, there is an increased risk of serious cardiovascular events and death.

649

56.1.1.5.2 Cancer Patients.

Postmarketing reports indicate that ESAs can accelerate tumor progression and shorten life in certain cancer patients—especially when hemoglobin has been driven above 12 gm/dL. In patients with advanced head and neck cancer who are undergoing radiation therapy, ESAs have shortened the time to tumor progression. In patients with metastatic breast cancer who are receiving chemotherapy, ESAs have shortened overall survival and increased deaths from tumor progression. Also, ESAs have increased the risk of death in patients with active malignant disease who are not receiving either radiation or chemotherapy, and hence ESAs are contraindicated for this group.

56.1.1.5.3 Renal Failure Patients.

In patients with anemia of chronic renal failure, ESAs can increase the risk of serious cardiovascular events and death if hemoglobin levels are driven too high. Accordingly, dosage should be individualized to produce hemoglobin levels in the range of 10 to 12 gm/dL.

56.1.1.5.4 Preoperative Patients.

When given to preoperative patients to reduce the need for RBC transfusion, ESAs have increased the risk of deep vein thrombosis—but only in patients who were not given an anticoagulant. Accordingly, anticoagulant therapy should be considered for all preoperative patients receiving an ESA.

56.1.1.6 Monitoring

Hemoglobin level should be measured at baseline and twice weekly thereafter until the target level (10 to 12 gm/dL) has been reached and a maintenance dose established. Complete blood counts with a differential should be done routinely. Blood chemistry—blood urea nitrogen (BUN), uric acid, creatinine, phosphorus, and potassium—should be monitored. Iron should be measured periodically and maintained at an adequate level.

56.1.1.7 Preparations, Dosage, and Administration

56.1.1.7.1 Preparations.

Epoetin alfa [Epogen, Procrit] is supplied in 1-mL vials (2000, 3000, 4000, 10,000, 20,000, and 40,000 units) for subQ and IV injection. Vials should not be shaken (because epoetin is a protein that can be denatured by agitation). Don't mix epoetin with other drugs. Store at 2°C to 8°C; don't freeze.

56.1.1.7.2 General Dosing Guidelines.

Use the lowest dosage needed to gradually increase the hemoglobin concentration to the lowest level sufficient to eliminate the need for RBC transfusion. For most patients, the treatment goal is a hemoglobin level of 10 to 12 gm/dL. *Regimens that raise hemoglobin above 12 gm/dL are associated with an increased risk of serious cardiovascular events and death.* Accordingly, dosage should be reduced when hemoglobin approaches 12 gm/dL, or when hemoglobin increases by more than 1 gm/dL in any 2-week interval. If hemoglobin rises above 13 gm/dL, withhold treatment until hemoglobin drops below 12 gm/dL. When treatment resumes, decrease the dose by 25%, and then titrate upward as needed.

56.1.1.7.3 Dosing in Patients with Chronic Renal Failure.

56.1.1.7.3.1 Route.

Administration may be IV or subQ. Initially, IV administration was preferred, in part because subQ administration was reputedly painful, and in part because bioavailability following subQ injection is reduced—although the half-life is prolonged. In 1998, a study comparing IV therapy with subQ therapy indicated that both produce equivalent effects. Furthermore, with subQ administration, 30% less epoetin is required, and reported discomfort at the injection site is minimal. Because epoetin is expensive, and because subQ therapy is equivalent to IV therapy and cheaper, it seems likely that subQ therapy will become the new standard.

56.1.1.7.3.2 Dosage.

The initial dosage is 50 to 100 units/kg 3 times a week. Administration is by IV bolus for dialysis patients and by IV bolus or subQ injection for nondialysis patients. Once the target hemoglobin level has been achieved, an individualized maintenance dosage should be established: For dialysis patients, the median maintenance dosage is 75 units/kg 3 times a week; for nondialysis patients, the median maintenance dosage is 75 to 100 units/kg once a week. If the hematocrit rises above 12 gm/dL, epoetin should be temporarily withheld.

56.1.1.7.4 Dosing in HIV-Infected Patients Taking Zidovudine.

Prior to treatment, measure the endogenous erythropoietin level. If this level is already at or above 500 milliunits/mL, epoetin alfa is unlikely to help.

The initial dosage is 100 units/kg (IV or subQ injection) 3 times/wk for 8 weeks. If the response is insufficient, the dosage may be increased by increments of 50 to 100 units/kg until a maximum of 300 units/kg 3 times a week has been reached.

56.1.1.7.5 Dosing in Patients Receiving Cancer Chemotherapy.

Two dosing schedules may be used: once weekly or thrice weekly.

56.1.1.7.5.1 Once-Weekly Dosing.

The initial dosage is 40,000 units subQ each week. If, after 4 weeks of therapy, hemoglobin has not increased by at least 1 gm/dL, the dosage should be increased to 60,000 units once weekly. If hemoglobin has not increased by 1 gm/dL after 4 weeks, treatment should stop, since further increases are not likely to succeed.

56.1.1.7.5.2 Thrice-Weekly Dosing.

The initial dosage is 150 units/kg subQ 3 times a week. If the response is inadequate by 8 weeks, the dosage may be increased to 300 units/kg 3 times a week.

56.1.1.7.6 Dosing in Anemic Patients Scheduled for Surgery.

The recommended dosage is 300 units/kg/day subQ for 15 days starting 10 days before surgery.

56.1.2 Darbepoetin Alfa (Erythropoietin, Long Acting)

56.1.2.1 Actions and Therapeutic Use

Darbepoetin alfa [Aranesp], also known as novel erythrocyte stimulation protein (NESP), is a long-acting analog of epoetin alfa [Epogen, Procrit]. Both drugs act on erythroid progenitor cells to stimulate production of erythrocytes. Darbepoetin differs structurally from epoetin in that it has two additional carbohydrate chains. Because of these chains, darbepoetin is cleared more slowly than epoetin, and hence has a longer half-life (49 hours vs. 18 to 24 hours). As a result, darbepoetin can be administered less frequently, and thus is more convenient.

Darbepoetin is approved for maintaining erythrocyte counts in (1) patients with CRF and (2) patients with nonmyeloid malignancies who have anemia secondary to chemotherapy. As discussed above, epoetin has additional indications.

56.1.2.2 Adverse Effects and Warnings

Darbepoetin is generally well tolerated. As with epoetin, the most common problem is hypertension. The risk can be minimized by ensuring that the rate of rise in hemoglobin does not exceed 1 gm/dL every 2 weeks. If hypertension develops, it should be controlled with antihypertensive drugs. Patients already taking antihypertensive drugs may need to increase their dosage.

Like epoetin alfa, darbepoetin increases the risk of PRCA, MI, HF, stroke, cardiac arrest, and other cardiovascular events, especially when the hemoglobin level exceeds 12 gm/dL or when the rate of rise in hemoglobin exceeds 1 gm/dL in 2 weeks.

Like epoetin alfa, darbepoetin can promote tumor progression and shorten survival in some cancer patients.

56.1.2.3 Monitoring

When initiating darbepoetin or changing dosage, the hemoglobin level should be measured weekly until it stabilizes. Thereafter, hemoglobin should be measured at least once a month.

56.1.2.4 Preparations, Dosage, Administration, and Monitoring

56.1.2.4.1 Preparations and Storage.

Darbepoetin alfa [Aranesp] is available in 1-mL, single-dose vials (25, 40, 60, 100, 200, 300, and 500 mcg/mL) for subQ and IV injection. Don't dilute darbepoetin or mix it with other

649

drugs. Because darbepoetin is a protein that can be denatured by agitation, don't shake the vials. Discard preparations that are discolored or contain particles. Store at 2°C to 8°C; don't freeze.

56.1.2.4.2 General Dosing Guidelines.

The treatment goal is to increase hemoglobin to a maximum of 12 gm/dL. Dosage should be reduced when hemoglobin approaches 12 gm/dL, or when hemoglobin increases by more than 1 gm/dL in any 2-week interval. If hemoglobin rises to 13 gm/dL or higher, withhold treatment until hemoglobin drops below 12 gm/dL.

56.1.2.4.3 Dosing in Patients with Chronic Renal Failure.

The initial dosage is 0.45 mcg/kg, given either IV or subQ once a week. The target hemoglobin level is 12 gm/dL. Because responses develop gradually, dosage should be adjusted no more than once every 4 weeks. Quite often, the maintenance dosage is less than the initial dosage.

When switching from epoetin to darbepoetin, the new dosage and dosing frequency are based on the existing epoetin usage. For example, patients receiving 5000 to 11,000 units of epoetin each week should be given 25 mcg of darbepoetin each week. If the epoetin dosing frequency was 2 to 3 times a week, darbepoetin should be given once a week; if epoetin was given once a week, darbepoetin should be given once every 2 weeks.

56.1.2.4.4 Dosing in Patients Undergoing Cancer Chemotherapy.

The initial dosage is 2.25 mcg/kg injected subQ once a week. If the increase in hemoglobin is less than 1 gm/dL after 6 weeks, dosage should be increased to 4.5 mcg once a week. If the increase in hemoglobin exceeds 1 gm/dL in 2 weeks, or if hemoglobin rises above 12 gm/dL, dosage should be reduced by 25%.

56.1.3 Methoxy Polyethylene Glycol–Epoetin Beta (Erythropoietin, Very Long Acting)

56.1.3.1 Description and Therapeutic Use

Methoxy polyethylene glycol (MPEG)–epoetin beta [Mircera], approved in 2007, is a long-acting derivative of erythropoietin. Like the natural hormone, MPEG–epoetin beta acts on erythroid progenitor cells to stimulate production of red blood cells.

MPEG–epoetin beta has a unique structure, created by conjugating one molecule of epoetin beta (a recombinant form of erythropoietin) to one molecule of methoxy propylene glycol. Because of this structure, MPEG–epoetin beta has a very long half-life (about 135 hours)—about 6 times that of darbepoetin alfa and 27 times that of epoetin alfa. Because it stays in the body so long, MPEG–epoetin beta can be dosed less frequently than the other two ESAs, making treatment more convenient.

MPEG–epoetin beta is indicated only for anemia associated with CRF. The drug is not approved for use by cancer patients. Why? Because in clinical trials, there were more deaths among patients taking MPEG–epoetin beta than among patients taking a comparator ESA.

As of this writing, MPEG–epoetin beta cannot be marketed in the United States. Why? Because there is an ongoing patent dispute between Hoffman LaRoche, the company that makes Mircera, and Amgen, the company that makes two other ESAs (Aranesp and Epogen).

56.1.3.2 Adverse Effects and Warnings

Adverse effects are like those of other ESAs. Hypertension is the most common (11%). The risk can be minimized by keeping the rate of rise in hemoglobin below 1 gm/dL every 2 weeks. If hypertension develops, it should be controlled with antihypertensive drugs.

Like other ESAs, MPEG–epoetin beta increases the risk of serious cardiovascular events, including PRCA, MI, HF, stroke, and cardiac arrest. Risk is greatest when the hemoglobin level exceeds 12 gm/dL or when the rate of rise in hemoglobin exceeds 1 gm/dL in 2 weeks.

More than other ESAs, MPEG–epoetin beta can promote tumor progression and shorten survival in some cancer patients. Accordingly, MPEG–epoetin beta is contraindicated for patients with cancer.

56.1.3.3 Monitoring

When initiating MPEG–epoetin beta or when changing the dosage, the hemoglobin level should be measured every 2 weeks until it stabilizes. Thereafter, hemoglobin should be measured every 2 to 4 weeks.

56.1.3.4 Preparations, Dosage, Administration, and Monitoring

56.1.3.4.1 Preparations and Storage.

MPEG–epoetin beta [Mircera] is available in single-use vials (50, 100, 200, 300, 400, 600, and 1000 mcg/mL) and in two sizes of single-use pre-filled syringes: 0.3 mL (containing 50,

75, 100, 150, 200, 250, or 300 mcg) and 0.6 mL (containing 400, 600, or 800 mcg). The syringes and vials should be stored cold (2°C to 8°C [36°F to 46°F]) and protected from light.

56.1.3.4.2 Administration.

Administration is by IV injection or subQ injection (into the abdomen, arm, or thigh).

56.1.3.4.3 Dosage.

Dosage differs for patients currently stabilized on another ESA versus patients not currently using an ESA.

56.1.3.4.3.1 Patients Not Currently Using an ESA.

The initial dosage is 0.6 mcg/kg once every 2 weeks. When the hemoglobin level reaches 10 to 12 gm/dL, dosing should be done every 4 weeks, using twice the dose that had been given every 2 weeks.

56.1.3.4.3.2 Patients Already Stabilized on Epoetin Alfa or Darbepoetin Alfa.

The dosage of MPEG–epoetin beta is based on the *total weekly* dosage of the current ESA as follows:

- *Less than 8000 units epoetin alfa or less than 40 mcg darbepoetin alfa*—give 60 mcg every 2 weeks or 120 mcg every month
- *8000 to 16,000 units epoetin alfa or 40 to 80 mcg darbepoetin alfa*—give 100 mcg every 2 weeks or 200 mcg every month
- *More than 16,000 units epoetin alfa or more than 80 mcg darbepoetin alfa*—give 180 mcg every 2 weeks or 360 mcg every month

56.2 LEUKOPOIETIC GROWTH FACTORS

The leukopoietic growth factors stimulate production of leukocytes (white blood cells). Three preparations are available: filgrastim, pegfilgrastim, and sargramostim.

56.2.1 Filgrastim (Granulocyte Colony-Stimulating Factor)

Filgrastim [Neupogen] is a leukopoietic growth factor produced by recombinant DNA technology. The drug is essentially identical in structure and actions to human granulocyte colony-stimulating factor (G-CSF), a naturally occurring hormone. Filgrastim has two principal uses: elevation of neutrophil counts in cancer patients and treatment of severe chronic neutropenia.

56.2.1.1 Physiology

G-CSF acts on cells in bone marrow to increase production of neutrophils (granulocytes). In addition, it enhances phagocytic and cytotoxic actions of mature neutrophils. The hormone is produced by monocytes, fibroblasts, and endothelial cells in response to inflammation and allergic challenge, suggesting that its natural role is to help fight infection and cancer.

56.2.1.2 Therapeutic Uses

56.2.1.2.1 Cancer.

56.2.1.2.1.1 Patients Undergoing Myelosuppressive Chemotherapy.

Filgrastim is given to reduce the risk of infection in patients undergoing cancer chemotherapy. Many anticancer drugs act on the bone marrow to suppress production of neutrophils, thereby greatly increasing the risk of infection. By stimulating neutrophil production, filgrastim can decrease infection risk. Clinical trials have shown that treatment (1) reduces the incidence of severe neutropenia, (2) produces a dose-dependent increase in circulating neutrophils, (3) reduces the incidence of infection, (4) reduces the need for hospitalization, and (5) reduces the need for intravenous antibiotics. Unfortunately, this useful drug is very expensive: The cost for a single course of treatment is over \$3500. Because filgrastim stimulates proliferation of bone marrow cells, it should be used with great caution in patients with cancers that originated in the marrow.

56.2.1.2.1.2 Patients Undergoing Bone Marrow Transplantation

Filgrastim is given to shorten the duration of neutropenia in patients who have undergone high-dose chemotherapy followed by BMT. As noted, the drug is not used when the cancer is of myeloid origin.

650

651

56.2.1.2.1.3 Harvesting of Peripheral Blood Progenitor Cells

Peripheral blood progenitor cells (PBPCs) are harvested prior to bone marrow ablation with high-dose chemotherapy. Following chemotherapy, the PBPCs are infused back into the patient to accelerate repopulation of the bone marrow. Treatment with filgrastim prior to harvesting increases the number of circulating PBPCs, and therefore facilitates collection.

56.2.1.2.2 Severe Chronic Neutropenia.

Filgrastim provides effective treatment for *congenital neutropenia* (Kostmann's syndrome), a condition characterized by pronounced neutropenia and frequent, severe infections. Therapy helps resolve existing infections and decreases the incidence of subsequent infections.

Because treatment is chronic, the cost is very high. In addition to congenital neutropenia, filgrastim is used in patients with *idiopathic neutropenia* and *cyclic neutropenia*.

56.2.1.2.3 Investigational Uses.

Filgrastim can reverse *zidovudine-induced neutropenia* in HIV-infected patients. However, the drug does not reduce the incidence of opportunistic infections. In patients with *acute myelogenous leukemia*, filgrastim has been given to stimulate division of cancer cells, thereby making them more sensitive to chemotherapeutic agents. Filgrastim has also been employed in patients with *aplastic anemia* and *myelodysplasia*.

56.2.1.3 Pharmacokinetics

Administration is parenteral (IV or subQ). Filgrastim cannot be used orally because, being a protein, it would be destroyed in the GI tract. The drug is eliminated by renal excretion. Its serum half-life is about 3.5 hours.

56.2.1.4 Adverse Effects and Interactions

When used short-term, filgrastim is generally devoid of serious adverse effects. There are no drug interactions of note.

56.2.1.4.1 Bone Pain.

Filgrastim causes bone pain in about 25% of patients. Pain is dose related and usually mild to moderate. In most cases, relief can be achieved with a nonopioid analgesic (eg, acetaminophen). If not, an opioid may be tried.

56.2.1.4.2 Leukocytosis.

When administered in doses greater than 5 mcg/kg/day, filgrastim has caused white blood cell counts to rise above $100,000/\text{mm}^3$ in 2% of patients. Although no adverse effects were associated with this degree of leukocytosis, avoiding leukocytosis would nonetheless be prudent. Excessive white cell counts can be avoided by obtaining complete blood counts twice weekly during treatment and by reducing filgrastim dosage if leukocytosis develops.

56.2.1.4.3 Other Adverse Effects.

Treatment frequently causes elevation of plasma uric acid, lactate dehydrogenase, and alkaline phosphatase. Increases are usually moderate and reverse spontaneously. Long-term therapy has caused splenomegaly.

56.2.1.5 Preparations, Dosage, and Administration

56.2.1.5.1 Preparations and Storage.

Filgrastim [Neupogen] is supplied in solution (300 mcg/mL) in 1-mL and 1.6-mL single-dose vials. The drug is stored at 2°C to 8°C—not frozen.

56.2.1.5.2 Dosage and Administration.

General Considerations.

Prior to administration, filgrastim can be kept at room temperature for up to 6 hours. It should not be agitated. Only one dose per vial should be used, and the vial should not be re-entered.

56.2.1.5.2.1 Cancer Chemotherapy.

The usual dosage is 5 mcg/kg once daily, given IV or subQ. Therapy should start no sooner than 24 hours after termination of chemotherapy, and should continue up to 2 weeks after the expected chemotherapy-induced nadir, or until the absolute neutrophil count has reached 10,000/mm³. Administer by subQ bolus, short IV infusion, or continuous IV or subQ infusion. A complete blood count and platelet count should be obtained prior to treatment and twice weekly during treatment.

56.2.1.5.2.2 Bone Marrow Transplant.

The initial dosage is 10 mcg/kg/day, administered by slow IV or subQ infusion. During the period of neutrophil recovery, dosage is titrated against the neutrophil count.

56.2.1.5.2.3 Severe Chronic Neutropenia.

Dosage is 6 mcg/kg subQ administered twice a day every day.

56.2.2 Pegfilgrastim (Granulocyte Colony-Stimulating Factor, Long Acting)

Pegfilgrastim [Neulasta] is a long-acting derivative of filgrastim [Neupogen]. Both drugs stimulate myeloid cells to increase production of neutrophils. Pegfilgrastim is made by

conjugating filgrastim with polyethylene glycol (PEG), in a process known as pegylation. Pegylation increases the size of filgrastim, and thereby delays its excretion by the kidneys. As a result, the drug's half-life is greatly increased—from 3.5 hours (for native filgrastim) up to about 17 hours. Because pegfilgrastim has a longer half-life than filgrastim, the drug is easier to use: A course of treatment consists of just one dose, rather than one dose every day for 2 weeks. At this time, pegfilgrastim has only one approved application: prevention of febrile neutropenia in patients undergoing chemotherapy of nonmyeloid malignancies. As discussed above, filgrastim has additional uses.

Adverse effects are much like those of filgrastim. Bone pain is the most common, occurring in 26% of patients. About 6% require an opioid analgesic for relief. Other side effects include reversible elevations of lactate dehydrogenase, alkaline phosphatase, and uric acid.

56.2.2.1 Preparations, Dosage, and Administration.

Pegfilgrastim [Neulasta] is available in solution (10 mg/mL) in pre-filled, single-dose syringes. For all patients, treatment consists of one 6-mg subQ dose, injected 24 hours after each round of chemotherapy. Because stimulated myeloid cells are highly vulnerable to anticancer drugs, and because pegfilgrastim has a prolonged duration of action, at least 14 days must elapse between injecting pegfilgrastim and the next round of chemotherapy. Accordingly, if the scheduled interval between rounds of chemotherapy is less than 15 days (24 hours plus 14 days), pegfilgrastim cannot be used. Instead, filgrastim, with its shorter duration of action, should be employed. Pegfilgrastim has not been evaluated in infants, children, or adolescents who weigh less than 45 kg. Accordingly, the drug should not be used in these patients. Pegfilgrastim is expensive, costing over \$3000 per dose. A comparable course of filgrastim costs about the same.

56.2.3 Sargramostim (Granulocyte-Macrophage Colony-Stimulating Factor)

Sargramostim [Leukine] is a hematopoietic growth factor produced by recombinant DNA technology. The drug is nearly identical in structure and actions to human granulocyte-macrophage colony-stimulating factor (GM-CSF), a naturally occurring hormone. Sargramostim is given to accelerate bone marrow recovery following bone marrow transplantation (BMT).

56.2.3.1 Physiology

GM-CSF acts on cells in bone marrow to increase production of neutrophils, monocytes, macrophages, and eosinophils. In addition, the hormone acts on the mature forms of these cells to enhance their function. For example, GM-CSF acts on neutrophils and macrophages to increase their chemotactic, antifungal, and antiparasitic actions. Also, the hormone acts on

monocytes and polymorphonuclear leukocytes to enhance their actions against cancer cells. GM-CSF is synthesized by T lymphocytes, monocytes, fibroblasts, and endothelial cells. Like G-CSF, GM-CSF is produced in response to inflammation and allergic challenge, suggesting that its natural role is to help fight infection and cancer.

651

652

56.2.3.2 Therapeutic Uses

56.2.3.2.1 Adjunct to Autologous Bone Marrow Transplantation.

Sargramostim can accelerate myeloid recovery in cancer patients who have undergone autologous BMT following high-dose chemotherapy (with or without concurrent irradiation). The drug is approved for promoting myeloid recovery following BMT in patients with acute lymphoblastic leukemia, non-Hodgkin's lymphoma, and Hodgkin's disease. In these patients, sargramostim can (1) accelerate neutrophil engraftment, (2) reduce the duration of antibiotic use, (3) reduce the duration of infectious episodes, and (4) reduce the duration of hospitalization. Therapy is expensive: The cost for a 21-day course of sargramostim is more than \$5000.

56.2.3.2.2 Treatment of Failed Bone Marrow Transplants.

Sargramostim is approved for patients in whom an autologous or allogenic bone marrow transplant has failed to take. For these patients, the drug can produce a significant increase in survival time.

56.2.3.2.3 Patients with Acute Myelogenous Leukemia (AML).

Sargramostim is given following induction chemotherapy in older patients with AML. The goal is to accelerate neutrophil recovery and reduce the incidence of life-threatening infections.

56.2.3.2.4 Investigational Uses.

In *HIV-infected patients*, sargramostim can reverse neutropenia caused by zidovudine (a drug that inhibits HIV replication) and by ganciclovir (a drug for cytomegalovirus retinitis).

In patients with *aplastic anemia* (a syndrome characterized by pancytopenia and high mortality from infection and bleeding), sargramostim can increase neutrophil counts and reduce the incidence and severity of infections.

Sargramostim is beneficial for patients with *myelodysplastic syndrome* (MDS), a chronic disorder characterized by greatly reduced hematopoiesis. Patients with MDS are neutropenic,

thrombocytopenic, and anemic, putting them at high risk for serious infections and bleeding. The syndrome has a mortality rate of 66%—and those who survive often develop leukemia. Treatment with sargramostim can increase counts of neutrophils, eosinophils, and monocytes. However, the premalignant clone still exists and may eventually cause leukemia.

56.2.3.3 Pharmacokinetics

Sargramostim is administered by IV infusion. Since the drug is a protein and hence would be degraded in the digestive tract, it cannot be administered by mouth. Other aspects of its kinetics are unremarkable.

56.2.3.4 Adverse Effects and Interactions

Sargramostim is generally well tolerated. A variety of acute reactions have been observed, including diarrhea, weakness, rash, malaise, and bone pain that can be managed with nonopioid analgesics (eg, acetaminophen). Pleural and pericardial effusions have occurred, but only when sargramostim dosage was massive (16 times the recommended dosage). There are no drug interactions of note.

56.2.3.4.1 Leukocytosis and Thrombocytosis.

Stimulation of the bone marrow can cause excessive production of white blood cells and platelets. Complete blood counts should be done twice weekly during therapy. If the white cell count rises above $50,000/\text{mm}^3$, if the absolute neutrophil count rises above $20,000/\text{mm}^3$, or if the platelet count rises above $500,000/\text{mm}^3$, sargramostim should be interrupted or the dosage reduced.

56.2.3.5 Preparations, Dosage, and Administration

56.2.3.5.1 Preparations.

Sargramostim [Leukine] is available as a powder (250 mcg) to be reconstituted in 1 mL of sterile water for IV infusion. A solution formulation (500 mcg/mL) has been withdrawn from the market.

56.2.3.5.2 Dilution.

To prepare the final infusion solution, dilute the reconstituted powder in either (1) 0.9% sodium chloride (if the final concentration of sargramostim is to be 10 mcg/mL or more) or (2) 0.9% sodium chloride plus 0.1% albumin (if the final concentration is to be less than 10

mcg/mL). Since the solution contains no antibacterial preservatives, it should be used as soon as possible—and no later than 6 hours after preparation.

56.2.3.5.3 Storage.

All sargramostim preparations should be stored at 2°C to 8°C (never frozen).

56.2.3.5.4 Dosage and Administration.

To accelerate myeloid recovery after autologous BMT, the recommended dosage is 250 mcg/m² (as a 2-hour IV infusion) administered once daily for 21 days beginning 2 to 4 hours after the bone marrow infusion.

For patients in whom an autologous or allogenic bone marrow transplant has failed or in whom engraftment has been delayed, the recommended dosage is 250 mcg/m² (as a 2-hour IV infusion) administered once daily for 14 days. After a 7-day hiatus, the 14-day series of infusions can be repeated if needed. After another 7-day hiatus, the 14-day series can be repeated once more if needed. If the graft still has not taken, further treatment is unlikely to help.

To accelerate neutrophil recovery following chemotherapy for AML, the recommended dosage is 250 mcg/m²/day (as a 4-hour IV infusion), starting on day 11 (or 4 days after completing the course of chemotherapy). Continue daily infusions for 42 days or until the absolute neutrophil count exceeds 1500 cells/mm³ on 3 consecutive days, whichever is less.

56.3 THROMBOPOIETIC GROWTH FACTOR

Thrombopoietic growth factors are compounds that stimulate production of thrombocytes (platelets). At this time, oprelvekin is the only thrombopoietic growth factor available.

56.3.1 Oprelvekin (Interleukin-11)

Oprelvekin [Neumega] is a thrombopoietic growth factor produced by recombinant DNA technology. The drug is a protein nearly identical in structure and actions to human *interleukin-11*, a cytokine produced in bone marrow. Oprelvekin is given to stimulate platelet production in patients undergoing myelosuppressive chemotherapy for nonmyeloid cancers.

56.3.1.1 Actions

Oprelvekin acts on platelet progenitor cells to increase platelet production. Specifically, it stimulates proliferation of hematopoietic stem cells and megakaryocyte progenitor cells, and

thereby increases synthesis of megakaryocytes, the cells that synthesize platelets. In addition to promoting megakaryocyte *synthesis*, oprelvekin induces megakaryocyte *maturation*. The net result is increased platelet production. In patients treated with oprelvekin daily for 14 days, platelet counts begin to increase 5 to 9 days after the first injection, peak about 7 days after the last injection, and return to baseline 14 days after that.

56.3.1.2 Therapeutic Use

Oprelvekin is administered to patients undergoing myelosuppressive chemotherapy to minimize thrombocytopenia (platelet deficiency) and to decrease the need for platelet transfusions. Because it stimulates the bone marrow, oprelvekin should *not* be given to patients with cancers of myeloid origin.

In clinical trials, oprelvekin was effective for some patients but not others. To assess its benefits, oprelvekin was given to patients who had required platelet transfusions following earlier rounds of chemotherapy. Some patients were on moderately myelosuppressive regimens and some were on highly suppressive regimens. Among those on moderately suppressive regimens, 30% were spared the need for platelet transfusions by combining oprelvekin with chemotherapy. Among

652

those on highly suppressive regimens, only 13% were spared the need for platelet transfusions.

653

Hence, although oprelvekin can increase platelet counts and decrease the need for platelet transfusions, not all patients benefit equally. As these data indicate, the more myelosuppressive the regimen, the less effective oprelvekin is likely to be.

56.3.1.3 Pharmacokinetics

Oprelvekin is administered by subQ injection. (The drug is a protein and hence cannot be administered by mouth.) Serum levels peak about 3 hours after administration. Elimination is by hepatic and renal tubular metabolism, followed by excretion of the metabolites in urine. Children eliminate the drug faster than adults.

56.3.1.4 Adverse Effects

56.3.1.4.1 Fluid Retention.

Oprelvekin causes retention of sodium and water by the kidney. The result is *peripheral edema* and a 10% to 15% *expansion of plasma volume*. Expansion of plasma volume decreases both the hematocrit and hemoglobin concentration, thereby causing anemia. As a result, about 48% of patients experience dyspnea (shortness of breath on exertion). Because of fluid retention, oprelvekin should be used with caution in patients with a history of heart

failure or pleural effusion. Fluid balance should be monitored throughout treatment. Following oprelvekin withdrawal, fluid balance normalizes within days.

56.3.1.4.2 Cardiac Dysrhythmias.

Tachycardia, atrial fibrillation, and atrial flutter are common. The incidence of tachycardia is higher in children (46%) than in adults. Conversely, atrial flutter and fibrillation are more likely in older adults. The cause of cardiac effects is unclear, although expansion of plasma volume is suspected. Oprelvekin does not affect the heart directly.

56.3.1.4.3 Severe Allergic Reactions.

Oprelvekin has been associated with severe allergic reactions, including anaphylaxis. Signs of oprelvekin-induced allergy include rash, urticaria, flushing, fever, hypotension, joint pain, chest pain, wheezing, shortness of breath, and edema of the face, tongue, and larynx. Patients and healthcare providers should be alert for these reactions and, if allergy is diagnosed, oprelvekin should be withdrawn and never used again.

56.3.1.4.4 Effects on the Eye.

Conjunctival injection is common. The incidence is 50% in children and 19% in adults. Other ophthalmic effects are transient visual blurring and papilledema (edema of the optic disk).

56.3.1.4.5 Sudden Death.

Two patients have died. Both had severe hypokalemia, and both had been treated with a diuretic and high doses of ifosfamide (an anticancer drug). Although oprelvekin is suspected, its precise role in these deaths is unknown.

56.3.1.5 Preparations, Dosage, and Administration

56.3.1.5.1 Preparation.

Oprelvekin [Neumega] is supplied as a powder in 5-mg single-dose vials. To reconstitute, add 1 mL of Sterile Water for Injection (supplied with the drug) and gently swirl; don't shake. Neither the powder nor the diluent contains preservatives, and hence the solution must be used within 3 hours to avoid infection. Oprelvekin and its diluent should be refrigerated at 2°C to 8°C.

56.3.1.5.2 Dosage and Administration.

Oprelvekin is administered by subQ injection into the abdomen, thigh, hip, or upper arm. The recommended adult dosage is 50 mcg/kg once daily; the pediatric dosage is 75 to 100 mcg/kg once daily. Dosing should begin 4 to 6 hours after chemotherapy and should continue until the platelet count rises above 50,000/mm³—but should not exceed 21 days. Treatment should cease 2 days before the next round of chemotherapy.

56.3.1.5.2.1

KEY POINTS

- Epoetin is given to increase red blood cell counts. Specific indications include anemia associated with (1) chronic renal failure, (2) zidovudine therapy in AIDS patients, and (3) cancer chemotherapy.
- By increasing the hematocrit, epoetin can cause or exacerbate hypertension.
- Epoetin increases the risk of cardiovascular events (eg, cardiac arrest, stroke, HF, MI), especially when the hemoglobin level exceeds 12 gm/dL or the rate of rise in hemoglobin exceeds 1 gm/dL in 2 weeks.
- In some cancer patients, epoetin can accelerate tumor progression and shorten life.
- Filgrastim is given to elevate neutrophil counts, and thereby reduce the risk of infection. Specific indications are chronic severe neutropenia and neutropenia associated with cancer chemotherapy or BMT.
- The principal adverse effects of filgrastim are bone pain and leukocytosis.
- Sargramostim is used to accelerate recovery from BMT, treat patients in whom a bone marrow transplant has failed, and accelerate neutrophil recovery in patients undergoing chemotherapy for AML.
- The principal adverse effect of sargramostim is leukocytosis.
- Oprelvekin is given to stimulate platelet production in patients undergoing myelosuppressive chemotherapy for nonmyeloid cancers. The goal is to minimize thrombocytopenia and platelet transfusions.
- The principal adverse effects of oprelvekin are fluid retention (which causes edema and anemia), cardiac dysrhythmias (tachycardia, atrial fibrillation, and atrial flutter), and severe allergic reactions, including anaphylaxis.

- Since epoetin alfa, filgrastim, sargramostim, and oprelvekin stimulate proliferation of bone marrow cells, these drugs should be used with great caution, if at all, in patients with cancers of bone marrow origin.

653

56.3.1.5.2.2

Summary of Major Nursing Implications*

654

56.3.1.5.2.2.1

EPOETIN ALFA (ERYTHROPOIETIN)

56.3.1.5.2.2.1.1

Preadministration Assessment

56.3.1.5.2.2.1...

Therapeutic Goal

Epoetin is used to restore and maintain erythrocyte counts in (1) patients with chronic renal failure, (2) HIV-infected patients receiving zidovudine, (3) patients receiving cancer chemotherapy, and (4) anemic patients facing elective surgery. For most patients, the hemoglobin target level is 10 to 12 gm/dL, and should never exceed 12 gm/dL.

56.3.1.5.2.2.1...

Baseline Data

56.3.1.5.2.2.1...

All Patients.

Obtain blood pressure; blood chemistry (BUN, uric acid, creatinine, phosphorus, potassium); complete blood counts with differential and platelet count; hemoglobin level; degree of transferrin saturation (should be at least 20%); and ferritin concentration (should be at least 100 ng/mL).

56.3.1.5.2.2.1...

HIV-Infected Patients.

Obtain an erythropoietin level. If the level is above 500 milliunits/mL, epoetin is unlikely to help.

56.3.1.5.2.2.1...

Identifying High-Risk Patients

Epoetin alfa is *contraindicated* for patients with uncontrolled hypertension or hypersensitivity to mammalian cell–derived products or albumin, and in cancer patients who are not undergoing either chemotherapy or radiation therapy.

Use with *caution* in patients with cancers of myeloid origin.

56.3.1.5.2.2.1.2

Implementation: Administration

56.3.1.5.2.2.1...

Routes

IV and subQ.

56.3.1.5.2.2.1...

Handling and Storage

Epoetin alfa is supplied in single-use and multi-use vials; don't re-enter the single-use vials. Don't agitate. Don't mix with other drugs. Store at 2°C to 8°C; don't freeze.

56.3.1.5.2.2.1...

Administration

56.3.1.5.2.2.1...

Chronic Renal Failure.

Administer by IV bolus or subQ injection.

56.3.1.5.2.2.1...

Zidovudine-Induced Anemia.

Administer by IV or subQ injection.

56.3.1.5.2.2.1...

Chemotherapy-Induced Anemia.

Administer by subQ injection.

56.3.1.5.2.2.1...

Surgery Patients.

Administer by subQ injection.

56.3.1.5.2.2.1.3

Ongoing Evaluation and Interventions

56.3.1.5.2.2.1...

Monitoring Summary

Measure hemoglobin level twice weekly until the target level (10 to 12 gm/dL) has been reached and a maintenance dosage established, and measure hemoglobin periodically thereafter. Obtain complete blood counts with a differential and platelet counts routinely. Monitor blood chemistry, including BUN, uric acid, creatinine, phosphorus, and potassium. Monitor iron stores and maintain at an adequate level. Monitor blood pressure.

56.3.1.5.2.2.1...

Minimizing Adverse Effects

56.3.1.5.2.2.1...

Hypertension.

Monitor blood pressure and, if necessary, control with antihypertensive drugs. If hypertension cannot be controlled, reduce epoetin dosage. In patients with pre-existing hypertension (a common complication of CRF), make certain that blood pressure is controlled prior to epoetin use.

56.3.1.5.2.2.1...

Autoimmune Pure Red-Cell Aplasia.

Epoetin use may lead to pure red-cell aplasia (PRCA), owing to production of neutralizing antibodies directed against epoetin and native erythropoietin. If evidence of PRCA develops, epoetin should be discontinued and blood assessed for neutralizing antibodies. If PRCA is diagnosed, transfusions will be needed for life.

56.3.1.5.2.2.1...

Cardiovascular Events.

Epoetin has been associated with an increase in cardiovascular events (eg, cardiac arrest, stroke, HF, and MI). Risk is greatest when the hemoglobin level exceeds 12 gm/dL or the rate of rise in hemoglobin exceeds 1 gm/dL in 2 weeks. To minimize risk, reduce dosage when hemoglobin approaches 12 gm/dL or when the rate of rise exceeds 1 gm/dL in 2 weeks, and temporarily stop dosing if hemoglobin rises to 13 gm/dL or more. CRF patients on dialysis may need a higher dosage of heparin to prevent clotting in the artificial kidney.

For patients taking the drug prior to elective surgery, anticoagulant treatment can reduce the risk of deep vein thrombosis.

56.3.1.5.2.2.1...

Cancer Patients: Tumor Progression and Shortened Survival.

Epoetin can accelerate tumor progression and shorten survival in some cancer patients. To reduce risk, dosage should be no higher than needed to bring hemoglobin gradually up to 12 gm/dL. Also, epoetin should be used only in cancer patients who are undergoing chemotherapy or radiation therapy. Those who are not receiving chemotherapy or radiation therapy should not get this drug.

56.3.1.5.2.2.2	FILGRASTIM (GRANULOCYTE COLONY-STIMULATING FACTOR)	
56.3.1.5.2.2.2.1	Preadministration Assessment	
56.3.1.5.2.2.2...	Therapeutic Goal	
	Filgrastim is given to promote neutrophil recovery in cancer patients following myelosuppressive chemotherapy or BMT. The drug is also used to treat severe chronic neutropenia.	
56.3.1.5.2.2.2...	Baseline Data	
	Obtain complete blood counts and platelet counts.	
56.3.1.5.2.2.2...	Identifying High-Risk Patients	
	Filgrastim is <i>contraindicated</i> for patients with hypersensitivity to <i>Escherichia coli</i> –derived proteins.	654
	Use with <i>caution</i> in patients with cancers of bone marrow origin.	655
56.3.1.5.2.2.2.2	Implementation: Administration	
56.3.1.5.2.2.2...	Routes	
	IV, subQ.	
56.3.1.5.2.2.2...	Handling and Storage	
	Filgrastim is supplied in single-use vials. Don't re-enter the vial; discard the unused portion. Don't agitate. Store at 2°C to 8°C; don't freeze. Prior to administration, filgrastim may be kept at room temperature for up to 6 hours.	
56.3.1.5.2.2.2...	Administration	
56.3.1.5.2.2.2...	Cancer Chemotherapy.	
	Administer by subQ bolus, short IV infusion, or continuous IV or subQ infusion.	
56.3.1.5.2.2.2...	Bone Marrow Transplantation.	
	Administer by slow IV or subQ infusion.	

56.3.1.5.2.2.2...

Chronic Severe Neutropenia.

Inject subQ twice daily every day.

56.3.1.5.2.2.2.3

Ongoing Evaluation and Interventions

56.3.1.5.2.2.2...

Evaluating Therapeutic Effects

Obtain complete blood counts twice weekly. Discontinue treatment when the absolute neutrophil count reaches 10,000/mm³.

56.3.1.5.2.2.2...

Minimizing Adverse Effects

56.3.1.5.2.2.2...

Bone Pain.

Evaluate for bone pain and treat with a nonopioid analgesic (eg, acetaminophen). Consider an opioid analgesic if the nonopioid is insufficient.

56.3.1.5.2.2.2...

Leukocytosis.

Massive doses can cause leukocytosis (white blood cell counts above 100,000/mm³). If leukocytosis develops, reduce filgrastim dosage.

56.3.1.5.2.2.3

SARGRAMOSTIM (GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR)

56.3.1.5.2.2.3.1

Preadministration Assessment

56.3.1.5.2.2.3...

Therapeutic Goal

Acceleration of myeloid recovery in cancer patients who have undergone autologous BMT following high-dose chemotherapy (with or without concurrent irradiation).

Treatment of patients for whom an autologous or allogenic bone marrow transplant has failed to take.

Acceleration of neutrophil recovery in older patients receiving induction chemotherapy for AML.

56.3.1.5.2.2.3...

Baseline Data

Obtain complete blood counts with differential and platelet count.

56.3.1.5.2.2.3...

Identifying High-Risk Patients

Sargramostim is *contraindicated* in the presence of hypersensitivity to yeast-derived products and excessive leukemic myeloid blasts in bone marrow or peripheral blood.

Exercise *caution* in patients with cardiac disease, hypoxia, peripheral edema, pleural or pericardial effusion, or cancers of bone marrow origin.

56.3.1.5.2.2.3.2

Implementation: Administration

56.3.1.5.2.2.3...

Route

IV (by infusion).

56.3.1.5.2.2.3...

Handling and Storage

Sargramostim is supplied in concentrated solution and as a powder, which must be reconstituted for IV infusion. To reconstitute the powder, add 1 mL of sterile water and gently swirl. Before infusing, dilute the concentrated solution or reconstituted powder. Administer as soon as possible after diluting—and no later than 6 hours after reconstitution. Store sargramostim (powder, reconstituted powder, final IV solution) at 2°C to 8°C until used.

56.3.1.5.2.2.3...

Administration

Administer by 2-hour or 4-hour IV infusion.

56.3.1.5.2.2.3.3

Ongoing Evaluation and Interventions

56.3.1.5.2.2.3...

Minimizing Adverse Effects

56.3.1.5.2.2.3...

Leukocytosis and Thrombocytosis.

Obtain complete blood counts with a differential and platelet counts twice weekly. If the white blood cell count rises above 50,000/mm³, if the absolute

	neutrophil count rises above 20,000/mm ³ , or if the platelet count rises above 500,000/mm ³ , temporarily interrupt sargramostim or reduce the dosage.	
56.3.1.5.2.2.4	OPRELVEKIN (INTERLEUKIN-11)	
56.3.1.5.2.2.4.1	Preadministration Assessment	
56.3.1.5.2.2.4...	Therapeutic Goal	
	Oprelvekin is given to minimize thrombocytopenia and the need for platelet transfusions in patients undergoing myelosuppressive therapy for nonmyeloid cancers.	
56.3.1.5.2.2.4...	Baseline Data	
	Determine baseline blood cell counts and platelet count, hematocrit, and fluid and electrolyte status.	
56.3.1.5.2.2.4...	Identifying High-Risk Patients	
	Use with <i>caution</i> in patients with cancers of myeloid origin; patients taking diuretics or ifosfamide; and patients with a history of atrial dysrhythmias, heart failure, pleural effusion, or papilledema.	
56.3.1.5.2.2.4.2	Implementation: Administration	
56.3.1.5.2.2.4...	Route	
	SubQ.	
56.3.1.5.2.2.4...	Handling and Storage	
	Oprelvekin is supplied in single-use vials; don't re-enter the vial. Don't agitate. Don't mix with other drugs. Store at 2°C to 8°C; don't freeze.	655
56.3.1.5.2.2.4...	Administration	656
	Administer once daily beginning 4 to 6 hours after chemotherapy. Continue for 21 days or until platelet counts exceed 50,000/mm ³ —whichever comes first.	

56.3.1.5.2.2.4.3

Ongoing Evaluation and Interventions

56.3.1.5.2.2.4...

Monitoring Summary

Monitor platelet counts from the time of the expected nadir until the count exceeds 50,000/mm³. Monitor blood cell counts, fluid status, and electrolyte status.

56.3.1.5.2.2.4...

Minimizing Adverse Effects

56.3.1.5.2.2.4...

Fluid Retention.

Fluid retention can result in edema, expanded plasma volume, anemia, and dyspnea. **Instruct patients with a history of congestive heart failure or pleural effusion to contact the prescriber if dyspnea worsens.**

56.3.1.5.2.2.4...

Cardiac Dysrhythmias.

Oprelvekin can cause tachycardia, atrial flutter, and atrial fibrillation. Use caution in patients with a history of these disorders.

⁵⁷CHAPTER 56 Drugs for Diabetes Mellitus

MARSHAL SHLAFFER

^{57.1}DIABETES MELLITUS: OVERVIEW OF THE DISEASE AND ITS TREATMENT

The term *diabetes mellitus* is derived from the Greek word for *fountain* and the Latin word for *honey*. Hence, the term describes one of the prominent symptoms of untreated diabetes: production of large volumes of glucose-rich urine. Indeed, very long ago, the disease we now call diabetes was “diagnosed” by the sweet smell of urine—and, yes, by its sweet taste as well. In this chapter we use the terms *diabetes mellitus* and *diabetes* interchangeably.

Diabetes is primarily a disorder of carbohydrate metabolism. Symptoms result from a deficiency of insulin or from cellular resistance to insulin's actions. The principal sign of diabetes is *sustained hyperglycemia*, which results from impaired glucose uptake by cells and from increased glucose production. When hyperglycemia develops, it can quickly lead to polyuria, polydipsia, ketonuria, and weight loss. Over time, hyperglycemia can lead to hypertension, heart disease, renal failure, blindness, neuropathy, amputations, impotence, and stroke. In addition to affecting carbohydrate metabolism, insulin deficiency disrupts metabolism of proteins and lipids as well.

Diabetes is a major public health concern. In the United States, diabetes is the most common endocrine disorder, and the sixth leading cause of death by disease. According to the Centers for Disease Control and Prevention, 23.6 million Americans have diabetes, and nearly one-quarter of them have not been diagnosed. Another 57 million Americans are prediabetic, and hence are at increased risk of developing diabetes in the future. In 2007, diabetes cost the U.S. economy an estimated \$174 billion (\$116 billion in direct medical expenditures and \$58 billion in lost productivity). These costs represent a 32% increase over the estimated costs for 2002. Put another way, the total cost of diabetes is going up by roughly \$8.4 billion every year.

^{57.1.1}Types of Diabetes Mellitus

There are two main forms of diabetes mellitus: type 1 diabetes mellitus and type 2 diabetes mellitus. Both forms have similar signs and symptoms. Major differences concern etiology, prevalence, treatments, and outcomes (illness severity and deaths). The distinguishing characteristics of type 1 and type 2 diabetes are summarized in [Table 56-1](#) and discussed immediately below. Another important form—gestational diabetes—is discussed below under *Diabetes and Pregnancy*.

57.1.1.1 Type 1 Diabetes

Type 1 diabetes accounts for about 5% to 10% of all diabetes cases. Between 1.2 million and 2.4 million Americans have this disorder. In the past, type 1 diabetes was called *insulin-dependent diabetes mellitus (IDDM)* or *juvenile-onset diabetes mellitus*. As a rule, type 1 diabetes develops during childhood or adolescence. Onset of symptoms is relatively abrupt.

657

658

TABLE 56-1 Characteristics of Type 1 and Type 2 Diabetes Mellitus

Characteristics	Type of Diabetes Mellitus	
	Type 1	Type 2
Alternative names	Insulin-dependent diabetes mellitus, juvenile-onset diabetes mellitus, ketosis-prone diabetes mellitus	Non-insulin-dependent diabetes mellitus, adult-onset diabetes mellitus
Age of onset	Usually childhood or adolescence	Usually over 40
Speed of onset	Abrupt	Gradual
Family history	Usually negative	Frequently positive
Prevalence	5% to 10% of diabetics have type 1 diabetes	90% to 95% of diabetics have type 2 diabetes
Etiology	Autoimmune process	Unknown—but there is a strong familial association, suggesting heredity is a risk factor
Primary defect	Loss of pancreatic beta cells	Insulin resistance and inappropriate insulin secretion
Insulin levels	Reduced early in the disease and completely absent later	Levels may be low (indicating deficiency), normal, or high (indicating resistance)
Treatment	Insulin replacement is mandatory, along with strict dietary control; oral hypoglycemic drugs are <i>not</i> effective	Exercise and a reduced-calorie diet may be sufficient; if not, an oral hypoglycemic agent and/or insulin is required
Blood glucose	Levels fluctuate widely in response to infection, exercise, and changes in caloric intake and insulin dose	Levels are more stable than in type 1 diabetes
Symptoms	Polyuria, polydipsia, polyphagia, weight loss	May be asymptomatic
Body composition	Usually thin and undernourished	Frequently obese
Ketosis	Common, especially if insulin dosage is insufficient	Uncommon

The primary defect in type 1 diabetes is destruction of pancreatic beta cells—the cells responsible for insulin synthesis. Insulin levels are reduced early in the disease and fall to zero later. Beta cell destruction is the result of an autoimmune process (ie, development of antibodies against the patient's own beta cells). The trigger for this immune response is unknown.

57.1.1.2 Type 2 Diabetes

Type 2 diabetes is the most prevalent form of diabetes. Approximately 22 million Americans have this disease. In the past, type 2 diabetes was called *non–insulin-dependent diabetes mellitus (NIDDM)* or *adult-onset diabetes mellitus*. The disease usually begins in middle age and progresses gradually. Obesity is almost always present. In contrast to type 1 diabetes, type 2 diabetes carries little risk of ketoacidosis. However, type 2 diabetes does carry the same long-term risks as type 1 diabetes (see below).

Symptoms result from a combination of *insulin resistance* and *impaired insulin secretion*. In contrast to patients with type 1 diabetes, those with type 2 diabetes are capable of insulin synthesis. In fact, insulin levels tend to be normal or slightly elevated. However, although insulin is still produced, its secretion is no longer tightly coupled to plasma glucose content: release of insulin is delayed and peak output is subnormal. More importantly, the target tissues of insulin (liver, muscle, adipose tissue) exhibit insulin resistance. Resistance appears to result from three causes: reduced binding of insulin to its receptors, reduced receptor number, and reduced receptor responsiveness. Over time, hyperglycemia leads to destruction of pancreatic beta cells, and hence insulin production and secretion eventually decline.

Although the underlying cause of type 2 diabetes is unknown, there is a strong familial association, suggesting that genetics may be a major factor. This possibility was reinforced by a study that implicated the gene for *insulin receptor substrate-2 (IRS-2)*, a compound that helps mediate intracellular responses to insulin. Mice that lack a functional IRS-2 gene develop symptoms identical to those of type 2 diabetes (eg, insulin resistance in muscle and liver, fasting hypoglycemia, and gradual beta cell failure).

57.1.2 Short-Term Complications of Diabetes

Acute complications are seen mainly in type 1 diabetes. Principal concerns are *hyperglycemia* and *hypoglycemia*. Hyperglycemia results when insulin dosage is insufficient. Conversely, hypoglycemia results when the insulin dosage is excessive. *Ketoacidosis*, a potentially fatal acute complication, develops when hyperglycemia is allowed to persist. As noted above, ketoacidosis is rare with type 2 diabetes, and relatively common in patients with type 1 diabetes. All three complications are discussed below.

658

659

57.1.3 Long-Term Complications of Diabetes

The long-term sequelae of type 1 and type 2 diabetes take years to develop. More than 90% of diabetic deaths result from long-term complications, not from hypoglycemia or ketoacidosis.

Ironically, among patients with type 1 diabetes, insulin therapy can be viewed as having made long-term complications possible: Prior to the discovery of insulin, these people died long before chronic complications could arise.

Most long-term complications occur secondary to disruption of blood flow, owing to either macrovascular or microvascular damage. There is strong evidence that tight control of blood glucose can reduce *microvascular* injury. Tight glycemic control also reduces *macrovascular* injury, although other measures (eg, exercise, healthy diet, control of blood pressure and blood lipids) are also important.

57.1.3.1 Macrovascular Damage

Cardiovascular disease (CVD) is the leading cause of death among diabetic patients. Diabetes carries an increased risk of heart disease, hypertension, and stroke. Much of this pathology is due to atherosclerosis, which develops earlier in diabetics than in nondiabetics and progresses at a faster rate. Macrovascular complications result from a combination of hyperglycemia and altered lipid metabolism.

57.1.3.2 Microvascular Damage

Damage to small blood vessels and capillaries is common. The basement membrane of capillaries thickens, causing blood flow in the microvasculature to fall. Destruction of small blood vessels contributes to kidney damage, blindness, and various neuropathies. Microvascular injury is directly related to the degree and duration of hyperglycemia.

57.1.3.2.1 Retinopathy.

Diabetes is the major cause of blindness among American adults. Every year, 12,000 to 24,000 diabetics lose their sight. Visual losses result most commonly from damage to retinal capillaries. Microaneurysms may occur, followed by scarring and proliferation of new vessels; the overgrowth of new retinal capillaries reduces visual acuity. Capillary damage may also impair vision by causing local ischemia, which can kill retinal cells. Retinopathy is accelerated by hyperglycemia, hypertension, and smoking. Accordingly, these risk factors should be controlled or eliminated. All patients with diabetes, whether type 1 diabetes or type 2 diabetes, should have a comprehensive eye exam (preferably by an ophthalmologist) at least once a year.

57.1.3.2.2 Nephropathy.

Diabetic damage to the kidneys—diabetic nephropathy—is characterized by proteinuria, reduced glomerular filtration, and increased arterial blood pressure. Diabetic nephropathy is

the most common cause of end-stage renal disease, a condition that requires dialysis or a kidney transplant for survival. Between 10% and 21% of people with diabetes have kidney disease. The risk of nephropathy among patients with type 1 diabetes is 12 times higher than among patients with type 2 diabetes. Nephropathy is the primary cause of morbidity and mortality in patients with type 1 diabetes. If the injured kidney is replaced with a transplant, the new kidney is likely to fail within a few years unless tight glycemic control is established.

We can screen for kidney damage by testing for *microalbuminuria* (the presence of small amounts of albumin in the urine). Recall that albumin is the blood's major protein. When the kidney is healthy, the urine contains no albumin. Why? Because albumin is so large it cannot be filtered by the glomerulus. However, when the glomerulus is damaged, even slightly, some albumin gets filtered and enters the urine. A clinical lab can measure these tiny amounts. If renal function undergoes further decline, larger amounts of albumin will enter the urine. When this happens, the patient is said to have *microalbuminuria*, or simply *albuminuria*. After that? Eventually, renal failure.

Treatment of diabetes can delay the onset of nephropathy and reduce its severity. The Diabetes Control and Complications Trial (DCCT) revealed that tight glucose control decreases the risk of nephropathy by 35% to 56%. As discussed in [Chapter 43](#), treatment with an *angiotensin-converting enzyme (ACE) inhibitor* or an *angiotensin II receptor blocker (ARB)* can delay the onset of nephropathy, and can slow progression of nephropathy that is already present. Of note, ACE inhibitors and ARBs have an additional benefit: they can help control hypertension, a common complication of diabetes.

57.1.3.2.3 Sensory and Motor Neuropathy.

Nerve degeneration often begins early in the course of diabetes, but symptoms are usually absent for years. Sensory and motor nerves may be affected. Symptoms of diabetic neuropathy—which are usually bilateral and symmetric—include tingling sensations in the fingers and toes (paresthesias), pain, suppression of reflexes, and loss of sensation (especially vibratory sensation). Nerve damage is directly related to sustained hyperglycemia, which may cause metabolic disturbances in nerves or may injure the capillaries that supply nerves. In the DCCT, tight glycemic control reduced the incidence of peripheral neuropathy by 60%.

57.1.3.2.4 Autonomic Neuropathy: Gastroparesis.

Diabetic gastroparesis (delayed stomach emptying) affects 20% to 30% of patients with long-standing diabetes. Manifestations include nausea, vomiting, delayed gastric emptying, and abdominal (gastric or intestinal) distention. Injury to the autonomic nerves that control GI motility is the underlying cause. Symptoms can be reduced with metoclopramide [Reglan], a

dopaminergic drug that promotes gastric emptying (see [Chapter 79](#)). In addition to affecting autonomic nerves that innervate the GI tract, diabetes can affect autonomic nerves that innervate other structures.

57.1.3.2.5 Amputations Secondary to Infection.

Diabetes is responsible for more than 50% of lower limb amputations in the United States. Each year about 54,000 diabetic patients lose a foot or leg. The underlying cause is severe infection, which can develop following local trauma, be it major or minor. There are three reasons why serious infection can occur. First, hyperglycemia provides a glucose-rich environment for bacteria to grow. Second, diabetes can suppress immune function, and thereby compromise host defenses against infection. And third, diabetic neuropathy can prevent the patient from feeling discomfort and other sensations that would signal that a serious infection is developing. Because of these factors, an infection that would be inconsequential and self-limiting in nondiabetics can become very serious in a diabetic. If the infection spreads and becomes gangrenous, the only realistic and effective solution is to amputate. Because of these possibilities, regular *foot exams and foot care* are an important part of diabetes management.

659

57.1.3.2.6 Erectile Dysfunction.

The combination of blood vessel injury and neuropathy can cause erectile dysfunction. About 13% of men with type 1 diabetes and 8% of men with type 2 diabetes suffer diabetes-related impotence.

660

57.1.4 Diabetes and Pregnancy

Before the discovery of insulin, virtually all babies born to mothers with severe diabetes died during infancy. Although insulin therapy has greatly improved outcomes, successful management of the diabetic pregnancy remains a challenge. Three factors contribute to the problem. First, the placenta produces hormones that antagonize insulin's actions. Second, production of cortisol, a hormone that promotes hyperglycemia, increases threefold during pregnancy. Both factors increase the need for insulin. Third, because glucose can pass freely from the maternal circulation to the fetal circulation, hyperglycemia in the mother will stimulate secretion of fetal insulin; the resultant hyperinsulinemia can have multiple adverse effects on the developing fetus.

Successful management of diabetes during pregnancy demands that proper glucose levels be maintained in both the fetus and mother; failure to do so may be teratogenic or otherwise detrimental to the fetus. Achieving glucose control requires diligence on the part of the mother

and her prescriber. Blood glucose levels must be monitored 6 to 7 times a day. Insulin dosage and food intake must be adjusted accordingly.

Because fetal death frequently occurs near term, it is desirable that delivery take place as soon as development of the fetus will permit. Hence, when tests indicate sufficient fetal maturation, it is common practice to deliver the infant early—either by cesarean section or by induction of labor with drugs.

Gestational diabetes is defined as diabetes that appears during pregnancy and then subsides rapidly after delivery. Gestational diabetes is managed in much the same manner as any other diabetic pregnancy: blood glucose should be monitored and then controlled with diet and insulin. In most cases, the diabetic state disappears almost immediately after delivery, permitting discontinuation of insulin. However, if the diabetic condition persists beyond parturition, it is no longer considered gestational and should be rediagnosed and treated accordingly.

In women taking an oral drug for type 2 diabetes, current practice is to discontinue the oral drug and switch to insulin. The only exception is the oral agent metformin, which is often satisfactory for managing type 2 diabetes in pregnancy. Women who discontinued oral medications can resume oral therapy after delivery.

57.1.5 Diagnosis of Diabetes

Excessive plasma glucose is diagnostic of diabetes. Three tests may be employed: a fasting plasma glucose (FPG) test, a casual plasma glucose test, and an oral glucose tolerance test (OGTT). Values diagnostic of diabetes are summarized in [Table 56-2](#). To make a definitive diagnosis, the patient must be tested on two separate days, and both tests must be positive. Any combination of two tests (eg, two FPG tests; one FPG test and one OGTT) may be used.

57.1.5.1 Fasting Plasma Glucose Test.

To determine FPG levels, blood is drawn at least 8 hours after the last meal. In normoglycemic individuals, FPG levels are less than 100 mg/dL. If FPG glucose levels are 126 mg/dL or higher, diabetes is indicated. Of the tests employed to diagnose diabetes, the FPG test is preferred. In fact, if an initial casual plasma glucose test suggests diabetes, a follow-up FPG test is almost always used for confirmation.

TABLE 56-2 Criteria for the Diagnosis of Diabetes Mellitus

Fasting plasma glucose ≥ 126 mg/dL [*]
or
Casual plasma glucose ≥ 200 mg/dL <i>plus</i> symptoms of diabetes [†]
or
Oral glucose tolerance test (OGTT): 2-hr plasma glucose ≥ 200 mg/dL [‡]
Adapted from Expert Committee on the Diagnosis and Classification of Diabetes Mellitus: Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. Diabetes Care 26(Suppl 1): S5–S24, 2003.

* *Fasting* is defined as no caloric intake for at least 8 hours.

† *Casual* is defined as any time of day without regard to meals. Classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.

‡ In this OGTT, plasma glucose content is measured 2 hours after ingesting the equivalent of 75 gm of anhydrous glucose dissolved in water. The OGTT is not recommended or needed for routine clinical use.

57.1.5.2 Casual Plasma Glucose Test.

For this test, blood can be drawn at any time, without regard to meals. Fasting is not required. Of note, the test can be performed in the office, using a finger-stick blood sample and the same type of test device employed by patients at home. A plasma glucose level that is 200 mg/dL or higher suggests diabetes. However, to make a definitive diagnosis, the patient must also display classic signs of diabetes: polyuria, polydipsia, and rapid weight loss. Ketonuria may also be present, but only if blood glucose is extremely high.

57.1.5.3 Oral Glucose Tolerance Test.

This test, often abbreviated as OGTT, is used when diabetes is suspected but could not be definitively diagnosed by measuring fasting or casual plasma glucose levels. The OGTT is performed by giving an oral glucose load (equivalent to 75 gm of anhydrous glucose), and measuring plasma glucose levels 2 hours later. In individuals who do not have diabetes, 2-hour glucose levels will be below 140 mg/dL. Diabetes is suggested if 2-hour plasma glucose levels are 200 mg/dL or higher. The OGTT test is more expensive and time consuming than the alternatives, and is not used routinely.

57.1.5.4 Glycosylated Hemoglobin (Hemoglobin A_{1c}) Test.

As described below, this test determines average blood glucose levels over a period of months, and is used primarily to monitor long-term glycemic control. In addition, it can help confirm a diagnosis of diabetes suggested by a casual plasma glucose test or FPG test.

57.1.6 Prediabetes

Prediabetes is a state defined by *impaired fasting plasma glucose* (FPG between 100 and 125 mg/dL), or *impaired glucose tolerance* (2-hour OGTT result of 140 to 199 mg/dL). These values are below those that define diabetes, but are too high to be considered normal. People with prediabetes are at increased risk of developing type 2 diabetes and CVD, but not the microvascular complications associated with diabetes (ie, retinopathy, nephropathy, neuropathy). The risk of CVD can be reduced by diet, exercise, and, if indicated, use of appropriate drugs to control blood lipids and blood pressure. The risk of progression to diabetes may be reduced by diet and exercise, and possibly by certain oral antidiabetic drugs.

660

661

57.1.7 Overview of Diabetes Treatment

The primary goal of treating diabetes—either type 1 or type 2—is prevention of long-term complications, especially CVD, retinopathy, kidney disease, and amputations. To minimize these complications, treatment must maintain “*tight*” *control of blood glucose* (or simply *tight glycemic control*), defined as keeping blood glucose in the normal range around-the-clock. In addition, treatment must keep blood pressure and blood lipids within an acceptable range. Major treatment targets are summarized in [Table 56-3](#).

57.1.7.1 Type 1 Diabetes

Preventing complications of diabetes requires a comprehensive plan directed at glycemic control and reduction of cardiovascular risk factors. Glycemic control is accomplished with an integrated program of diet, self-monitoring of blood glucose (SMBG), exercise, and insulin replacement. Of importance, tight control must be achieved *safely*, that is, without major drug side effects and without causing hypoglycemia.

57.1.7.1.1 Dietary Measures.

57.1.7.1.1.1 Proper diet, balanced by insulin replacement, is the cornerstone of treatment.

Because patients with type 1 diabetes are usually thin, the dietary goal is to maintain weight—not lose it. Dietary recommendations from the American Diabetes Association (ADA) include the following:

- Carbohydrates and monounsaturated fats, together, should provide 60% to 70% of daily energy intake.
- Protein should provide 15% to 20% of energy intake.
- Polyunsaturated fat should provide about 10% of energy intake.
- Saturated fats should provide less than 10% of energy intake.
- Cholesterol intake should be limited to 300 mcg/day.
- Total caloric intake should be spread evenly throughout the day, with meals spaced 4 to 5 hours apart.

Unfortunately, although following these guidelines is of clear benefit, many patients find long-term adherence difficult to achieve.

For people who like sweets, the ADA recommendations have good news: You can eat foods that contain sucrose (table sugar)—provided you reduce intake of other carbohydrates. What matters most is the total amount of carbohydrate ingested—not the type of carbohydrate or its source.

57.1.7.1.1.2 What's the glycemic index and is it important?

The glycemic index is an indicator of how a particular carbohydrate will affect blood glucose levels. Specifically, foods that have a *high* glycemic index (eg, white bread, unprocessed white rice) will raise glucose levels *more rapidly* and to a *higher peak* than will foods that have a *low* glycemic index (eg, rolled oats, 100% whole wheat bread, lentils and legumes, most fruits and nonstarchy vegetables). In theory, foods with a low index should permit better glycemic control, because the body has more time to process the glucose load. However, although this may be true, what matters much more is total carbohydrate intake. Put another way, we can achieve better glycemic control by consuming high-index foods in

moderate amounts than by consuming low-index foods in enormous amounts. But the best control would be achieved by consuming low-index foods in moderate amounts.

TABLE 56-3 General Treatment Targets for Patients with Diabetes^{*}

Glycemic Control	
Premeal plasma glucose	90–130 mg/dL
Peak postmeal plasma glucose	<180 mg/dL
Hemoglobin A _{1c}	<7% (equivalent to an eAG [†] of 154 mg/dL or less)
Blood Pressure	
Systolic	<130 mm Hg
Diastolic	<80 mm Hg
Blood Lipids	
LDL cholesterol	<100 mg/dL
Triglycerides	<150 mg/dL
HDL cholesterol	Men: >40 mg/dL Women: >50 mg/dL
Kidney Integrity	
Albumin/creatinine ratio	<30 mcg/mg [‡]

* Treatment targets for certain subgroups of diabetes patients may differ from the targets in this table.

† eAG = estimated average blood glucose, calculated from HbA_{1c} levels (see [Table 56-4](#)).

‡ An albumin/creatinine ratio above 30 mcg albumin/1 mg creatinine indicates too much albumin in urine owing to glomerular injury.

57.1.7.1.2 Exercise.

Unless specifically contraindicated, regular exercise should be part of the management program. Exercise increases cellular responsiveness to insulin, and may also increase glucose tolerance. Because strenuous exercise can produce hypoglycemia, patient and provider must work to establish a safe balance between exercise, glucose intake, and insulin dosage. Exercise should be avoided if glycemic control is unstable. Unfortunately, although the benefits of exercise are well established, long-term adherence to a program is often difficult to maintain.

57.1.7.1.3 Insulin Replacement.

57.1.7.1.3.1 Among patients with type 1 diabetes, survival requires daily dosing with insulin.

Before insulin replacement became available, people with type 1 diabetes invariably died within a few years after disease onset. The cause of death was ketoacidosis. It is essential to coordinate insulin dosage with caloric intake. If caloric intake is too great or too small with respect to insulin dosage, hyperglycemia or hypoglycemia will result.

Note that *oral* antidiabetic agents, which can help patients with type 2 diabetes, are not effective for patients with type 1 diabetes. Why? Because the oral agents cannot substitute for the insulin that type 1 patients lack.

57.1.7.1.4 Other Important Measures.

As noted earlier, an ACE inhibitor (eg, captopril) or an ARB (eg, losartan) can help protect against diabetic nephropathy. These same drugs are preferred agents for managing diabetic hypertension. As indicated in [Table 56-3](#), the goal is to drop blood pressure below 130/80 mm Hg.

To reduce high levels of LDL cholesterol, statins (eg, atorvastatin) are preferred drugs. Not only do statins reduce cardiovascular events in patients with high cholesterol, they reduce cardiovascular events in patients with normal or low cholesterol. Accordingly, some authorities recommend that *all* diabetic patients use a statin, regardless of their cholesterol status. Another cholesterol-lowering drug—colesevelam—is discussed separately below.

661

662

57.1.7.2 Type 2 Diabetes

As with type 1 diabetes, preventing long-term complications requires a comprehensive treatment plan. In addition to controlling blood glucose, the plan should address other factors that can increase morbidity and mortality. Accordingly, all patients should be screened and treated for hypertension, nephropathy, retinopathy, and neuropathy. In addition, dyslipidemias (high LDL cholesterol, low HDL cholesterol, and high triglycerides) should be corrected.

57.1.7.2.1 Glycemic Control: Diet and Exercise.

In patients with type 2 diabetes, blood glucose is controlled primarily by *diet and exercise*; insulin and other drugs are employed only as adjuncts. Because patients are often obese, the usual dietary goal is to promote weight loss, and thereby establish leaner body composition.

Clinical experience has shown that dietary measures, by themselves, often normalize insulin release and decrease insulin resistance. Frequently, these beneficial responses precede loss of weight. Exercise provides the additional benefit of promoting glucose uptake by muscle, even when insulin is low or absent.

57.1.7.2.2 Glycemic Control: Drug Therapy.

If diet and exercise fail to produce adequate glycemic control, pharmacotherapy is indicated. Options include *oral antidiabetic agents*, the new injectable hypoglycemic drugs—*pramlintide* and *exenatide*—and, if needed, daily *insulin*. It must be stressed, however, that insulin and the other drugs should be used only as supplements to caloric restriction and exercise; drugs are not a substitute for nondrug measures.

Drug selection in type 2 diabetes can be complex, owing to the many options that are available. Furthermore, because the disease is progressive, therapy needs to be more aggressive as time passes. For example, after 3 years of treatment, 50% of patients who responded to monotherapy initially will require a second drug; and after 9 years, 75% will require a second drug.

To achieve glycemic control, a stepwise approach is often used. Lack of glycemic control (or a decline in control) indicates a need to move up a step.

- *Step 1.* Implement lifestyle changes: caloric and carbohydrate restriction, exercise, and weight loss.
- *Step 2.* Initiate therapy with just *one* oral hypoglycemic drug. Drug selection is based on the patient's body composition and degree of hyperglycemia. For lean patients, try a sulfonylurea. Why? Because lean patients are usually insulin deficient, and sulfonylureas stimulate insulin release. For obese patients, try metformin. Why? Because in obese patients, insulin's target cells tend to be insulin resistant. Metformin can reduce insulin resistance, and has the added benefit of suppressing appetite, which can help the patient lose weight.
- *Step 3.* Treat with *two* oral hypoglycemic drugs. As a rule, hypoglycemic effects are additive. Of course, the drugs employed should have different mechanisms of action. Accordingly, using a sulfonylurea plus metformin would make sense, whereas using two sulfonylureas would be irrational. The three most popular combinations are (1) metformin plus a sulfonylurea, (2) metformin plus a thiazolidinedione, and (3) a sulfonylurea plus a thiazolidinedione. (This should give you a good idea of the importance of metformin in type 2 diabetes.)

- *Step 4a.* Treat with *three* oral hypoglycemic drugs (eg, metformin plus a sulfonylurea plus a thiazolidinedione). There is no proof that any particular combination is superior to others at lowering glucose levels or preventing complications. Rather than using three oral agents, some clinicians would go directly to Step 4b.
- *Step 4b.* Treat with an oral hypoglycemic *plus* insulin. For lean patients, try a sulfonylurea plus insulin. For obese patients, try metformin plus insulin.
- *Step 5.* Treat with insulin alone. Increase the dose as needed.

TABLE 56-4 HbA_{1C} Levels and Their Corresponding eAG Levels*

HbA _{1C} Level (% of total Hb)	Corresponding eAG Level	
	mg/dL	mmol/L
6	126	7
6.5	140	7.8
7†	154	8.6
7.5	169	9.4
8	183	10.1
8.5	197	10.9
9	212	11.8
9.5	226	12.6
10	240	13.4

Source: American Diabetes Association.
eAG = estimated average blood glucose; HbA_{1C} = hemoglobin A_{1C}.

* The formula to convert from HbA_{1C} (%) to average glucose concentration equivalents (expressed in mg/dL) is: $eAG = (HbA_{1C} \times 28.7) - 46.7$.

† 7% HbA_{1C} (corresponding to an eAG of 154 mg/dL) is considered to be the maximum acceptable level for long-term glycemic control. For many patients, achieving this degree of control is difficult or impossible.

57.1.8 Monitoring Treatment

We need monitoring to (1) determine whether glucose levels are being maintained in a safe range, both short term and long term, and to (2) guide changes in the regimen when the range is not safe.

Self-measurement of blood glucose levels is the standard method for day-to-day monitoring. Glycosylated hemoglobin (HbA_{1c}) is measured to assess long-term glycemic control. Target levels for these tests are summarized in [Table 56-4](#).

57.1.8.1 Self-Monitoring of Blood Glucose (SMBG)

SMBG is the standard way to monitor diabetes therapy. Many devices for measuring blood glucose (generally called glucometers) are available. With most of them, the patient places a small drop of blood on a chemically treated strip, which is then read by the machine. The test is rapid and can be performed in almost any setting. Information on blood glucose concentration provides a guide for “fine tuning” dosages of insulin or other antidiabetic drugs. For patients with type 1 diabetes, SMBG should be done 3 or more times a day, typically upon awakening, and then before or after exercise or a meal. For many patients with type 2 diabetes, testing just once a day can be adequate. Target values for blood glucose are 90 to 130 mg/dL before meals and 100 to 140 mg/dL at bedtime.

Newly diagnosed patients tend to be diligent about testing their blood. Which is good, in that doing so provides essential information for adjusting the regimen. Unfortunately, just as many patients start out getting proper exercise and eating right, and then go back to their old habits, they often follow the same pattern regarding SBGM.

A final note on SMBG. Glucometers are both amazing and sophisticated—and often not used to their full potential. By pushing a few buttons, you can get the current blood glucose measurement, and can label the reading as to when it was taken (eg, after exercise, before a meal). Many meters can calculate the average glucose level at a given time of day; track trends in glucose levels over a variety of time ranges; or give just about any other information you might want or need. However, there's a problem: In order to use a glucometer properly, and take full advantage of the information it can provide, you need to be able to read, understand, and follow the directions—directions that can be both complicated and lengthy (the manual may be 50 pages long). Clearly, the task can be daunting, especially for older people. Why? Just ask someone older—say your mom or dad—if they can program and use all the features of their cordless phone, never mind the HDTV, DVD player, and other high-tech gizmos in the house. More likely than not, they can't. The glucometer is no different.

662

663

57.1.8.2 Glycosylated Hemoglobin: Hemoglobin A_{1c}

Measurement of glycosylated hemoglobin (also called glycated hemoglobin) provides an index of *average glucose levels* over the prior 2 to 3 months. Glucose interacts spontaneously with hemoglobin in red blood cells to form glycosylated derivatives. The most prevalent species is

named *hemoglobin A_{1c}* (HbA_{1c}). With *prolonged hyperglycemia*, levels of HbA_{1c} gradually increase. Since red blood cells have a long life span (120 days), levels of HbA_{1c} reflect *average* glucose levels over an extended time. Hence, by measuring HbA_{1c} every 3 to 6 months, we can get a picture of *long-term* glycemic control. These measurements are an essential adjunct to daily blood glucose monitoring, but are not a substitute. When HbA_{1c} is measured, the results have traditionally been expressed as a percent of total hemoglobin in blood. For patients with diabetes, the goal is to keep HbA_{1c} below 7% of total hemoglobin. According to a 2008 statement issued jointly by the American Diabetes Association and the European Association for the Study of Diabetes, HbA_{1c} should be measured every 3 months until the value drops to 7%, and at least every 6 months thereafter.

In addition to being reported as a percent of total glucose, HbA_{1c} results are now also reported as a value for *estimated Average Glucose* (eAG), expressed as mg glucose/dL of blood (ie, the same units patients see every day when doing SMBG). As shown in [Table 56-4](#), the desired HbA_{1c} target of 7% is equivalent to an eAG of 154 mg/dL. Why express the results in two ways? Because the “percent of total hemoglobin” value is unfamiliar to patients, making it hard for them to know if their long-term glycemic control is poor, OK, or fantastic. By reporting the results as an eAG, we make it much easier for patients to grasp their meaning.

57.2 INSULIN I: PHYSIOLOGY

57.2.1 Structure

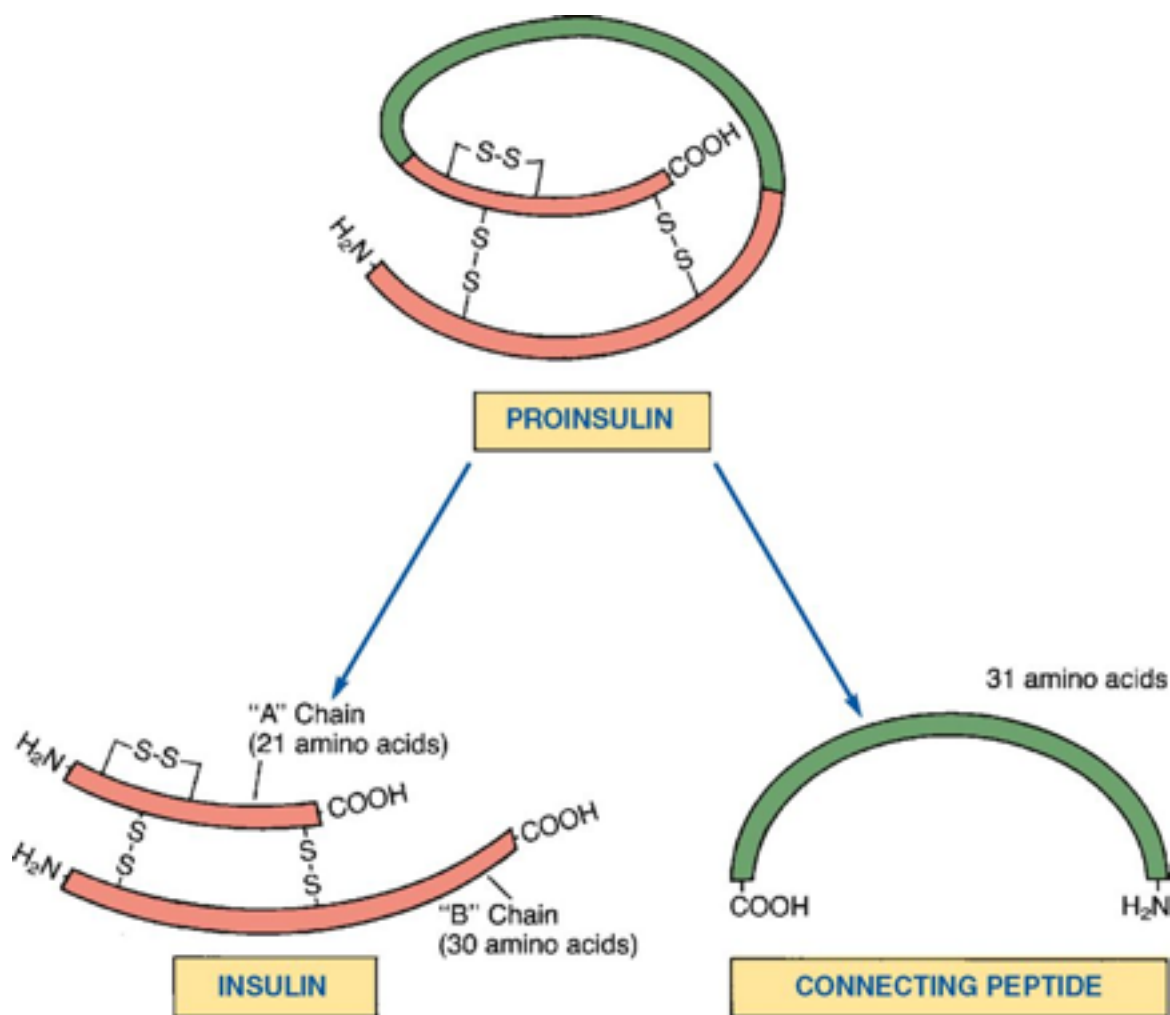

The structure of insulin is depicted in [Figure 56-1](#). As indicated, insulin consists of two amino acid chains: the “A” (acidic) chain and the “B” (basic) chain. The A and B chains are linked to each other by two disulfide bridges.

57.2.2 Biosynthesis

Insulin is synthesized in the pancreas by beta cells within the islets of Langerhans. The immediate precursor of insulin is called proinsulin (see [Fig. 56-1](#)).

Proinsulin consists of insulin itself plus a peptide loop that runs from the A chain to the B chain. This loop is named *con*

Figure 56-1 **Conversion of proinsulin to insulin.** Proinsulin is the immediate precursor of the insulin secreted by our pancreas. Enzymes clip off connecting peptide (C-peptide) to release active insulin, composed of two peptide chains (A and B) connected by two disulfide (S-S) bonds. Since C-peptide arises only from endogenous insulin, its presence in blood indicates that at least some pancreatic insulin is being made.

necting peptide or C-peptide. In the final step of insulin synthesis, C-peptide is enzymatically clipped from the proinsulin molecule.

663

664

Measurement of plasma C-peptide levels offers a way to assess residual capacity for insulin synthesis. Since commercial insulin preparations lack C-peptide, and since endogenous C-peptide is only present as a by-product of insulin biosynthesis, the presence of C-peptide in the blood indicates the pancreas is still producing some insulin of its own.

57.2.3 Secretion

The principal stimulus for insulin release is a rise in blood glucose. And the most common cause of glucose elevation is eating a meal, especially one rich in carbohydrates. Under normal conditions, there is tight coupling between rising levels of blood glucose and increased secretion of insulin. Insulin release may also be triggered by amino acids, fatty acids, and ketone bodies.

The sympathetic nervous system provides additional control of release. Activation of beta₂-adrenergic receptors in the pancreas *promotes* secretion of insulin. Conversely, activation of alpha-adrenergic receptors in the pancreas *inhibits* insulin release. Of the two modes of regulation, activation of beta receptors is more important.

57.2.4 Metabolic Actions

The metabolic actions of insulin are primarily *anabolic* (ie, conservative or constructive). Insulin promotes conservation of energy and buildup of energy stores. The hormone also promotes cell growth and division.

Insulin acts in two ways to promote anabolic effects. First, insulin stimulates cellular transport (uptake) of glucose, amino acids, nucleotides, and potassium. Second, insulin promotes synthesis of complex organic molecules. Under the influence of insulin and other factors, glucose is converted into glycogen, amino acids are assembled into proteins, and fatty acids are incorporated into triglycerides. The principal metabolic actions of insulin are summarized in [Table 56-5](#).

57.2.5 Metabolic Consequences of Insulin Deficiency

Insulin deficiency puts the body into a *catabolic* mode (ie, a metabolic state that favors the breakdown of complex molecules into their simpler constituents). Hence, in the absence of insulin, glycogen is converted into glucose, proteins are degraded into amino acids, and fats are converted to glycerol (glycerin) and free fatty acids. These catabolic effects contribute to the signs and symptoms of diabetes. Note that the catabolic effects resulting from insulin deficiency are opposite to the anabolic effects when insulin levels are normal.

Insulin deficiency promotes *hyperglycemia* by three mechanisms: (1) increased glycogenolysis, (2) increased gluconeogenesis, and (3) reduced glucose utilization. *Glycogenolysis*, by definition,

generates free glucose by breaking down glycogen. The raw materials that allow increased *gluconeogenesis* are the amino acids and fatty acids produced by metabolic breakdown of proteins and fats. *Reduced glucose utilization* occurs because insulin deficiency decreases cellular uptake of glucose, and decreases conversion of glucose to glycogen.

TABLE 56-5 Metabolic Actions of Insulin

Substance Affected	Insulin Action	Site of Action
Carbohydrates	↑ Glucose uptake	Muscle, adipose tissue
	↑ Glucose oxidation	
	↑ Glucose storage	Muscle
	↑ Glycogen synthesis	Muscle, liver
	↓ Glycogenolysis	Liver
	Gluconeogenesis*	
Amino Acids and Proteins	↑ Amino acid uptake	Muscle
	↓ Amino acid release	Muscle
	↑ Protein synthesis	Muscle
Lipids	↑ Triglyceride synthesis	Adipose tissue
	↓ Release of FFA† and glycerol	Adipose tissue
	↑ Oxidation of FFA to ketoacids‡	Liver

* Because of decreased delivery of substrate (fatty acids and amino acids) to the liver.

† FFA = free fatty acids.

‡ Because of decreased delivery of FFA to the liver.

57.3 INSULIN II: PREPARATIONS AND ADMINISTRATION

There are many insulin preparations or formulations. All of them have identical mechanisms. Major differences concern time course, appearance (clear or cloudy), concentration, and route of administration. Because of these differences, insulin preparations cannot be used interchangeably. In fact, if a patient is given the wrong preparation, the consequences can be dire. Unfortunately, medication errors with insulins remain all too common, which explains why these drugs appear on all lists of “high-alert” agents.

57.3.1 Sources of Insulin

57.3.1.1 Recombinant DNA Technology.

All forms of insulin currently manufactured in the United States are produced using recombinant DNA technology. Some products, referred to as *human insulin*, are identical to insulin produced by the human pancreas. Other products, referred to as *human insulin analogs*, are modified forms of human insulin. The analogs have the same pharmacologic actions as human insulin, but have different time courses.

57.3.1.2 Beef and Pork Pancreas.

Insulins extracted from beef or pork pancreas are no longer available in the United States. Beef insulin was discontinued in 1998, and pork insulin was discontinued in 2006. Information on importing these insulins for personal use is available online at www.fda.gov/cder/drug/beefandporkinsulin/default.htm.

57.3.2 Types of Insulin

There are seven types of insulin: “natural” insulin (aka regular insulin or native insulin) and six modified insulins. Three of the modified insulins—insulin lispro, insulin aspart, and insulin glulisine—act more rapidly than natural insulin but have a shorter duration of action. The other modified insulins act more slowly than natural insulin but have a longer duration. Two processes are used to prolong insulin effects: (1) complexing natural insulin with a protein, and (2) altering the insulin molecule itself. When the insulin molecule has been altered, we refer to the product as a *human insulin analog*. Specific alterations made to create the insulin analogs are summarized in [Table 56-6](#).

664

665

TABLE 56-6 Amino Acids Substitutions in Human Insulin Analogs*

Insulin Type	Amino Acids in A-Chain Position			Amino Acids in B-Chain Position					
	A8	A10	A21	B3	B28	B29	B30	B31	B32
Human Insulin									
Native†	Thr	Ile	Asn	Asn	Pro	Lys	Thr	—	—
Human Insulin Analogs									
Glargine	Thr	Ile	Gly	Gly	Pro	Lys	Thr	Arg	Arg
Aspart	Thr	Ile	Asn	Asn	Asp	Lys	Thr	—	—
Lispro	Thr	Ile	Asn	Asn	Lys	Pro	Thr	—	—
Glulisine	Thr	Ile	Asn	Lys	Pro	Glu	Thr	—	—
Detemir	Thr	Ile	Asn	Asn	Pro	Lys‡	§	—	—
Arg = arginine; Asn = asparagine; Asp = aspartic acid; Glu = glutamine; Gly = glycine; Ile = isoleucine; Lys = lysine; Pro = proline; Thr = threonine.									

* The human insulin analogs have the same physiologic effects as native human insulin—they just have different pharmacokinetics, such as onset and duration of action.

† Human insulin (ie, the form of insulin made by the human pancreas) is also known as *native insulin*.

‡ A fatty acid chain has been added to the lysine in position B29.

§ The amino acid normally in position B30 has been deleted.

TABLE 56-7 Types of Insulin: Time Course of Action After Subcutaneous Injection

		Time Course		
Generic Name	Trade Name	Onset (min)	Peak (hr)	Duration (hr)
Short Duration: Rapid Acting				
Insulin lispro	Humalog	15–30	0.5–2.5	3–6.5
Insulin aspart	NovoLog	10–20	1–3	3–5
Insulin glulisine	Apidra	10–15	1–1.5	3–5
Short Duration: Slower Acting				
Regular insulin	Humulin R, Novolin R	30–60	1–5	6–10
Intermediate Duration				
NPH insulin	Humulin N, Novolin N	60–120	6–14	16–24
Insulin detemir	Levemir	6–8	12–24*	
Long Duration				
Insulin glargine	Lantus	70	None†	24
* Duration is dose dependent: At 0.2 units/kg, duration is 12 hours; at 2.4 units/kg, duration is 20 to 24 hours.				
† Levels are steady with no discernible peak.				

When classified according to time course, insulin preparations fall into three major groups: short duration, intermediate duration, and long duration ([Table 56-7](#)). The short-duration insulins can be subdivided into two groups: rapid acting (insulin lispro, insulin aspart, and insulin glulisine) and slower acting (regular or “natural” insulin). Time courses for different insulin types are depicted graphically in [Figure 56-2](#). Selected properties of insulin types are summarized in [Table 56-8](#).

57.3.2.1 Short Duration: Rapid Acting

Short-duration insulins are administered in association with meals to control the postprandial rise in blood glucose. To provide glycemic control between meals and at night, short-acting insulins must be used in conjunction with an intermediate- or long-acting agent. *All three of the rapid-acting insulins are formulated as clear solutions*, and all three require a prescription. For routine therapy, all three are given subQ. If needed, all three may also be given IV.

57.3.2.1.1 Insulin Lispro.

Insulin lispro [Humalog] is a rapid-acting analog of regular insulin. Effects begin within 15 to 30 minutes of subQ injection and persist for 3 to 6 hours. Insulin lispro acts faster than regular insulin but has a shorter duration of action. Because of its rapid onset, insulin lispro can be administered immediately before eating, or even after eating. In contrast,

665

666

Figure 56-2 Time-effect relationship for different types of insulin following subcutaneous injection.

regular insulin is generally administered 30 to 60 minutes before meals. The usual route is subQ. Intravenous infusion may be done in an emergency.

The structure of insulin lispro is nearly identical to that of natural insulin. The only difference is that the positions of two amino acids have been switched. Because of this switch, molecules of insulin lispro aggregate less than do molecules of regular insulin, which explains why insulin lispro acts more rapidly.

57.3.2.1.2 Insulin Aspart.

Insulin aspart [NovoLog] is an analog of human insulin with a rapid onset (10 to 20 minutes) and short duration (3 to 5 hours). The drug is structurally identical to human insulin except

that one amino acid—proline in position 28 of the B chain—has been changed to aspartic acid. Insulin aspart is very similar to insulin lispro.

Insulin aspart (100 units/mL) is available in 10-mL vials and 3-mL *PenFill* cartridges. Dosing is almost always done by subQ injection or subQ infusion, although IV infusion may be used in emergencies. Because insulin aspart acts rapidly, injections should be made 5 to 10 minutes before meals.

57.3.2.1.3 Insulin Glulisine.

Like insulin lispro and insulin aspart, insulin glulisine [Apidra] is a synthetic analog of natural human insulin with a rapid onset (10 to 15 minutes) and short duration (3 to 5 hours). Owing to its rapid onset, the drug should be administered close to the time of eating (within 15 minutes before and 20 minutes after starting to eat). Because of its short duration, insulin glulisine should be used in conjunction with an intermediate- or long-acting insulin to provide basal glycemic control. Administration is almost always by subQ injection or continuous subQ infusion. Intravenous dosing may be done in emergencies. Insulin glulisine differs from natural insulin by two amino acids.

57.3.2.2 Short Duration: Slower Acting

57.3.2.2.1 Regular Insulin Injection.

Regular insulin [Humulin R, Novolin R] is unmodified human insulin. The product has four approved routes: subQ injection, subQ infusion, IM injection (used rarely), and oral inhalation (approved but not currently used). In addition, regular insulin is used off label for intravenous therapy. For IV therapy, only the U-100 formulation should be used.

For routine treatment of diabetes, regular insulin can be (1) injected before meals to control postprandial hyperglycemia, and (2) infused subQ to provide basal glycemic control. Following *subQ injection*, molecules of regular insulin form small aggregates (dimers and hexamers) at the injection site. As a result, absorption is slightly delayed. As indicated in [Table 56-7](#), effects begin in 30 to 60 minutes, peak in 1 to 5 hours, and last up to 10 hours. Onset is slower than with the rapid-acting insulins, and faster than with the longer acting insulins.

Regular insulin is supplied as a clear solution. Two concentrations are available: U-100 (100 units/mL) and U-500 (500 units/mL). Regular insulin is the only type available in a U-500 strength. U-100 preparations are used by most patients. The U-500 concentration is reserved for patients with insulin resistance. Because it is so concentrated, U-500 insulin should never

be given IV. Except for the U-500 formulation, all formulations of regular insulin are available without prescription.

57.3.2.3 Intermediate Duration

57.3.2.3.1 Neutral Protamine Hagedorn (NPH) Insulin Suspension.

NPH insulin [Humulin N, Novolin N], also known as *isophane insulin*, is prepared by conjugating regular insulin with protamine (a large protein). The presence of protamine decreases the solubility of NPH insulin and thereby retards absorption. As a result, onset of action is delayed and duration of action is extended. Because onset is delayed, NPH insulin cannot be administered at mealtime to control postprandial hyperglycemia. Rather, the drug is injected twice daily to provide glycemic control between meals and during the night. Of the longer acting insulins in current use, NPH insulin is the only one suitable for mixing with short-acting insulins. Because protamine is a foreign protein, allergic reactions are possible.

666

667

NPH insulins are supplied as cloudy suspensions that must be gently agitated before administration. Administration is by subQ injection only. Like regular insulin, NPH insulins are available without prescription.

TABLE 56-8 Properties of Insulin Types

Generic Name [Trade Name]	Class*	Rx or OTC†	Strength‡	Appearance	Route	Administration Options§
Short Duration: Rapid Acting						
Insulin lispro [Humalog]	HA	Rx	U-100	Clear	subQ, IV	<i>subQ inf:</i> within 15 min before or just after meals <i>subQ inj:</i> continuous, with bolus just before meals
Insulin aspart [Novolog]	HA	Rx	U-100	Clear	subQ, IV	<i>subQ inj:</i> 5–10 min before meals <i>subQ inf:</i> continuous, with bolus 5–10 min before meals <i>IV:</i> approved route, but rarely used
Insulin glulisine [Apidra]	HA	Rx	U-100	Clear	subQ, IV	<i>subQ inj:</i> within 15 min before meals or within 20 min after <i>subQ inf:</i> continuous, with bolus 15–20 min before meals <i>IV:</i> approved route, but rarely used
Short Duration: Slower Acting						

Pharmacology for Nursing Care, 7th Edition

Regular insulin [Humulin R, Novolin R]	H	OTC†	U-100, U-500	Clear	subQ, IV, IM	<i>subQ inj</i> : 30 min before meals <i>subQ inf</i> : continuous, with bolus 20–30 min before meals <i>IV</i> : for emergencies (unlabeled use, never use U-500 IV) <i>IM</i> : approved route, but rarely used
Intermediate Duration						
NPH insulin [Humulin N, H Novolin N]	H	OTC	U-100	Cloudy	subQ	<i>subQ inj</i> : twice daily at the same times each day; gently agitate before use
Insulin detemir [Levemir]	HA	Rx	U-100	Clear	subQ	<i>subQ inj</i> : twice daily or once daily (at evening meal or bedtime)
Long Duration						
Insulin glargine [Lantus]	HA	Rx	U-100	Clear	subQ	<i>subQ inj</i> : once daily at the same time each day

* H = human insulin, HA = human insulin analog.

† Rx = prescription needed, OTC = over the counter (no prescription needed).

‡ U-100 = 100 units/mL, U-500 = 500 units/mL.

§ inj = injection, inf = infusion.

¶ U-100 formulations are OTC, the U-500 formulation is Rx.

57.3.2.3.2

Insulin Detemir.

Insulin detemir [Levemir] is a human insulin analog with a slow onset and dose-dependent duration of action. At low doses (0.2 units/kg), effects persist about 12 hours. At higher doses (0.4 units/kg), effects persist 20 to 24 hours. Because of its slow onset and prolonged duration, insulin detemir is used to provide basal glycemic control. It is not given before

meals to control postprandial hyperglycemia. Compared with NPH insulin, insulin detemir has a slower onset and longer duration.

Insulin detemir differs from natural insulin in two ways. First, one amino acid has been removed. Second, a 14-carbon fatty-acid chain has been attached to the B chain. Because of these structural changes, molecules of insulin detemir adhere strongly to each other, and hence absorption is delayed. Because of the fatty-acid chain, insulin detemir binds strongly with plasma albumin, and hence distribution to target sites is delayed even further.

Insulin detemir is supplied as a clear, colorless solution (100 units/mL) in 10-mL vials, 3-mL cartridges, a 3-mL *FlexPen*, and a 3-mL *Innolet* dosing device. Dosing is done once or twice daily by subQ injection. Insulin detemir should not be mixed with other insulins, and must not be given IV. The drug is available by prescription only.

57.3.2.4 Long Duration

57.3.2.4.1 Insulin Glargine.

Insulin glargine [Lantus] is a modified human insulin with a prolonged duration of action (at least 24 hours). The drug is indicated for once-daily subQ administration to treat adults and children with type 1 diabetes and adults with type 2 diabetes. According to package labeling, the once-daily injection should be made at bedtime. However, administration at other times of day (eg, in the morning or after dinner) seems to provide equivalent glycemic control.

Insulin glargine differs from natural human insulin by three amino acids (see [Table 56-6](#)). Because of these modifications, insulin glargine has low solubility at physiologic pH. Hence, when injected subQ, it forms microprecipitates that slowly dissolve, and thereby release insulin glargine in small amounts over an extended time. In contrast to other long-acting insulins (ie, NPH insulin, insulin detemir), whose blood levels rise to a distinct peak and then fall to a trough, insulin glargine achieves blood levels that are relatively steady over 24 hours. As a result, there is less risk of hypoglycemia (from excessive levels) or hyperglycemia (from insufficient levels).

667

668

TABLE 56-9 Premixed Insulin Combinations*

Description	Trade Name	Time Course		
		Onset (min)	Peak (hr)	Duration (hr)
70% NPH insulin/30% regular insulin	Humulin 70/30	30–60	1.5–16	Up to 24
	Novolin 70/30	30–60	2–12	Up to 24
50% NPH insulin/50% regular insulin	Humulin 50/50	30–60	2–5.5	Up to 24
70% insulin aspart protamine/30% insulin aspart	NovoLog Mix 70/30	Rapid*	1–4	Up to 24
75% insulin lispro protamine/25% insulin lispro	Humalog Mix 75/25	Rapid†	1–6.5	Up to 24

* Faster than Humulin 70/30, Humulin 50/50, or Novolin 70/30.

† Use only after the dosages and ratios of the components have been established as correct for the patient.

Insulin glargine is supplied as a *clear solution* in 10-mL vials containing 100 units/mL, and in 3-mL cartridges for use in an *OptiClik Pen*. As with other long-acting insulins, administration is by subQ injection. The drug should not be mixed with other insulins, and should never be given IV.

57.3.3 Appearance

In the past, most insulins were formulated as cloudy suspensions. Today, the opposite is true: with the exception of NPH insulins, all insulins made in the United States are formulated as *clear, colorless solutions*. NPH insulin is still a cloudy suspension. Patients should inspect their insulin before using it, and should discard the vial if the insulin looks abnormal.

Because most insulin preparations—and not just regular insulin—are now formulated as clear solutions, generalities that applied in the past are no longer true. Accordingly, patients and providers should note the following changes:

In the past: *All insulins available as clear solutions are short acting.* This was true when regular insulin was the only preparation available as a clear solution.

Today: Of the insulins available as clear solutions, four preparations—regular, lispro, aspart, and glulisine insulin—are short acting, and two preparations—detemir and glargine insulin—have more prolonged actions.

In the past: *All insulins available as clear solutions can be administered IV.* Again, this was true when regular insulin was the only preparation available as a clear solution.

Today: Of the insulins available as clear solutions, four preparations—regular, aspart, lispro, and glulisine insulin—can be administered IV. The rest—detemir and glargine insulin—cannot.

In the past: *All insulins that are clear solutions can be mixed in the same syringe with other insulins.* Again, this was true when regular insulin was the only preparation available as a clear solution.

Today: Of the insulins available as clear solutions, only the short-acting preparations—regular, lispro, aspart, and glulisine insulin—can be mixed with other insulins (usually NPH insulin).

57.3.4 Concentration

In the United States, insulin is available in two concentrations: 100 units/mL (U-100) and 500 units/mL (U-500). Preparations containing 40 units/mL are available in other countries but not here. U-100 insulins are employed for routine replacement therapy. All insulin types are available in U-100 formulations. Only one product—the *Humulin R* brand of regular insulin—is formulated in the U-500 strength. This product, which is available from the manufacturer by special request, is reserved for emergencies and for patients with severe insulin resistance, defined as needing more than 200 units/day.

57.3.5 Mixing Insulins

When the treatment plan calls for using a short-acting insulin in combination with a longer acting insulin, it is usually desirable to mix the preparations (in a single syringe) rather than inject them separately, so as to eliminate the need for an additional shot. However, although mixing offers convenience, it can alter the time course of the response. Therefore, to ensure a consistent response, mixing should be done only with insulins of proven compatibility. Of the three longer acting insulins in current use, *only NPH insulin is appropriate for mixing with short-acting*

insulins (ie, regular, lispro, aspart, and glulisine insulins). When a mixture is prepared, the short-acting insulin should be drawn into the syringe first. Why? To avoid contaminating the stock vial of the short-acting insulin with NPH insulin. As a rule, the mixtures are stable for 28 days.

Commercially available premixed combinations are described in [Table 56-9](#).

57.3.6 Administration

57.3.6.1 Subcutaneous Injection

Insulin is usually given by subQ injection. Why? Owing to its peptide structure, insulin would be inactivated by the digestive system if it were given by mouth. All types of insulins may be injected subQ.

668

57.3.6.1.1 Preparing for Injection.

669

Initial preparation depends on whether the insulin product is in solution or suspension. With the exception of NPH insulins, all insulins available today are supplied as clear, colorless solutions. These solutions are ready to use—unless they have become colored or cloudy, or contain a precipitate, in which case they should be discarded. Because NPH insulins are suspensions, their particles must be evenly dispersed prior to loading the syringe. Dispersion is accomplished by rolling the vial between the palms of the hands. Mixing must be gentle, because vigorous agitation will cause frothing and render accurate dosing impossible. If granules or clumps remain after gentle agitation, the vial should be discarded.

Before loading the syringe, the bottle cap should be swabbed with alcohol. Air bubbles should be eliminated from the syringe and needle after loading. The skin should be cleaned with alcohol (or soap and water) prior to injection.

57.3.6.1.2 Injection Sites.

The most common sites of subQ injection are the upper arm, thigh, and abdomen. Absorption is fastest and most consistent following abdominal injection, and slowest following injection in the thigh. Because rates of absorption vary among sites, patients should make all injections into the same general area (eg, thigh or abdomen). To reduce the risk of lipodystrophy (see below), injections within the chosen area should be made in different spots, preferably about 1 inch apart. Ideally, each spot should be used only once a month.

57.3.6.1.3 Injection Devices.

57.3.6.1.3.1 Syringe and Needle

Syringes and needles for insulin injection are made in several sizes, so they can be matched to individual needs. Three syringe sizes are available: 1 cc, $\frac{1}{2}$ cc, and $\frac{1}{3}$ cc, which can deliver up to 100, 50, and 30 units of insulin, respectively. Patients should choose the syringe that best matches their dosage. For example, a patient who injects 25 units of insulin per dose should choose a $\frac{1}{3}$ -cc syringe, which can deliver up to 30 units of insulin. Patients should use the smallest syringe that will hold the required volume.

Needles for injecting insulin are available in three lengths: 12.7 mm ($\frac{1}{2}$ inch), 8 mm ($\frac{5}{16}$ inch), and 5 mm ($\frac{3}{16}$ inch). Since the objective is to penetrate the skin and enter the subcutaneous fat, the longest needle might be best for an overweight adult, whereas the shortest might be best for a small child.

Injection technique can affect the rate of insulin absorption, and hence can alter glycemic control. Accordingly, consistent delivery into subQ fat is important. If the needle is not inserted deep enough, insulin will be injected intradermally. Conversely, if the needle is inserted too deep, insulin will be injected into muscle. Intramuscular injection will accelerate insulin absorption, and hence will shorten the period of glycemic control. Also, IM injection hurts more.

57.3.6.1.3.2 Pen Injectors

These devices are similar to a syringe and needle but are more convenient. Pen injectors look like a fountain pen but have a disposable needle (where the writing tip would be) and a disposable insulin-filled cartridge inside. Administration is accomplished by sticking the needle under the skin and injecting the insulin manually. Dosage can be adjusted in 2-unit increments.

57.3.6.1.3.3 Jet Injectors.

These devices shoot insulin directly through the skin into subcutaneous tissue. No needle is used. Hence, for patients who dislike needles, a jet injector may be attractive. However, these devices do have a downside. They're expensive (\$500 to \$900) and can be difficult to use. Moreover, because insulin is delivered under high pressure, jet injectors can cause stinging, burning, and pain. In addition, bruising can occur in people with reduced subcutaneous fat (children, the elderly, thin people).

57.3.6.2 Subcutaneous Infusion

57.3.6.2.1 Portable Insulin Pumps.

These computerized devices deliver a basal infusion of insulin (regular, lispro, aspart, or glulisine) plus bolus doses before each meal. The basal infusion is usually about 1 unit/hr and can be programmed to match the patient's metabolic requirements. Mealtime boluses are calculated to match caloric intake. The pumps are about the size of a small cell phone, weigh only 4 ounces, and are worn on the belt or in a pocket. An infusion set delivers insulin from the pump to a subcutaneous catheter, usually located on the abdomen. The infusion set should be replaced every 1 to 3 days, at which time the needle should be moved to a new site (at least 1 inch away from the old one). Because the pump delivers short-acting insulin, insulin levels will drop quickly if the pump is removed. Accordingly, the pump should remain in place most of the day. However, it can be removed for an hour or two on special occasions. External insulin pumps cost between \$3000 and \$5000. Infusion sets, insulin, and glucose monitoring materials add another \$300 per month to the bill. Aside from expense, the main drawback of the pumps is delivery of too little insulin owing to formation of insulin microdeposits.

57.3.6.2.2 Implantable Insulin Pumps

These devices are surgically implanted in the abdomen and deliver insulin either intraperitoneally or intravenously. Like external pumps, internal pumps deliver a basal insulin infusion plus bolus doses with meals. Insulin delivery is adjusted by external telemetry. Compared with multiple daily injections, implantable pumps produce superior glycemic control, cause less hypoglycemia and weight gain, and improve quality of life. As with external pumps, delivery of insulin can be impeded by formation of insulin microprecipitates. Implantable pumps are experimental and not yet available for general use.

57.3.6.3 Intravenous Infusion

Intravenous infusion is reserved for emergencies that require a rapid reduction in blood glucose. Not long ago, regular insulin (U-100 strength) was the only formulation considered safe for IV use. Today, three other short-acting insulins—insulin aspart [Novolog], insulin lispro [Humalog], and insulin glulisine [Apidra]—may also be used. When given IV, all of these products, including regular insulin, should be diluted to a concentration of 0.05 to 1 unit/mL.

57.3.6.4 Inhalation

Inhalation of insulin is an attractive alternative to needle-based dosing. In clinical trials, patient satisfaction with inhaled insulin has been much higher than with insulin injections. Several delivery systems for insulin inhalation have been in development, and, in 2006, one of them—Exubera—received FDA approval. However, sales of this product were so poor that it was voluntarily withdrawn in 2007. Factors underlying poor sales included complaints about side effects (cough and bitter taste), hypoglycemia, and high cost relative to injectable insulins. In addition, there were growing concerns about allergic reactions, pulmonary irritation, and even lung cancer. At this time, we don't know if these problems are unique to Exubera, or if they will apply to all inhaled insulins. Until more is known, we can't answer the question “Will we see another inhaled insulin in the future?”

669

57.3.7 Storage

670

Insulin in *unopened vials* should be stored *under refrigeration* until needed. Vials should not be frozen. When stored unopened under refrigeration, insulin can be used up to the expiration date on the vial.

The vial in current use can be kept at room temperature for up to 1 month without significant loss of activity. Direct sunlight and extreme heat must be avoided. Partially filled vials should be discarded after several weeks if left unused. Injecting insulin stored at room temperature causes less pain than injecting cold insulin and reduces the risk of lipodystrophy.

Mixtures of insulin prepared in *vials* are stable for 1 month at room temperature and for 3 months under refrigeration.

Mixtures of insulin in *pre-filled syringes* (plastic or glass) should be stored in a refrigerator, where they will be stable for at least 1 week and perhaps 2. The syringe should be stored vertically with the needle pointing up to avoid clogging the needle. Prior to administration, the syringe should be agitated gently to resuspend the insulin.

57.4 INSULIN III: THERAPEUTIC USE

57.4.1 Indications

The principal indication for insulin is *diabetes mellitus*. Insulin is required by all patients with type 1 diabetes and by some with type 2 diabetes. Intravenous insulin is used to treat *diabetic ketoacidosis*. Because of its ability to promote cellular uptake of potassium and thereby lower plasma potassium levels, insulin infusion is employed to treat *hyperkalemia*. Lastly, insulin can

aid the *diagnosis of growth hormone (GH) deficiency*.^{*} The use of insulin in diabetes is discussed further below.

* The *insulin hypoglycemia test* can aid diagnosis of suspected GH deficiency in preadolescent children who are not growing as fast as their peers. The test is based on the fact that even modest insulin-induced hypoglycemia can trigger GH release, causing blood levels of GH to rise. In children with GH deficiency, the rise in blood GH will be lower than in children with normal pituitary function.

57.4.2 Insulin Therapy of Diabetes

Insulin is given to all patients who have type 1 diabetes and to many who have type 2. In addition, insulin is the preferred drug to manage gestational diabetes. In treating these disorders, the objective is to prevent complications by keeping blood glucose within an acceptable range (see [Table 56-3](#)). When therapy is successful, both hyperglycemia and hypoglycemia are avoided, and the long-term complications of diabetes are minimized.

57.4.2.1 Tight Glucose Control: Benefits and Drawbacks

The process of maintaining glucose levels within a normal range, around the clock, is referred to as tight glucose control. In terms of HbA_{1c}, the recommended target is 7% or less. However, many practitioners would try for 6% or less. Maintaining tight glucose control is difficult, but worth the trouble: compared with conventional therapy, tight control can greatly reduce morbidity and mortality. Unfortunately, these benefits come with a price: tight glucose control increases the risk of hypoglycemia, and is less convenient and more expensive than conventional therapy.

57.4.2.1.1 Benefits of Tight Control.

The benefits of tight glucose control were demonstrated conclusively in two landmark studies: (1) the Diabetes Control and Complications Trial (DCCT), and (2) the United Kingdom Prospective Diabetes Study (UKPDS). The DCCT evaluated tight control in patients with *type 1 diabetes*; the UKPDS evaluated tight control in patients with *type 2 diabetes*.

In the DCCT, patients received either *conventional insulin therapy* (ie, 1 or 2 injections a day) or *intensive insulin therapy* (4 injections a day). After 6.5 years, the patients who received intensive therapy experienced a 50% decrease in clinically significant kidney disease, a 35% to 56% decrease in neuropathy, and a 76% decrease in serious ophthalmic complications. Moreover, onset of ophthalmic problems was delayed and progression of existing problems was slowed. In addition to reducing these *microvascular* complications, tight control can

decrease *macrovascular* complications: 17-year follow-up data from the DCCT, released in December 2005, showed a significant reduction in myocardial infarction, coronary revascularization, and angina. Hence, with rigorous control of blood glucose, the high degree of morbidity and mortality traditionally associated with type 1 diabetes can be markedly reduced.

In the UKPDS, the principal benefit of tight glucose control was a reduction in *micro* vascular complications. In one branch of the study, nonobese patients were given either intensive therapy or conventional therapy. Intensive therapy consisted of drugs (insulin or a sulfonylurea) in doses sufficient to keep FPG below 108 mg/dL. Conventional therapy consisted primarily of dietary counseling; drugs were used only if FPG exceeded 270 mg/dL. Mean values for HbA_{1c} were 7% in the intensive group and 7.9% in the conventional group. Compared with patients in the conventional group, patients in the intensive group had a 12% reduction in total diabetes-related endpoints (cardiovascular, retinal, and renal damage). However, a reduction in microvascular complications (especially retinal damage) accounted for most of the benefit. In a parallel branch of the study, obese patients were given either conventional therapy or intensive therapy with metformin. Outcomes were similar to those seen with nonobese patients. Overall, the UKPDS study has shown that intensive treatment of type 2 diabetes is more beneficial than conventional treatment—although the benefits do not seem to be as great as in type 1 diabetes.

57.4.2.1.2

Drawbacks of Tight Control.

Unfortunately, intensive therapy does have drawbacks. The greatest concern is *hypoglycemia*. Because glucose levels are kept relatively low, the possibility of hypoglycemia increases. Why? Because even a modest overdose with insulin or an oral hypoglycemic agent can cause blood glucose to fall too low. Also, a meal that is skipped or exercise that is too strenuous can do the same. Results of the DCCT showed that, compared with patients using conventional therapy, those using intensive insulin experienced 3 times as many hypoglycemic events requiring the assistance of another person, and 3 times as many episodes of hypoglycemia-induced coma or seizures. In addition, patients on intensive insulin therapy gained more weight (about 10 pounds, on average). Other disadvantages are greater inconvenience, increased complexity, and a need for greater patient motivation. Finally, for patients treated with insulin, the expense is much higher: Whereas traditional therapy costs about \$1700/year, intensive therapy costs about \$4000/year (for multiple daily injections) or \$5800 (for continuous infusion with a pump). The cost of test strips for the patient's glucometer adds substantially more to the bill.

670

671

57.4.2.2 Dosage

To achieve tight glucose control, insulin dosage must be closely matched with insulin needs. If caloric intake is increased, insulin dosage must be increased as well. When a meal is missed or is low in calories, or when exercise gets excessive, the dosage of insulin must be decreased.

Dosage must undergo additional adjustments to meet specialized needs. For example, insulin needs are *increased* by infection, stress, obesity, the adolescent growth spurt, and pregnancy after the first trimester. Conversely, insulin needs are *decreased* by exercise and during the first trimester of pregnancy. To ensure that insulin dosage is coordinated with insulin requirements, the patient and the healthcare team must work together to establish an integrated program of nutrition, exercise, insulin replacement therapy, and rigorous blood glucose monitoring.

Total daily dosages may range from 0.1 unit/kg body weight to more than 2.5 units/kg. For patients with type 1 diabetes, initial dosages typically range from 0.5 to 0.6 units/kg/day. For patients with type 2 diabetes, initial dosages typically range from 0.2 to 0.6 units/kg/day.

57.4.2.3 Dosing Schedules

The schedule of insulin administration helps determine the extent to which tight glucose control is achieved. Three dosing schedules are compared below. These modes are referred to as (1) conventional therapy, (2) intensive conventional therapy, and (3) continuous subcutaneous insulin infusion.

57.4.2.3.1 Conventional Therapy.

Several dosing schedules fall under the heading of conventional therapy. A representative schedule is summarized in [Table 56-10](#). In this schedule, a combination of regular insulin (a short-acting, fast-onset preparation) plus NPH insulin (an intermediate-acting preparation) is administered 15 to 30 minutes before breakfast and again before the evening meal. No insulin is administered with the noon meal. Typically, two-thirds of the total daily dose is given in the morning and the remainder is given late in the day. Dosage remains rigidly fixed from one day to the next.

57.4.2.3.1.1 Conventional therapy does not provide tight glucose control.

The weak point of this schedule is that there is no provision for adjusting insulin dosage in response to ongoing changes in insulin needs. Hence, if a meal is abnormally large, insulin levels will be insufficient, causing hyperglycemia. Conversely, if a meal is delayed, reduced in size, or missed entirely, hypoglycemia will follow.

57.4.2.3.2 Intensive Conventional Therapy (ICT).

This form of therapy is designed to provide tight glucose control. A representative regimen is presented in [Table 56-10](#). In this regimen, the patient injects insulin glargine (a long-acting preparation) in the evening and also injects regular insulin (a short-acting, fast-onset preparation) 15 to 30 minutes before each meal.* Insulin glargine provides a *basal* level of insulin throughout the night and the following day. The mealtime doses of *regular* insulin accommodate the acute needs that occur at times of caloric loading. Note that insulin is injected *4 times each day*, rather than just twice as in conventional therapy.

The most significant feature of ICT is *adaptability*. Unlike conventional therapy, in which doses never change, the *preprandial doses in ICT are adjusted to match the caloric content of each meal*: if no meal is eaten, no insulin is administered; if a meal is delayed, so is the dose of regular insulin; if a meal is larger than usual, the insulin dose is increased proportionately. Because insulin dosage is determined by the timing and size of each meal, ICT offers patients a degree of glycemic control and dietary flexibility that is not possible with conventional therapy.

SMBG is an essential component of ICT. Blood glucose should be measured 3 to 5 times a day. SMBG is discussed above under *Monitoring Treatment*.

* Insulin lispro, insulin aspart, or insulin glulisine can be used instead of regular insulin. The advantage of these alternatives is that they can be injected just a few minutes before eating, and one of them—insulin aspart—can even be injected after eating.

57.4.2.3.3 Continuous Subcutaneous Insulin Infusion.

Continuous subcutaneous insulin infusion (CSII) is accomplished using a portable infusion pump connected to an indwelling subcutaneous catheter. Four types of insulin may be used: regular, lispro, aspart, and glulisine. To provide a basal level of insulin, the pump is set to infuse insulin continuously at a slow but steady rate. To accommodate insulin needs created by eating, the pump is triggered manually to provide a bolus dose matched in size to the caloric content of each meal. Hence, like ICT, CSII can adapt to altered insulin needs. As with ICT, SMBG is essential. CSII is equivalent to ICT for achieving tight glucose control. Infusion pumps are discussed above in the section on *Subcutaneous Infusion* under *Administration*.

671

672

TABLE 56-10 Insulin Therapy of Diabetes Mellitus: Conventional Versus Intensive Conventional Therapy

Regimen	Insulin Type and Dosing Schedule			
	Breakfast	Lunch	Supper	Bedtime
Conventional therapy [*]	Regular + NPH	None	Regular + NPH	None
Intensive conventional therapy [†]	Regular	Regular	Regular	Glargine

^{*} Dosage is *fixed* (two-thirds of daily total in AM, one-third of daily total in PM). As a result, flexibility of timing and composition of meals is not possible.

[†] Dosage of regular insulin is *adjusted for each meal*; hence, timing and composition of meals can be varied.

57.4.2.4 Achieving Tight Glucose Control

As we have seen, the primary requirement for achieving tight glucose control is a method of insulin delivery that permits dosage adjustments that accommodate ongoing variations in insulin needs. ICT and CSII meet this criterion. In addition to an adaptable method of insulin delivery, achieving tight glucose control requires the following:

- Careful attention to all elements of the treatment program (diet, exercise, insulin replacement therapy)
- A defined glycemic target (see [Tables 56-3](#) and [56-4](#))
- Self-monitoring of blood glucose 3 to 5 times daily
- A high degree of patient motivation
- Extensive patient education

Tight glucose control cannot be achieved without the informed participation of the patient. Accordingly, patients must receive thorough instruction on the following:

- The nature of diabetes
- The importance of tight glucose control

- The major components of the treatment routine (insulin replacement, SMBG, diet, exercise)
- Procedures for purchasing insulin, syringes, and needles
- The importance of avoiding arbitrary changes between insulins from different manufacturers
- Methods of insulin storage
- Procedures for mixing insulins
- Calculation of dosage adjustments
- Techniques of insulin administration
- Methods for monitoring blood glucose

In the final analysis, responsibility for managing diabetes rests with the patient. The healthcare team can design a treatment program and provide education and guidance. However, tight glucose control can only be achieved if the patient is actively involved in his or her own therapy.

57.4.3 Complications of Insulin Treatment

57.4.3.1 Hypoglycemia

Hypoglycemia (blood glucose below 50 mg/dL) occurs when insulin levels exceed insulin needs. A major cause of insulin excess is overdose. Imbalance between insulin levels and insulin needs can also result from reduced intake of food, vomiting and diarrhea (which reduce absorption of nutrients), excessive consumption of alcohol (which promotes hypoglycemia), unusually intense exercise (which promotes cellular glucose uptake and metabolism), and childbirth (which reduces insulin requirements).

Diabetic patients and their families should be familiar with the signs and symptoms of hypoglycemia. Some symptoms result from activation of the sympathetic nervous system; others arise from the central nervous system (CNS). When glucose levels fall *rapidly*, activation of the sympathetic nervous system occurs, resulting in tachycardia, palpitations, sweating, and nervousness. However, if glucose declines *gradually*, symptoms may be limited to those of CNS origin. Mild CNS symptoms include headache, confusion, drowsiness, and fatigue. If hypoglycemia is severe, convulsions, coma, and death may follow.

Rapid treatment of hypoglycemia is mandatory: If hypoglycemia is allowed to persist, irreversible brain damage or even death may result. In conscious patients, glucose levels can be restored with a fast-acting oral sugar (eg, glucose tablets, orange juice, sugar cubes, honey, corn syrup, nondiet soda). However, if the swallowing reflex or the gag reflex is suppressed, nothing should be administered by mouth. In cases of severe hypoglycemia, IV glucose is the preferred therapy. Parenteral *glucagon* is an alternative method of treatment. (The pharmacology of glucagon is discussed at the end of the chapter.)

In anticipation of hypoglycemic episodes, diabetic patients should always have an oral carbohydrate available (eg, sugared candy, sugar cubes, glucose tablets). Some prescribers recommend that patients keep glucagon on hand as well. Patients should carry some sort of identification (eg, Medic Alert bracelet) to inform emergency personnel of their condition.

In some patients, hypoglycemia occurs without producing the symptoms noted above. As a result, the patient remains unaware of hypoglycemia until blood sugar has become dangerously low. Hypoglycemia unawareness is a particular problem among patients practicing tight glucose control. The risk of dangerous hypoglycemia can be minimized by frequently monitoring blood glucose.

Both severe hypoglycemia and diabetic ketoacidosis (see below) can produce coma. Of the two causes, hypoglycemia is more common. Since treatment of these two conditions is very different (hypoglycemia involves withholding insulin, whereas ketoacidosis requires giving insulin), it is essential that coma from these causes be differentiated. The most definitive diagnosis is made by measuring plasma or urinary glucose levels: in hypoglycemic coma, glucose levels are very low; in ketoacidosis, glucose levels are very high.

57.4.3.2 Other Complications

57.4.3.2.1 Lipodystrophies

Altered deposition of subcutaneous fat (lipodystrophy) can occur at sites of insulin injection. Two types of change may be seen: (1) *lipoatrophy* (loss of subcutaneous fat), and (2) *lipohypertrophy* (accumulation of subcutaneous fat).

Lipoatrophy produces a depression in the skin at the site of insulin injection. The cause of atrophy appears to be immunologic. Accordingly, fat atrophy is most likely with use of insulin preparations that have a high concentration of antigenic contaminants. Because the insulin preparations in use today are much purer than those used in the past, lipoatrophy is now rare.

When lipoatrophy occurs, subcutaneous fat can often be restored by injecting a highly purified

insulin preparation (eg, human insulin) directly into the site of fat loss. Some improvement can be seen in 4 weeks, but full recovery can take 3 to 6 months.

Lipohypertrophy occurs at sites of too-frequent insulin injection. Fat accumulates because insulin stimulates fat synthesis. When use of the site is discontinued, excess fat is eventually lost. Lipohypertrophy can be minimized through systematic rotation of injection sites.

57.4.3.2.2

Allergic Reactions

Insulin injection can produce local and systemic allergic responses. Fortunately, allergic reactions are rare.

With local reactions, the injection site becomes red and hardened. These reactions are usually delayed, taking several hours to develop. Local reactions occur in response to a contaminant in the insulin preparation—not to the insulin itself. Because insulins in use today are highly purified, local reactions are uncommon.

Systemic reactions take place rapidly, and are characterized by the widespread appearance of red and intensely itchy welts. Breathing difficulty may develop. Systemic reactions occur in response to insulin itself, not to a contaminant. Prior to being discontinued, beef insulin, which differs from human insulin by three amino acids, was the most frequent cause of systemic allergy. Generalized reactions are much less likely with the human insulins employed now. If severe allergy develops in a patient who nonetheless must continue insulin use, a desensitization procedure can be performed. This process entails giving small initial doses of human insulin, followed by a series of progressively larger doses.

672

673

57.4.3.2.3

Hypokalemia

Insulin promotes uptake of potassium by cells. How? By activating a membrane-bound enzyme— $\text{Na}^1, \text{K}^1\text{-ATPase}$ —that pumps potassium into cells and pumps sodium out. Hence, in addition to lowering blood levels of glucose, insulin can also lower blood levels of potassium as well. When insulin dosage is proper, effects on potassium are unremarkable. However, if insulin dosage is excessive, clinically significant hypokalemia can result. Effects on the heart are of greatest concern: Hypokalemia can reduce contractility and can cause potentially fatal dysrhythmias.

57.4.4 Drug Interactions

57.4.4.1 Hypoglycemic Agents

Drugs that lower blood glucose levels can intensify hypoglycemia induced by insulin. Among these drugs are *sulfonylureas*, *glinides*, *beta-adrenergic blocking agents*, and *alcohol* (used acutely or long term in excessive doses). When these drugs are combined with insulin, special care must be taken to ensure as best as possible that blood glucose does not fall too low.

57.4.4.2 Hyperglycemic Agents.

Drugs that raise blood glucose (eg, *thiazide diuretics*, *glucocorticoids*, *sympathomimetics*) can counteract the desired effects of insulin. When these agents are combined with insulin, insulin dosage may need to be increased.

57.4.4.3 Beta-Adrenergic Blocking Agents.

Beta blockers can delay awareness of and response to hypoglycemia by masking signs that are associated with stimulation of the sympathetic nervous system (eg, tachycardia, palpitations) that hypoglycemia normally causes. Furthermore, since beta blockade impairs glycogenolysis, and since glycogenolysis is one means by which the body can counteract a fall in blood glucose, beta blockers can make insulin-induced hypoglycemia even worse.

57.5 ORAL AGENTS FOR TYPE 2 DIABETES

There are six main families of oral antidiabetic drugs: biguanides, sulfonylureas, glinides (meglitinides), thiazolidinediones (glitazones), alpha-glucosidase inhibitors, and gliptins. These agents are used only for type 2 diabetes, and only after a program of diet modification and exercise has failed to yield glycemic control. Actions and adverse effects of the oral agents are summarized in [Table 56-11](#).

For two reasons, the oral agents are not used for patients with type 1 diabetes. First, since all of these patients must use insulin, there's no need for additional antidiabetic medication. And second, even if additional medication were needed, most of the oral agents couldn't help much. Why?

Because, with the exception of the alpha-glucosidase inhibitors, the oral agents work, at least in part, by increasing insulin release and/or reducing insulin resistance. In either case, insulin is needed for full benefits, and type 1 patients don't have any.

673

674

TABLE 56-11 Oral Hypoglycemics for Type 2 Diabetes

Class and Specific Agents	Actions	Major Adverse Effects
Biguanide		
Metformin [Fortamet, Glucophage, Glumetza, Riomet]	Decreases glucose production by the liver, increases tissue response to insulin	GI symptoms: decreased appetite, nausea, diarrhea Lactic acidosis (rarely)
Sulfonylureas		
Tolbutamide [Orinase]	Promote insulin secretion by the pancreas; may also increase tissue response to insulin	Hypoglycemia
Glipizide [Glucotrol]		
Glyburide* [Micronase] (see Table 56-12 for other sulfonylureas)		
Glinides		
Repaglinide [Prandin]	Promote insulin secretion by the pancreas	Hypoglycemia
Nateglinide [Starlix]		
Thiazolidinediones		
Rosiglitazone [Avandia]	Decrease insulin resistance, and thereby increase glucose uptake by muscle and decrease glucose production by the liver	Hypoglycemia, but only in the presence of excessive insulin
Pioglitazone [Actos]		
Alpha-Glucosidase Inhibitors		
Acarbose [Precose]	Inhibit carbohydrate digestion and absorption, thereby decreasing the postprandial rise in blood glucose	GI symptoms: flatulence, cramps, abdominal distention, borborygmus
Miglitol [Glyset]		
Gliptins		
Sitagliptin [Januvia]	Enhances the activity of incretins (by inhibiting their breakdown), and thereby increases insulin release, reduces glucagon release, and decreases hepatic glucose production	None identified yet

* Commonly known as *glibenclamide* outside the United States.

The oral agents work in two basic ways. Some of them—notably the sulfonylureas, glitazones, and glinides—actively drive blood glucose down. Others—notably metformin (a biguanide) and the alpha-glucosidase inhibitors—don't drive blood glucose down; rather, they simply modulate the rise in glucose that happens after a meal. This distinction is not just academic: If taken when blood

glucose is normal or low, agents that drive glucose down can cause *hypoglycemia*. Hypoglycemia is not a risk with the drugs that simply impair the postprandial rise in blood glucose.

57.5.1 Biguanides: Metformin

Metformin [Glucophage, Glucophage XR, Fortamet, Glumetza, Riomet], classified chemically as a biguanide, is the drug of choice for initial therapy in most patients with type 2 diabetes. The most common side effects are GI disturbances. Lactic acidosis, a potentially fatal complication, is rare.

57.5.1.1 Mechanism of Action.

Metformin lowers blood glucose and improves glucose tolerance in three ways. First, it inhibits glucose production in the liver. Second, it reduces (slightly) glucose absorption in the gut. And third, it sensitizes insulin receptors in target tissues (fat and skeletal muscle), and thereby can increase glucose uptake in response to whatever insulin may be available. In contrast with the sulfonylureas (see below), metformin does not stimulate insulin release from the pancreas. As a result, metformin does not actively drive blood glucose levels down, and hence does not pose a risk of hypoglycemia.

57.5.1.2 Pharmacokinetics.

Following oral dosing, metformin is slowly absorbed from the small intestine. Of particular interest, the drug is excreted unchanged by the kidneys. Hence, in the event of renal impairment, metformin can accumulate to toxic levels.

57.5.1.3 Therapeutic Uses.

57.5.1.3.1 Glycemic Control.

Metformin is used to lower blood sugar in patients with type 2 diabetes who have not responded adequately to a program of diet modification and exercise. The drug may be used alone or in combination with a sulfonylurea, a glitazone, or exenatide. When used alone, metformin lowers basal and postprandial blood glucose levels. When metformin is combined with a sulfonylurea, glitazone, or exenatide, the combination lowers blood sugar more effectively than either drug alone—which is to be expected because they act by different mechanisms.

Metformin is well suited for patients who tend to skip meals. Here's why. When meals are skipped, blood sugar can drop below a level that is healthy. Because metformin does not lower blood glucose any further, it won't make the situation any worse. In contrast, drugs that

actively lower blood glucose, such as the glitazones and sulfonylureas, can convert normal or slightly low blood glucose into clinically significant hypoglycemia.

57.5.1.3.2 Prevention of Type 2 Diabetes.

Data from the Diabetes Prevention Program (DPP), a large study sponsored by the National Institutes of Health, indicate that metformin can delay development of type 2 diabetes in high-risk individuals. The DPP enrolled 3234 people ages 25 to 85. All participants had impaired glucose tolerance (as determined by an oral glucose tolerance test) and all were severely overweight. Participants were randomly assigned to one of three protocols: (1) intensive lifestyle changes with the aim of reducing body weight by 7% through moderate exercise (eg, vigorous walking 30 minutes a day 5 days a week) combined with a low-fat diet, (2) treatment with metformin (850 mg twice daily), or (3) treatment with placebo. The results? Metformin reduced the risk of developing type 2 diabetes by 31%. However, benefits were limited primarily to younger patients and to those who were most overweight; the drug was relatively ineffective in older patients and those less overweight. It must be stressed, however, that metformin is not a substitute for diet and exercise. In fact, the DPP showed that lifestyle changes are even more effective than metformin: the combination of moderate exercise plus weight loss (5% to 7% of initial weight) reduced the average risk of type 2 diabetes by 58%. Benefits were greatest (71%) for people over the age of 60.

57.5.1.3.3 Gestational Diabetes.

Recent clinical studies have compared metformin with insulin in pregnant women with type 2 diabetes. Multiple outcomes were assessed, including glycemic control in the mother, and blood glucose and Apgar scores in the neonate. The result? Outcomes with metformin were essentially the same as those with insulin, the traditional agent for managing gestational diabetes—suggesting that metformin may become an acceptable alternative for many women. (Note: The data obtained with metformin do *not* apply to other classes of oral agents, such as the sulfonylureas and glitazones.)

57.5.1.3.4 Polycystic Ovary Syndrome (PCOS).

PCOS is a combined endocrine/metabolic disorder characterized by androgen excess and insulin resistance. Symptoms include irregular periods, anovulation, infertility, acne, and hirsutism. Although not approved for PCOS, metformin can be very helpful. Treatment increases insulin sensitivity and decreases insulin levels, which, through an indirect mechanism, lowers androgen levels. The net result is improved glucose tolerance, improved

ovulation, and increased pregnancy rates. PCOS and its management are discussed further in [Chapter 62](#) (Drug Therapy of Infertility).

57.5.1.4 Side Effects.

The most common side effects are decreased appetite, nausea, and diarrhea. These generally subside over time. However, in 3% to 5% of patients, GI effects lead to discontinuation of treatment. Metformin decreases absorption of vitamin B₁₂ and folic acid, and can thereby cause vitamin deficiency.

In contrast to sulfonylureas, metformin does not cause weight gain. In fact, patients *lose* an average of 7 to 8 pounds. Appetite suppression and weight loss can occur both in the presence and absence of nausea, indicating that metformin-induced nausea is not the only reason for weight loss.

57.5.1.5 Toxicity: Lactic Acidosis.

Metformin and other biguanides inhibit mitochondrial oxidation of lactic acid, and can thereby cause lactic acidosis. This condition is a medical emergency and has a mortality rate of about 50%. Fortunately, lactic acidosis is rare (about 3 cases/100,000 patient-years) when metformin is used at recommended doses in patients with good renal function. However, in patients with renal insufficiency, metformin can rapidly accumulate to toxic levels. Accordingly, the drug must never be used by these people. In addition, metformin must be avoided in patients who are prone to increased lactic acid production. Among these are patients with liver disease, severe infection, or a history of lactic acidosis; patients who consume alcohol to excess; and patients with shock and other conditions that can result in hypoxemia.

674

All patients should be informed about early signs of lactic acidosis—hyperventilation, myalgia, malaise, and unusual somnolence—and instructed to report these to the prescriber. Metformin should be withdrawn until lactic acidosis has been ruled out. If lactic acidosis is diagnosed, hemodialysis can correct the condition and remove accumulated metformin.

675

Because heart failure (HF) can predispose to lactic acidosis, metformin is contraindicated for people with failing hearts. However, in one study, patients with HF who took the drug were *less* likely to die than those who took a sulfonylurea. These data suggest that use of metformin in HF is much safer than previously believed.

57.5.1.6 Drug Interactions.

57.5.1.6.1 Alcohol.

Like metformin, alcohol can inhibit breakdown of lactic acid, and can thereby intensify lactic acidoses caused by metformin. To minimize risk, patients should avoid consuming alcohol in excess, whether acutely or long term. Discontinuing alcohol entirely would be even safer.

57.5.1.6.2 Cimetidine.

Cimetidine [Tagamet], a histamine₂ (H₂) blocker used to reduce gastric acidity, can increase the risk of lactic acidosis. Accordingly, if an H₂ blocker is indicated, another member of the family should be used, since cimetidine is the only H₂ blocker that poses this risk.

57.5.1.6.3 Iodinated Radiocontrast Media.

Intravenous radiocontrast media that contain iodine pose a risk of acute renal failure, which could exacerbate metformin-induced lactic acidosis. To reduce risk, patients should discontinue metformin a day or two before elective radiography. Metformin can then be resumed 48 hours after the procedure, provided lab tests show that renal function is normal.

57.5.1.7 Preparations, Dosage, and Administration.

Metformin is available *alone* in immediate-release (IR) tablets (500, 850, and 1000 mg) as *Glucophage*; in extended-release (ER) tablets (500, 750, and 1000 mg) as *Glucophage XR*, *Fortamet*, and *Glumetza*; and in an oral solution (500 mg/5 mL) as *Riomet*. In addition, the drug is available in six fixed-dose *combinations* with other antidiabetic agents (see below).

With the IR tablets and oral solution, the recommended initial dosage is 500 mg twice daily (taken with the morning and evening meals) or 850 mg once daily, taken with a meal. The usual maintenance dosage is 850 mg twice daily. The maximum dosage is 850 mg 3 times a day (for adults) or 2000 mg/day (for children 10 to 16 years old).

With the ER tablets, dosing is done once daily with the *evening* meal. Why the evening meal? Because this timing may enhance absorption owing to slower GI transit time at night. For previously untreated patients, the initial dosage is 500 mg a day (or 1000 mg once a day using Fortamet). For patients already taking metformin, the total daily dosage remains the same; it's simply taken all at once. The maximum daily dosage is 2000 mg (or 2500 mg using Fortamet).

57.5.2 Sulfonylureas

The sulfonylureas, introduced in the 1950s, were the first oral hypoglycemics available. They work by promoting insulin release, and hence can only be used in type 2 diabetes. The sulfonylureas were a major advance in diabetes therapy: For the first time, some patients could be treated with an oral medication, rather than with daily injections of insulin. The major side effect with these drugs is hypoglycemia.

The sulfonylureas fall into two groups: *first-generation agents* and *second-generation agents*. Both generations reduce glucose levels to the same extent. How, then, do the generations differ? First, the second-generation agents are *much more potent* than the first-generation agents, and hence dosages are much lower (as much as 1000 times lower in some cases). Second, and more importantly, with the second-generation agents, *significant drug-drug interactions are less common*, and the outcomes tend to be milder. Because of these differences, the second-generation agents have largely replaced the first-generation agents in clinical practice.

Eight sulfonamides are available: four first-generation agents and three second-generation agents ([Table 56-12](#)). All have similar actions and side effects, and they all share the same application: treatment of type 2 diabetes.

57.5.2.1 Mechanism of Action.

Sulfonylureas act primarily by stimulating the release of insulin from pancreatic islets. If the pancreas is incapable of insulin synthesis, sulfonylureas will be ineffective—which is why they are ineffective in patients with type 1 diabetes. With prolonged use, sulfonylureas may increase target cell sensitivity to insulin.

How do sulfonylureas promote insulin release? They bind with and thereby block ATP-sensitive potassium channels in the cell membrane. As a result, the membrane depolarizes, thereby permitting influx of calcium, which in turn causes insulin release. The extent of release is glucose dependent, and diminishes when plasma glucose declines.

57.5.2.2 Therapeutic Use.

Sulfonylureas are indicated only for type 2 diabetes. These drugs are of no help to patients with type 1 diabetes. Sulfonylureas should be employed only if blood glucose cannot be lowered by a program of caloric restriction and exercise. When these agents are to be used, they should be employed as an *adjunct* to nondrug therapy—not as a substitute. The sulfonylureas may be used alone or together with other hypoglycemic drugs.

57.5.2.3 Adverse Effects.

57.5.2.3.1 Hypoglycemia.

Sulfonylureas can cause excessive lowering of blood glucose. Although hypoglycemia is usually mild, fatalities have occurred. Hypoglycemia is sometimes persistent, requiring infusion of dextrose for several days. Hypoglycemic reactions are most likely in patients with kidney or liver dysfunction. Why? Because sulfonylureas are eliminated by hepatic metabolism and renal excretion, and hence may accumulate to dangerous levels when liver and kidney function is impaired. If signs of hypoglycemia develop (fatigue, excessive hunger, profuse sweating, palpitations), the prescriber should be notified.

57.5.2.3.2 Cardiovascular Toxicity.

There has been controversy regarding the possibility of adverse cardiovascular reactions to oral hypoglycemics. In 1970, the large multicenter University Group Diabetes Program (UGDP) published results indicating that tolbutamide (the first sulfonylurea available), was linked to an increased risk of mortality from sudden cardiac death. In the UGDP study, cardiac mortality was 2.5 times greater among subjects treated with a combination of diet plus tolbutamide than among control subjects who received diet therapy alone. The UGDP study has been criticized on several grounds, including design, patient selection, dosing, and compliance. Subsequent clinical trials, including the UKPDS, have failed to confirm the conclusions of the UGDP report. The American Diabetes Association, which initially endorsed the UGDP study, has since withdrawn its support. Nonetheless, the risk of sudden cardiac death remains a concern—albeit small—and hence appropriate caution should be exercised.

57.5.2.3.3 Use in Pregnancy and Lactation.

57.5.2.3.3.1 Sulfonylureas should be avoided during pregnancy.

Although adequate studies in humans are lacking, sulfonylureas are teratogenic in animals. Furthermore, since sulfonylurea therapy during pregnancy often fails to provide good glycemic control, and since even mild hyperglycemia may be hazardous to the fetus, insulin is generally preferred for managing the diabetic pregnancy.

It is especially important to avoid sulfonylureas near term. Newborns exposed to these agents at the time of delivery have experienced severe hypoglycemia lasting as long as 4 to

10 days. Hence, if a sulfonylurea has been taken during pregnancy, it should be discontinued at least 48 hours prior to the anticipated time of delivery.

675

TABLE 56-12 Sulfonylureas: Time Course and Dosage

Generic Name [Trade Name]	Duration (hr)	Dosage*	Approximate Equivalent Dose (mg/24 hr) [†]
First-Generation Agents			
Tolbutamide [Orinase]	6–12	<i>Initial:</i> 1–2 gm/day in 1–3 doses <i>Maximum:</i> 2–3 gm/day in 1–3 doses	1000–1500
Acetohexamide [Dymelor]	12–24	<i>Initial:</i> 0.25–1.5 gm/day in 1 or 2 doses <i>Maximum:</i> 1.5 gm/day in 1 or 2 doses	500–750
Tolazamide [Tolinase]	12–24	<i>Initial:</i> 100–250 mg/day with breakfast <i>Maximum:</i> 0.75–1 gm/day in 2 doses	250–375
Chlorpropamide [Diabinese]	24–60	<i>Initial:</i> 250 mg/day with breakfast <i>Maximum:</i> 750 mg once a day	250–375
Second-Generation Agents			
Glipizide	10–24	<i>Initial:</i> 5 mg/day with breakfast <i>Maximum:</i> 40 mg/day in 2 doses	10
<i>Immediate release</i> [Glucotrol]			
<i>Sustained release</i> [Glucotrol XL]	24	<i>Initial:</i> 5 mg/day with breakfast <i>Maximum:</i> 20 mg/day with breakfast	10
Glyburide	16–24	<i>Initial:</i> 2.5–5 mg day with breakfast <i>Maximum:</i> 20 mg/day in 1 or 2 doses	5
<i>Nonmicronized</i> [DiaBeta, Micronase]			
<i>Micronized</i> [Glynase PresTab]	12–24	<i>Initial:</i> 1.5–3 mg/day with breakfast <i>Maximum:</i> 12 mg/day in 1 or 2 doses	3

Glimepiride [Amaryl]	24	<i>Initial:</i> 1–2 mg/day with breakfast <i>Maximum:</i> 8 mg/day with breakfast	2
* Elderly patients should use a smaller dose than those noted here.			
† These values reflect differences in potency, and can be used to estimate what dose to use when switching from one sulfonylurea to another.			

Sulfonylureas should not be taken by women who are nursing. These drugs are excreted into breast milk, posing a risk of hypoglycemia to the infant. If a woman wishes to breast-feed, she should substitute insulin for the sulfonylurea.

57.5.2.4 Drug Interactions.

57.5.2.4.1 Alcohol.

When alcohol is combined with a sulfonylurea (especially a first-generation agent), a disulfiram-like reaction may occur. This syndrome includes flushing, palpitations, and nausea. Disulfiram reactions are discussed fully in [Chapter 38](#). Also, alcohol can potentiate the hypoglycemic effects of sulfonylureas. Accordingly, patients using the drug must be warned against alcohol consumption.

57.5.2.4.2 Drugs That Can Intensify Hypoglycemia.

A variety of drugs, acting by diverse mechanisms, can intensify hypoglycemic responses to most sulfonylureas. Included are *nonsteroidal anti-inflammatory drugs*, *sulfonamide antibiotics*, *alcohol* (used acutely in large amounts), and *cimetidine*. Caution must be exercised when a sulfonylurea is used in combination with these drugs.

57.5.2.4.3 Beta-Adrenergic Blocking Agents.

Beta blockers can diminish the benefits of sulfonylureas by suppressing insulin release. (Recall that activation of beta receptors is one way to promote insulin release.) In addition, because beta blockers can mask sympathetic responses (primarily tachycardia) to declining blood glucose, use of beta blockers can delay awareness of sulfonylurea-induced hypoglycemia.

57.5.3 Glinides

Glinides—also known as *meglitinides*—are hypoglycemic agents that have the same mechanism as the sulfonylureas: stimulation of pancreatic insulin release. Only two glinides are available: repaglinide and nateglinide.

57.5.3.1 Repaglinide

57.5.3.1.1 Actions and Uses.

Like the sulfonylureas, repaglinide [Prandin] blocks ATP-sensitive potassium channels on pancreatic beta cells, and thereby facilitates calcium influx, which leads to increased insulin release. In clinical trials, repaglinide was about as effective as glyburide and glipizide (second-generation sulfonylureas). Over time, repaglinide can lower HbA_{1c} by about 1.7%. The drug is approved for type 2 diabetes only. Because repaglinide has the same mechanism as the sulfonylureas, patients who do not respond to sulfonylureas will not respond to this agent either. Repaglinide is approved for monotherapy or combined therapy with metformin or a glitazone.

57.5.3.1.2 Pharmacokinetics.

Repaglinide undergoes rapid absorption followed by rapid elimination. Blood levels peak within 1 hour of oral dosing and return to baseline about 4 hours later. Elimination results from hepatic metabolism followed by biliary excretion. The drug's half-life is only 1 hour. Blood levels of insulin rise and fall in parallel with levels of repaglinide—and since levels of repaglinide rise and fall quickly, so do blood levels of insulin.

57.5.3.1.3 Adverse Effects.

Repaglinide is generally well tolerated. The only significant adverse effect is *hypoglycemia*. In patients with liver dysfunction, metabolism of repaglinide may be slowed, and hence the risk of hypoglycemia may be increased. Because of possible hypoglycemia, it is imperative that patients eat no later than 30 minutes after taking the drug.

57.5.3.1.4 Drug Interactions.

Gemfibrozil [Lopid], a drug used to lower triglyceride levels, can inhibit the metabolism of repaglinide, thereby causing its level to rise. Hypoglycemia can result. If possible, the combination should be avoided. Fenofibrate can be used instead of gemfibrozil.

57.5.3.1.5 Preparations, Dosage, and Administration.

Repaglinide [Prandin] is available in 0.5-, 1-, and 2-mg tablets. Administration must always be associated with a meal. For patients who have not used another oral hypoglycemic, the initial dosage is 0.5 mg taken 0 to 30 minutes before each meal. Patients who *have* used another oral hypoglycemic may take 1 or 2 mg before each meal. The maximum daily dose is 16 mg (4 mg with each meal for up to four meals).

676

677

57.5.3.2 Nateglinide

57.5.3.2.1 Basic Pharmacology and Therapeutic Use.

The pharmacology of nateglinide [Starlix] is nearly identical to that of repaglinide. Both drugs have the same indication: treatment of type 2 diabetes, either as monotherapy or combined with metformin or a glitazone. They also have the same mechanism of action (promotion of insulin release), and major adverse effect (hypoglycemia), and perhaps the same major drug interaction (elevation of their blood level by gemfibrozil). The two drugs differ primarily with respect to time course. Specifically, nateglinide has a slightly faster onset (30 minutes vs. 1 hour) and a significantly shorter duration (2 hours vs. 4 hours). Because of its more rapid onset, nateglinide may be better suited for controlling the postprandial rise in glucose. However, because of its shorter duration, nateglinide is less effective than repaglinide (or metformin or a sulfonylurea) for controlling fasting glucose. Because the glinides and sulfonylureas have the same mechanism of action, nateglinide, like repaglinide, will not work in patients who have not responded to a sulfonylurea. Nateglinide undergoes extensive metabolism by cytochrome P450 enzymes, followed by rapid and complete excretion, primarily in the urine.

57.5.3.2.2 Preparations, Dosage, and Administration.

Nateglinide [Starlix] is available in 60- and 120-mg tablets. The initial dosage is 120 mg 3 times a day taken 0 to 30 minutes before a meal. For patients with HbA_{1c} concentrations close to the target value, the initial dosage is lower: 60 mg 3 times a day taken 0 to 30 minutes before a meal. Please note that dosing must always be associated with a meal. Otherwise, nateglinide-induced insulin release could cause hypoglycemia. Nateglinide costs a little more than repaglinide (\$85.50 for a 30-day supply vs. \$68.40) and *much* more than sulfonylureas (eg, generic glipizide costs only \$9.60 for a 30-day supply).

57.5.4 Thiazolidinediones (Glitazones)

The thiazolidinediones, also known as *glitazones* or simply *TZDs*, reduce glucose levels by decreasing insulin resistance. These agents are not related chemically or functionally to sulfonylureas, biguanides, or alpha-glucosidase inhibitors. Their only use is type 2 diabetes. Currently, two glitazones are available: rosiglitazone [Avandia] and pioglitazone [Actos]. A third drug—troglitazone [Rezulin]—can cause severe liver injury, and has been withdrawn. Although the glitazones are generally well tolerated, they can expand blood volume and cause edema, thereby posing a risk for patients with heart failure.

57.5.4.1 Rosiglitazone

57.5.4.1.1 Actions and Use.

Rosiglitazone [Avandia] reduces insulin resistance. The underlying mechanism is activation of a specific receptor type in the cell nucleus, known as the *peroxisome proliferator-activated receptor gamma* (PPAR gamma). By activating PPAR gamma, rosiglitazone turns on insulin-responsive genes that help regulate carbohydrate and lipid metabolism. As a result, cellular responses to insulin are increased (especially uptake of glucose). Hence, if rosiglitazone is to have an effect, insulin must be present. Benefits take several weeks to develop. In animal models of diabetes, glitazones increased uptake of glucose by muscle and decreased glucose production by the liver. In clinical trials, rosiglitazone decreased fasting plasma glucose by 76 mg/dL and reduced HbA_{1c} by about 1%. Rosiglitazone is approved for use as monotherapy, and for use in combination with metformin, a sulfonylurea, or insulin.

57.5.4.1.2 Pharmacokinetics.

Rosiglitazone is well absorbed, both in the presence and absence of food. Plasma levels peak 1 hour after dosing. The drug undergoes hepatic metabolism followed by excretion in the urine and feces. Its half-life is 3 to 4 hours.

57.5.4.1.3 Adverse Effects.

Rosiglitazone is generally well tolerated. Minor side effects, which occur in 10% of patients or less, include headache, myalgia, sore throat, and upper respiratory tract infections.

The most prominent side effect is renal *retention of fluid*, with resultant edema and weight gain (2 to 3 kg). For most patients, fluid retention is of little concern. However, in patients with heart failure, fluid retention can make symptoms worse. Accordingly, rosiglitazone should be used with caution in patients with *mild* heart failure, and should be avoided by those

with *severe* failure. Patients using the drug should be informed about signs of heart failure (dyspnea, edema, weight gain, fatigue), and instructed to consult the prescriber if these develop.

Rosiglitazone *raises levels of plasma lipids*. Specifically, it raises levels of high-density lipoprotein (HDL) cholesterol, which is good, but also raises levels of triglycerides (TGs) and low-density lipoprotein (LDL) cholesterol, which is bad.

Because rosiglitazone is related to troglitazone (a highly hepatotoxic drug), there was concern that rosiglitazone might be hepatotoxic too. However, years of experience with rosiglitazone have failed to reveal significant liver damage. Hence, intensive monitoring of liver function is no longer recommended. Rather, serum alanine aminotransferase (ALT) should be determined at baseline and periodically thereafter (eg, every 3 to 6 months). If ALT levels rise to more than 3 times the upper limit of normal, or if jaundice develops, rosiglitazone should be withdrawn. Patients should be informed about symptoms of liver injury (nausea, vomiting, abdominal pain, fatigue, anorexia, dark urine, jaundice) and instructed to notify the prescriber if these develop.

57.5.4.1.4 Drug Interactions.

Like rosiglitazone, *insulin* promotes fluid retention, and hence the combination poses an increased risk of heart failure. Accordingly, using rosiglitazone and insulin together should be done with caution.

Gemfibrozil [Lopid], a drug for hypertriglyceridemia, can raise plasma levels of rosiglitazone. The apparent mechanism is inhibition of rosiglitazone metabolism. High rosiglitazone levels may lead to hypoglycemia.

57.5.4.1.5 Preparations, Dosage, and Administration.

Rosiglitazone is available alone as *Avandia*, and in combination with metformin as *Avandamet* (see below). As *Avandia*, rosiglitazone is formulated in 2-, 4-, and 8-mg tablets. The recommended starting dosage is either 4 mg once a day or 2 mg twice a day, administered with or without food. If the response is inadequate after 12 weeks, the dosage may be doubled—to 8 mg once a day or 4 mg twice a day.

57.5.4.2 Pioglitazone.

Pioglitazone [Actos] is the newest member of the glitazone family. Like rosiglitazone—and unlike troglitazone—pioglitazone appears devoid of serious hepatotoxicity. In addition, pioglitazone has a more favorable effect on plasma lipids than does rosiglitazone.

57.5.4.2.1 Actions and Uses.

Like rosiglitazone, pioglitazone activates PPAR gamma, and thereby reduces insulin resistance. In patients with type 2 diabetes, monotherapy with pioglitazone can decrease fasting blood glucose by 30 to 56 mg/dL, and can lower HbA_{1c} by about 0.9%. Combining pioglitazone with insulin, metformin, or a sulfonylurea can further improve glycemic control. Pioglitazone is approved for monotherapy or combined therapy with insulin, metformin, or a sulfonylurea.

57.5.4.2.2 Pharmacokinetics.

Pioglitazone is well absorbed from the GI tract. Food reduces the rate of absorption but not the extent. In the absence of food, blood levels peak about 2 hours after dosing, compared with 3 to 7 hours in the presence of food. Pioglitazone undergoes hepatic metabolism to active and inactive metabolites. The half-life is 3 to 7 hours.

57.5.4.2.3 Adverse Effects and Interactions.

Adverse effects are generally mild. The most common reactions are upper respiratory tract infection (13%), headache (9%), sinusitis (6%), and myalgia (5%). There is no proof that pioglitazone is hepatotoxic. Nonetheless, liver function should be tested at baseline and periodically thereafter. Like rosiglitazone, pioglitazone promotes water retention, and can thereby cause weight gain (0.5 to 2.8 kg) and edema. Hence, as with rosiglitazone, the drug should be used with caution in patients with mild heart failure, and should be avoided by those with severe failure. In addition, since insulin increases the risk of fluid retention, combining the two drugs should be done with caution. The incidence of hypoglycemia is low with pioglitazone alone, but rises to between 8% and 15% when the drug is combined with insulin.

Compared with rosiglitazone, pioglitazone has a more favorable impact on plasma lipids. The most striking difference is that pioglitazone lowers plasma TG levels (which is good), whereas rosiglitazone raises TG levels. Although both drugs raise LDL levels (which is bad), the increase with pioglitazone is smaller. Similarly, although both drugs raise HDL levels (which is good), the increase with pioglitazone is larger.

Gemfibrozil [Lopid], which raises levels of rosiglitazone, may also raise levels of pioglitazone. If gemfibrozil and pioglitazone are combined, the risk of hypoglycemia may be increased.

677

678

57.5.4.2.4 Preparations, Dosage, and Administration.

Pioglitazone [Actos] is available in 15-, 30-, and 45-mg tablets. The initial dosage for monotherapy is 15 or 30 mg once a day, taken with or without food. Dosage may be increased to 45 mg once a day if needed.

57.5.5 Alpha-Glucosidase Inhibitors

The alpha-glucosidase inhibitors—acarbose and miglitol—act in the intestine to delay absorption of carbohydrates. The drugs are indicated for type 2 diabetes.

57.5.5.1 Acarbose

57.5.5.1.1 Mechanism of Action.

Acarbose [Precose] delays absorption of dietary carbohydrates, and thereby reduces the rise in blood glucose after a meal. In order to be absorbed, oligosaccharides and complex carbohydrates must be broken down to monosaccharides by alpha-glucosidase, an enzyme located on the brush border of cells that line the intestine. Acarbose inhibits this enzyme, and thereby slows digestion of carbohydrates, which reduces the postprandial rise in blood glucose.

Of note, the alpha-glucosidase inhibitors are the only oral antidiabetic agents whose effects do not depend at all on the presence of insulin. All of the other oral agents act, at least in part, by increasing insulin secretion and/or decreasing insulin resistance.

57.5.5.1.2 Therapeutic Use.

Acarbose is indicated for patients with type 2 diabetes whose hyperglycemia is not controlled by diet modification and exercise. The drug may be used alone or in combination with insulin, metformin, or a sulfonylurea. In clinical trials, 24 weeks of therapy with acarbose alone reduced mean peak postprandial glucose levels by 56 mg/dL, compared with 71 mg/dL for tolbutamide (a sulfonylurea) alone and 85 mg/dL for acarbose plus tolbutamide. In addition to lowering glucose levels after meals, acarbose lowers HbA_{1c} levels, indicating an overall improvement in glycemic control.

57.5.5.1.3 Pharmacokinetics.

Acarbose is administered by mouth, and only 2% is absorbed as active drug. As a result, systemic effects are minimal. Because acarbose acts locally in the intestine, lack of absorption

is considered beneficial. In the gut, acarbose is converted to inactive products by bacteria and digestive enzymes.

57.5.5.1.4 Adverse Effects and Interactions.

Acarbose frequently causes *flatulence*, *cramps*, *abdominal distention*, *borborygmus* (rumbling bowel sounds), and *diarrhea*. These responses result from bacterial fermentation of unabsorbed carbohydrates in the colon. In addition to its GI effects, acarbose can decrease absorption of iron, thereby posing a risk of anemia.

Hypoglycemia does not occur with acarbose alone, but may develop when acarbose is combined with *insulin* or a *sulfonylurea*. When hypoglycemia develops, sucrose cannot be used for oral therapy. Why? Because acarbose will impede its hydrolysis and thereby delay absorption. Accordingly, in patients taking acarbose, oral therapy of hypoglycemia must be accomplished with glucose itself.

Long-term, high-dose therapy may cause *liver dysfunction*. Asymptomatic elevation of plasma transaminases (which come from damaged liver cells) occurs in about 15% of patients. However, overt jaundice is rare. Liver function tests should be monitored every 3 months for the first year, and periodically thereafter. Liver dysfunction reverses when acarbose is discontinued.

The combination of metformin and acarbose should probably be avoided. Both drugs cause significant GI side effects, and hence the combination could be very unpleasant. Furthermore, acarbose decreases metformin absorption.

57.5.5.1.5 Preparations, Dosage, and Administration.

Acarbose [Precose] is available in tablets (25, 50, and 100 mg) to be taken with the first bite of main meals. The recommended initial dosage is 25 mg 3 times a day. Depending on tolerability and postprandial blood glucose levels, the dosage may be increased at 4- to 8-week intervals. The maximum dosage is 50 mg 3 times a day (for patients under 60 kg) and 100 mg 3 times a day (for patients over 60 kg).

57.5.5.2 Miglitol.

Miglitol [Glyset] is the second alpha-glucosidase inhibitor approved in the United States. Like acarbose, miglitol delays conversion of oligosaccharides and complex carbohydrates to glucose and other monosaccharides, and thereby reduces the postprandial rise in blood glucose. In clinical trials, the drug was especially effective among Latinos and African Americans. Hypoglycemia does not occur with miglitol monotherapy, but may occur if the drug is

combined with insulin or a sulfonylurea. Like acarbose, miglitol causes flatulence, abdominal discomfort, and other GI effects. In contrast to acarbose, miglitol has not been associated with liver dysfunction. As with acarbose therapy, oral sucrose cannot be used to treat hypoglycemia. Rather, oral glucose must be given. Miglitol is available in 25-, 50-, and 100-mg tablets. The initial dosage is 25 mg 3 times daily before meals. The maintenance dosage is 50 or 100 mg 3 times a day.

57.5.6 Sitagliptin

57.5.6.1 Description and Mechanism.

Sitagliptin [Januvia] is the first representative of a new class of drugs, known as *gliptins*. These agents enhance the actions of *incretin hormones*, endogenous compounds that (1) stimulate glucose-dependent release of insulin and (2) suppress postprandial release of glucagon (a hormone that decreases glucose production in the liver). Both actions help keep blood glucose from climbing too high. How does sitagliptin boost incretin actions? It inhibits dipeptidyl peptidase 4 (DPP-4), an enzyme that inactivates the incretin hormones. As discussed below, another drug—exenatide—also boosts incretin actions, but by a different mechanism: rather than preventing incretin breakdown, it mimics incretin actions.

57.5.6.2 Therapeutic Use.

Sitagliptin is indicated only for type 2 diabetes, either as monotherapy or combined with metformin or a glitazone. Since benefits are largely dependent on insulin, the drug will not work in patients with type 1 diabetes. Like all the other agents for managing diabetes, sitagliptin should be used as an adjunct to diet and exercise.

57.5.6.3 Adverse Effects and Interactions.

Sitagliptin is generally well tolerated. In clinical trials, the most common side effects were upper respiratory tract infection (6.3%), headache (5.1%), and inflammation of the nasal passages and throat (5.2%)—rates similar to those seen with placebo. The incidence of hypoglycemia was about 1.2%, compared with 0.9% with placebo—again a nonsignificant difference. The drug has no known clinically relevant drug interactions, and no contraindications, including pregnancy.

678

679

57.5.6.4 Preparations, Dosage, and Administration.

Sitagliptin [Januvia] is supplied in film-coated tablets (25, 50, and 100 mg). The usual dosage is 100 mg once daily, taken with or without food. Because sitagliptin is eliminated primarily by

renal excretion, dosages should be reduced in patients with renal impairment, as indicated by reduced creatinine clearance. Dosage should be reduced to 50 mg once daily (in moderate renal disease) and 25 mg once daily (in severe renal disease).

A combination of sitagliptin and metformin, marketed as Janumet, is discussed below.

57.5.7 Colesevelam

Colesevelam [Welchol] is best known as bile-acid sequestrant used to lower plasma cholesterol (see [Chapter 49](#)). However, the drug can also help lower blood glucose. Accordingly, in 2008, the FDA approved colesevelam for use in type 2 diabetes. Since many patients with diabetes also have high cholesterol, a drug that can help in both disorders is clearly welcome. The pharmacology of colesevelam is discussed at length in [Chapter 49](#).

57.5.8 Combination Products

Many patients with type 2 diabetes take two different oral drugs, often metformin combined with either a sulfonylurea or a glitazone. Once the efficacy and safety of the regimen has been established by taking separate pills, we can simplify dosing by switching to a combination product that has the same amounts of the same drugs. Available combinations are discussed below.

57.5.8.1 Metformin/Glyburide.

Metformin (a biguanide) and glyburide (a sulfonylurea) are available in a combination sold as *Glucovance*. Glyburide acts primarily by increasing insulin secretion; metformin acts primarily by decreasing hepatic glucose production, and partly by increasing glucose uptake and utilization by muscle.

Glucovance is indicated for initial therapy for patients with type 2 diabetes and for previously treated patients when glucose control has been inadequate with metformin or a sulfonylurea alone. The only advantage of the combination (over taking separate doses of metformin and a sulfonylurea) is convenience. Although Glucovance is approved for initial therapy, it would seem prudent to try either component alone initially, reserving the combination for patients who don't respond adequately. After all, why expose patients to the adverse effects of *two* drugs if treatment with just one would suffice?

Adverse effects of Glucovance are basically the sum of the adverse effects of glyburide and metformin. Glyburide poses a risk of *hypoglycemia*. Metformin can cause *GI disturbances* (nausea, diarrhea) and *appetite reduction*. Of greater concern, metformin poses a risk of *lactic acidosis*. Because of this risk, the combination is contraindicated for patients with renal

insufficiency, metabolic acidosis, heart failure, or any of the other contraindications noted above for metformin.

Glucovance tablets are available in three metformin/glyburide strengths: 250/1.25 mg, 500/2.5 mg, and 500/5 mg. For previously untreated patients, the initial dosage is 250/1.25 mg once or twice daily. For previously treated patients, the recommended dosage is either 500/2.5 mg or 500/5 mg twice daily. The maximum dosage is 2000/20 mg/day. All doses are taken with meals.

57.5.8.2 Metformin/Glipizide.

Metformin and glipizide are available in a combination sold as *Metaglip*. The product is nearly identical to metformin/glyburide [Glucovance], having the same indications, actions, and adverse effects.

Metaglip tablets are available in three metformin/glipizide strengths: 250/2.5 mg, 500/2.5 mg, and 500/5 mg. For previously untreated patients, the initial dosage is 250/2.5 mg once a day. For previously treated patients, the recommended dosage is either 500/2.5 mg or 500/5 mg twice daily. The maximum dosage is 2000/20 mg/day, administered in divided doses. All doses are taken with meals.

57.5.8.3 Metformin/Rosiglitazone.

Metformin and rosiglitazone (a glitazone) are available in combination as *Avandamet*. Rosiglitazone acts by decreasing insulin resistance; metformin acts primarily by decreasing hepatic glucose production, and partly by increasing glucose uptake and utilization by muscle. Avandamet is indicated for treating type 2 diabetes in previously treated patients who (1) have not responded adequately to rosiglitazone or metformin alone or (2) *have* responded adequately to rosiglitazone *plus* metformin, but want to simplify dosing. The combination is not approved for initial therapy of type 2 diabetes.

Adverse effects of Avandamet are simply the sum of the adverse effects of rosiglitazone and metformin. With rosiglitazone, the principal concern is *fluid retention*, which can exacerbate heart failure. Accordingly, Avandamet should be used with caution in patients with *mild* heart failure, and should be avoided in those with *severe* failure. Insulin increases the risk of heart failure, and hence Avandamet and insulin should not be combined. With metformin, the principal concern is *lactic acidosis*. Accordingly, Avandamet should be avoided by patients prone to developing acidosis, including those with renal insufficiency, metabolic acidosis, and heart failure. In addition to lactic acidosis, metformin can cause *GI disturbances* (nausea, diarrhea) and *appetite reduction*.

Avandamet tablets are available in three metformin/rosiglitazone strengths: 500/1 mg, 500/2 mg, and 500/4 mg. The maximum dosage is 2000/8 mg/day. Recommendations for initial dosages are as follows:

- *Patients already taking metformin alone:* Start with 4 mg rosiglitazone/day plus the dose of metformin already being used. Specifically, for patients taking 1000 mg metformin/day, give one 500/2-mg tablet twice daily, and for patients taking 2000 mg metformin/day, give two 500/1-mg tablets twice daily.
- *Patients already taking rosiglitazone alone:* Start with 1000 mg metformin/day plus the dose of rosiglitazone already being used. Specifically, for patients taking 4 mg rosiglitazone/day, give one 500/2-mg tablet twice daily, and for patients taking 8 mg rosiglitazone/day, give one 500/4-mg tablet twice daily.
- *Patients switching from rosiglitazone and metformin taken separately:* Start with the same dosage of each already in use.

57.5.8.4 Metformin/Pioglitazone.

Metformin and pioglitazone (a glitazone) are available in combination as ACTOplus Met. The product is much like metformin/rosiglitazone (Avandamet) with respect to actions, uses, and adverse effects. ACTOplus Met tablets are available in two metformin/pioglitazone strengths: 500/15 mg and 850/15 mg. Initial daily dosages are based on the dosage of pioglitazone or metformin the patient is already taking. The total daily dose can be taken all at once, or divided into two equal doses taken twice daily.

57.5.8.5 Metformin/Repaglinide.

Metformin and repaglinide are available in combination as *Prandimet* for treating patients with type 2 diabetes. Benefits derive from the insulin-releasing effects of repaglinide and from metformin's three-pronged attack on glycemic control: inhibition of hepatic glucose production, sensitization of insulin receptors on target cells, and a slight reduction in GI glucose absorption. Prandimet is available in two metformin/repaglinide strengths: 500/1 mg and 500/2 mg. Patients may start with either combination. Dosing is done 2 or 3 times a day with food. According to the package insert, the maximum *single* dose is 1000 mg metformin/4 mg repaglinide. The *daily total* should not exceed 2500 mg metformin/10 mg repaglinide.

57.5.8.6 Metformin/Sitagliptin.

Metformin and sitagliptin are available in combination under the trade name *Janumet* for treatment of type 2 diabetes. Sitagliptin inhibits the breakdown of incretin hormones (by inhibiting DPP-4), and thereby increases pancreatic secretion of insulin and decreases pancreatic secretion of glucagon. Metformin decreases hepatic glucose production, increases insulin sensitivity, and decreases GI absorption of glucose. Since adverse effects of sitagliptin are minimal (see above), adverse effects of the combination are primarily those of metformin: GI disturbances and, rarely, lactic acidosis. Janumet is available in two metformin/sitagliptin strengths: 500/50 mg and 1000/50 mg. Dosing is done twice daily with meals (to reduce GI upset). The starting dose is based on the patient's current regimen. The maximum daily dose is 2000 mg metformin and 100 mg sitagliptin.

57.5.8.7 Pioglitazone/Glimepiride.

Pioglitazone (a glitazone) and glimepiride (a sulfonylurea) are available in combination under the trade name *Duetact* for treatment of type 2 diabetes. Pioglitazone increases insulin sensitivity in target tissues (liver, fat, skeletal muscle) and glimepiride enhances insulin secretion from the pancreas. *Duetact* carries two types of risks. First, both components can cause dose-related *hypoglycemia* and, since they do so by different mechanisms, the combined risk is greater than with either drug alone. Second, both drugs can cause adverse cardiovascular effects: glimepiride (and other sulfonylureas) pose a risk, albeit small, of sudden cardiac death, and pioglitazone (and other glitazones) pose a risk of fluid retention, which can cause or exacerbate heart failure. *Duetact* tablets are available in two pioglitazone/glimepiride strengths: 30/2 mg and 30/4 mg. Dosing is done once daily with the first main meal of the day. Initial dosage is based on the current regimen. The maximum recommended daily dose is 30 mg pioglitazone/4 mg glimepiride, which is lower than the maximum when each drug is taken separately (45 mg pioglitazone and 8 mg glimepiride).

679

680

57.5.8.8 Rosiglitazone/Glimepiride.

Rosiglitazone (a glitazone) and glimepiride (a sulfonylurea) are available in combination under the trade name *Avandaryl* for treatment of type 2 diabetes. The actions and adverse effects of Avandia are essentially the same as those of pioglitazone/glimepiride [*Duetact*] discussed immediately above. Avandia tablets are available in six strengths: 4 mg rosiglitazone plus either 1, 2, or 4 mg glimepiride; and 8 mg rosiglitazone plus either 1, 2, or 4 mg glimepiride.

57.6 NEW INJECTABLE DRUGS FOR DIABETES

57.6.1 Pramlintide

Pramlintide [Symlin] is the first member of a new class of antidiabetic agents, the *amylin mimetics*. The drug is used to complement the effects of insulin in patients with type 1 or type 2 diabetes. Severe hypoglycemia is a concern, and nausea is common.

57.6.1.1 Description and Actions.

Pramlintide is a synthetic analog of *amylin*, a peptide hormone made in the pancreas and released with insulin. Both amylin and pramlintide, which mimics the effects of amylin, reduce postprandial levels of glucose, mainly by delaying gastric emptying and suppressing glucagon secretion. In addition, both agents act in the brain to increase the sense of satiety, and can thereby lower caloric intake.

57.6.1.2 Therapeutic Use.

Pramlintide is indicated as a supplement to mealtime insulin in patients with type 1 or type 2 diabetes who have failed to achieve glucose control despite optimal insulin therapy. Patients with type 2 diabetes may combine insulin and pramlintide with metformin and/or a sulfonylurea. In clinical trials, adding subQ pramlintide to mealtime insulin decreased postprandial glucose levels, smoothed out glucose fluctuations, and reduced the needed mealtime dose of insulin. Mean reductions in HbA_{1c} were about 0.39% for those with type 1 diabetes and 0.55% for those with type 2 diabetes.

57.6.1.3 Pharmacokinetics.

Blood levels peak about 20 minutes after subQ injection and decline with a half-life of 49 minutes. Unlike most drugs, pramlintide is metabolized in the kidneys rather than the liver. One active metabolite has been identified.

57.6.1.4 Adverse Effects.

Hypoglycemia is the biggest concern. Pramlintide does not cause hypoglycemia when used alone, but poses a risk of severe hypoglycemia when combined with insulin, especially in patients with type 1 diabetes. As a rule, hypoglycemia develops within 3 hours of dosing. To reduce risk, insulin dosage must be decreased, at least initially. Also, pramlintide should not be given to patients who have hypoglycemia unawareness, an HbA_{1c} level above 7%, or a history

of poor adherence to their insulin regimen, poor adherence to SBGM, or recurrent hypoglycemia needing assistance.

Nausea occurs early in therapy and is more common in patients with type 1 diabetes (37% to 48%) than type 2 diabetes (28% to 30%). The incidence and severity of nausea can be reduced by gradual titration of dosage.

Injection-site reactions—redness, swelling, or itching—may occur, but generally resolve within a few days to weeks.

57.6.1.5 Drug Interactions.

By delaying gastric emptying, pramlintide can delay the absorption of oral drugs. Accordingly, oral drugs should be taken 1 hour before injecting pramlintide or 2 hours after. Pramlintide should not be combined with other drugs that slow intestinal motility (eg, antimuscarinic agents, opioid analgesics) or with drugs that slow the absorption of nutrients (eg, acarbose, miglitol).

57.6.1.6 Preparations, Dosage, and Administration.

Pramlintide [Symlin] is supplied in solution (0.6 mg/mL) in 5-mL vials, which should be stored under refrigeration, but not frozen. Open vials, which can be kept cool or at room temperature, should be discarded after 28 days.

Dosing is done prior to major meals that contain at least 250 kcal or 30 gm of carbohydrates. Injections are made subQ into the abdomen or thigh, using a U-100 insulin syringe (preferably the 0.3-mL size). The manufacturer recommends against mixing pramlintide with insulin in the same syringe. However, a recent study indicates that mixing does not affect the absorption of either drug.

In patients with *type 1 diabetes*, the initial dosage is 15 mcg before meals. If there is no serious nausea for 3 days, dosage can be increased in 15-mcg steps to a maximum of 60 mcg. If 30 mcg causes too much nausea, discontinuation should be considered.

In patients with *type 2 diabetes*, the initial dosage is 60 mcg before meals. If there is no serious nausea for 3 to 7 days, dosage may be increased to 120 mcg.

In patients with *type 1* or *type 2 diabetes*, the premeal dose of rapid- or short-acting insulin should be decreased by 50% (to reduce the risk of hypoglycemia). When the maintenance dosage of pramlintide is established, the insulin dosage can be titrated up.

57.6.2 Exenatide

Exenatide [Byetta] is the first representative of a new class of antidiabetic agents, the *incretin mimetics*. The drug is used to improve glucose control in patients taking metformin or a sulfonylurea. Nausea is common, and hypoglycemia can occur. Long-term effects—both beneficial and adverse—are unknown.

57.6.2.1 Description and Actions.

Exenatide is a synthetic analog of glucagon-like peptide-1 (GLP-1), a peptide hormone in the *incretin* family. Under physiologic conditions, GLP-1 and other incretins are released from cells of the GI tract after a meal. Exenatide activates receptors for GLP-1, and thereby causes the same effects as endogenous incretins. That is, it slows gastric emptying, stimulates glucose-dependent release of insulin, inhibits postprandial release of glucagon, and suppresses appetite. As discussed above, another drug—sitagliptin—has identical effects. However, it works by a different mechanism: rather than activating incretin receptors directly, sitagliptin increases concentrations of endogenous incretins (by inhibiting their breakdown by DPP-4).

57.6.2.2 Therapeutic Use.

Exenatide is indicated as adjunctive therapy to improve glycemic control in patients with type 2 diabetes who are taking metformin, a sulfonylurea, or both. In clinical trials, injecting exenatide (5 or 10 mcg) subQ before meals produced a modest decrease in fasting blood glucose and a large decrease in postprandial blood glucose. Patients did not gain any weight, and many lost weight.

57.6.2.3 Pharmacokinetics.

Plasma levels peak 2.1 hours after subQ injection, and decline with a half-life of 2.4 hours. Exenatide is excreted unchanged in the urine. In patients with mild to moderate renal impairment, clearance is reduced only slightly, and hence no dosage reduction is needed. By contrast, in patients with end-stage renal disease, clearance is reduced significantly, and hence the drug should not be used.

680

681

57.6.2.4 Adverse Effects.

Dose-related *hypoglycemia* is common when exenatide is combined with a sulfonylurea (but not when combined with metformin). To minimize hypoglycemia, sulfonylurea dosage may need a reduction. *Gastrointestinal effects*—nausea (44%), vomiting (13%), and diarrhea (13%)—are

common. In some patients, *anti-exenatide antibodies* develop. These antibodies do not cause adverse effects, but they can reduce exenatide's effects.

In pregnant animals, doses of exenatide only 3 times the human dose caused *fetal harm*, manifesting as reduced growth and skeletal abnormalities. At this time, the drug is classified in FDA Pregnancy Risk Category C, and hence should be used only if the benefits are believed to outweigh the fetal risk. Furthermore, given the established safety and efficacy of insulin in pregnancy, there seems to be little reason to even try exenatide.

Exenatide poses a risk of *pancreatitis*. Severe cases have led to pancreatic necrosis, pancreatic hemorrhage, and even death. Patients should be informed about signs and symptoms of pancreatitis—typically severe and persistent abdominal pain, with or without vomiting—and instructed to stop exenatide immediately. If pancreatitis is confirmed, exenatide should not be resumed. Patients with a history of pancreatitis should probably not use this drug.

57.6.2.5 Drug Interactions.

Exenatide delays gastric emptying, and hence can slow the absorption of oral drugs, thereby decreasing peak plasma levels. Reduced absorption is of particular concern with oral contraceptives and antibiotics, which require high peak concentrations to be maximally effective. To minimize this interaction, give oral drugs at least 1 hour before exenatide.

57.6.2.6 Preparations, Dosage, and Administration.

Exenatide [Byetta] is supplied in pre-filled, 60-dose injector pens that deliver 5 or 10 mcg per dose. Injections are made subQ into the thigh, abdomen, or upper arm. The initial dosage is 5 mcg twice daily, administered 0 to 60 minutes before the morning and evening meals—never after the meal. After 1 month, the dosage may be increased to 10 mcg twice daily. If the patient is taking a sulfonylurea, its dosage may need a reduction (to avoid hypoglycemia). If the patient is taking metformin, no dosage reduction is needed. Because of greatly reduced clearance, exenatide should not be used by patients with severe renal impairment.

57.7 DIABETIC KETOACIDOSIS AND HYPERGLYCEMIC HYPEROSMOLAR NONKETOTIC SYNDROME

The cardinal feature of both disorders—diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar nonketotic syndrome (HHNS)—is hyperglycemic crisis and associated loss of fluid and electrolytes. Both conditions can be life threatening, and hence immediate treatment should be implemented. As indicated in [Table 56-13](#), these disorders have two principal differences. First,

hyperglycemia is more severe in HHNS. Second, whereas ketoacidosis is characteristic of DKA, it is absent in HHNS. Treatment of both disorders is similar.

57.7.1 Diabetic Ketoacidosis

Diabetic ketoacidosis is a severe manifestation of insulin deficiency. This syndrome is characterized by hyperglycemia, production of ketoacids, hemoconcentration, acidosis, and coma. These symptoms typically evolve quickly, over a period of several hours to a couple of days. Before insulin became available, practically all patients with type 1 diabetes died from ketoacidosis. Today, DKA remains a common complication in pediatric patients, and the leading cause of diabetes-related death in this group. DKA occurs much more often in patients with type 1 diabetes than in those with type 2 diabetes.

57.7.1.1 Pathogenesis

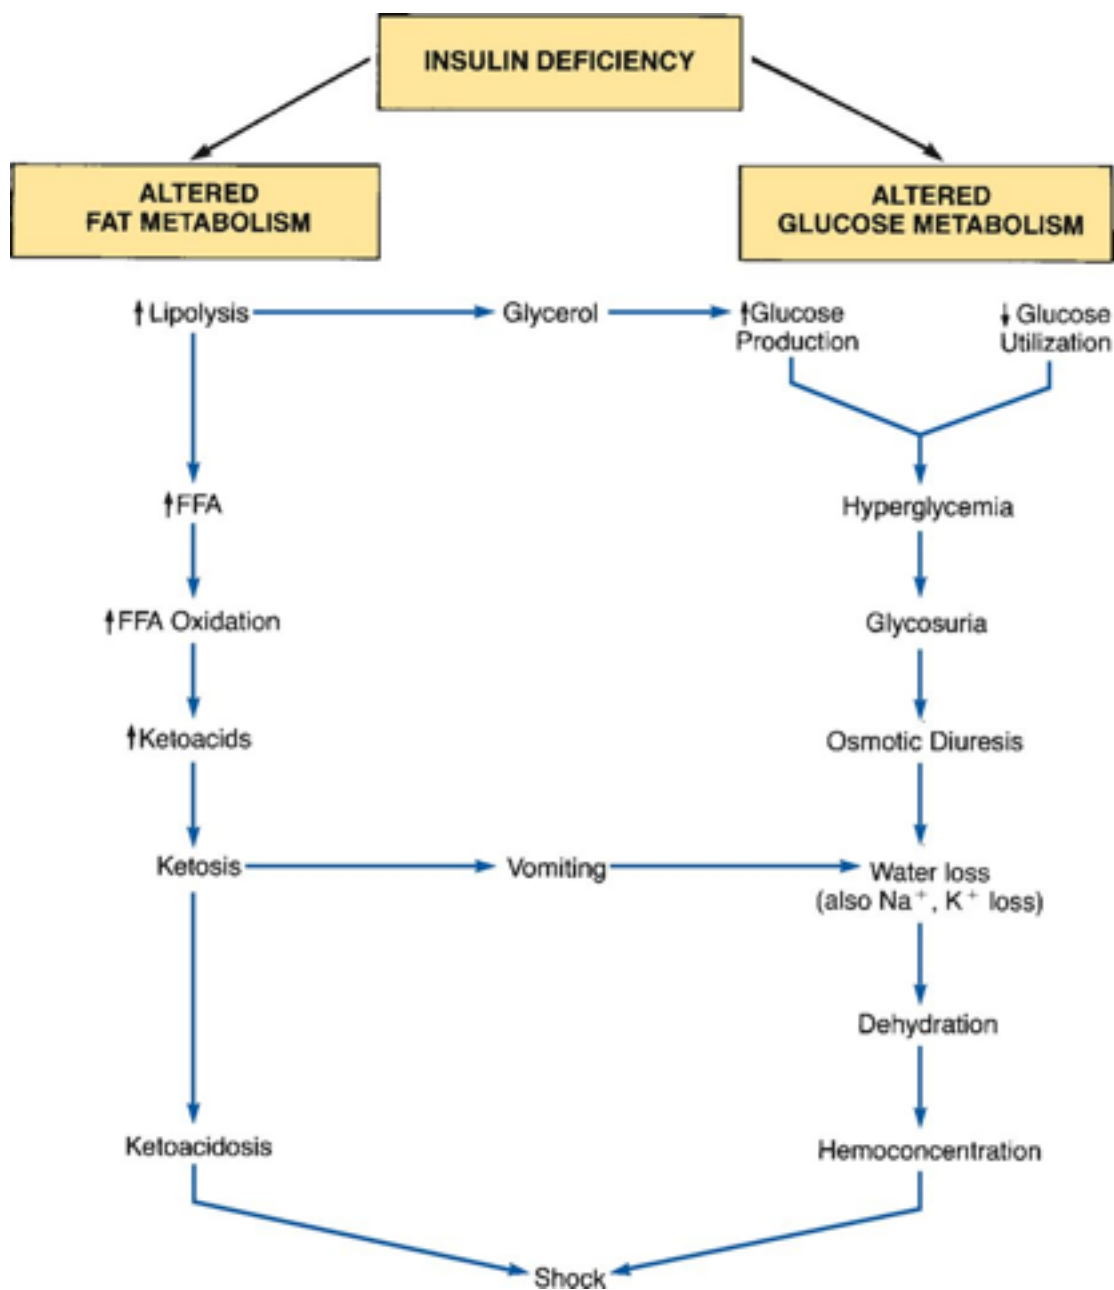

DKA is brought on by derangements of glucose and fat metabolism. Altered glucose metabolism causes hyperglycemia, water loss, and hemoconcentration. Altered fat metabolism causes production of ketoacids. [Figure 56-3](#) outlines the sequence of metabolic events by which ketoacidosis develops. Note that, in its final stages, the syndrome consists of hemoconcentration and shock in addition to ketoacidosis itself. The alterations in fat and glucose metabolism that lead to ketoacidosis are described in detail below.

57.7.1.1.1 Altered Fat Metabolism.

Alterations in fat metabolism lead to production of ketoacids. As indicated in [Figure 56-3](#), insulin deficiency promotes lipolysis (breakdown of fats) in adipose tissue. The products of lipolysis are glycerol and free fatty acids (FFA). Both of these metabolites are

681

Figure 56-3 **Pathogenesis of diabetic ketoacidosis.** The syndrome of diabetic ketoacidosis (DKA) is caused by severe derangements of glucose metabolism and fat metabolism that occur in response to lack of insulin (see text for details). (FFA 5 free fatty acids.)

transported to the liver. In the liver, oxidation of FFA results in the production of two ketoacids (beta-hydroxybutyric acid and acetoacetic acid), also known as ketone bodies. Accumulation of ketoacids puts the body in a state of ketosis. As buildup of ketoacids increases, frank acidosis develops. At this point, the patient's condition changes from ketosis to ketoacidosis. (Ketoacidosis can be distinguished from ketosis by the presence of hyperventilation.) Acidosis contributes to the development of shock.

TABLE 56-13 Contrasts Between Diabetic Ketoacidosis and Hyperglycemic Hyperosmolar Nonketotic Syndrome

Characteristic	Diabetic Ketoacidosis	Hyperglycemic Hyperosmolar Nonketotic Syndrome
Patient population	Mainly in type 1 diabetes	More likely in type 2 diabetes
Onset	Rapid	Gradual
Blood glucose (mg/dL)	≥ 300	≥ 600
Plasma osmolality (mOsm/L)*	< 320	> 320
pH of arterial blood	≤ 7.3	≥ 7.3
Blood ketones	Large increase	Little or no change
Urine ketones	Large increase	Normal or small increase
Urine and breath odor	Urine smells like rotten apples; breath smells sweet or like acetone (nail polish)	Normal

* The normal range is 285 to 295 mOsm/L.

Ketosis imparts characteristic smells to the urine and breath, which can be useful clues to the patient's condition. Ketones in the urine smell like rotten or decaying apples. Ketones in expired air give off a sweet smell, sometimes called *Juicy Fruit breath*, because it smells much like that flavorful chewing gum. Alternatively, the breath may smell like nail-polish remover, which contains the ketone acetone. To some degree, the breath of a ketotic person smells like the breath of someone who has been drinking alcohol. Because of this smell—coupled with the neurologic sequelae of ketosis (reduced alertness, impaired gait and balance)—some patients with DKA have been arrested for drunk driving, even though they hadn't been drinking at all.

57.7.1.1.2 Altered Glucose Metabolism.

Deranged glucose metabolism leads to hyperglycemia, water loss, and hemoconcentration. As shown in [Figure 56-3](#), insulin deficiency has two direct effects on the metabolism of glucose: (1) an increase in glucose production and (2) a decrease in glucose utilization. (The glycerol released by lipolysis is a substrate for glucose synthesis, and therefore helps increase glucose production.) Because more glucose is being made and less is being used, plasma levels of glucose rise, causing hyperglycemia. Glycosuria develops when plasma glucose content becomes so high that the amount of glucose filtered by the glomeruli exceeds the capacity of the renal tubules for glucose reuptake. As the concentration of glucose in the urine increases, osmotic diuresis develops, resulting in the loss of large volumes of water. Vomiting is a direct source of fluid loss and, more importantly, is an impediment to rehydration with oral fluids. (It should be noted that, along with loss of water, sodium and potassium are lost too. These ions are excreted in conjunction with ketone bodies, compounds that carry a negative charge.) As dehydration becomes more severe, hemoconcentration develops. Hemoconcentration causes cerebral dehydration, which, together with acidosis, leads to shock.

57.7.1.2 Treatment

Diabetic ketoacidosis is a life-threatening emergency. Treatment is directed at correcting hyperglycemia and acidosis, replacing lost water and sodium, and normalizing potassium balance. We begin with IV fluids and electrolytes, followed as soon as possible by IV insulin. Although it might seem reasonable to drive glucose levels down quickly with lots of insulin, doing so is unsafe and should be avoided. Instead, glucose levels should be reduced slowly, by about 50 mg/dL/hr.

682

57.7.1.2.1 Insulin Replacement.

683

Insulin levels are restored with an initial IV bolus of regular insulin (0.1 to 0.15 units/kg body weight) followed by continuous infusion at a rate of 0.1 units/kg/hr. When plasma glucose has fallen to 250 mg/dL, the infusion rate should be reduced to 0.05 to 0.2 units/kg/hr, and a dextrose solution (5% in half-normal saline) should be infused at a rate of 150 to 200 mL/hr. Thereafter, the insulin dosage should be adjusted as needed to maintain plasma glucose levels at 200 mg/dL until acidosis has resolved. Switching to subQ insulin is common and acceptable once the patient recovers from the acute episode.

Intravenous administration of insulin is preferred to subQ injection for initial management. Here's why. First, in patients with DKA, absorption of subQ insulin is apt to be both slow and erratic, making accurate dosing difficult. Second, when insulin is administered subQ, insulin

levels cannot be lowered quickly in response to inadvertent excessive dosing, and hence avoiding hypoglycemia may be difficult. Intravenous administration avoids these problems: Blood levels of insulin are established immediately; there is no uncertainty about the amount “absorbed”; and, if the blood level of insulin is too high, it can be quickly lowered by stopping the infusion, thereby permitting good control of blood glucose content.

57.7.1.2.2 Bicarbonate for Acidosis.

Treating acidosis with bicarbonate is controversial. Studies have failed to demonstrate any benefit of giving bicarbonate to patients with severe acidosis (blood pH 6.9 to 7.1). Nonetheless, some authorities recommend empiric therapy with bicarbonate if blood pH is below 6.9. The dose is 44.6 mEq of sodium bicarbonate (dissolved in 500 mL of 0.45% saline) infused over 1 hour. Because bicarbonate promotes hypokalemia, potassium should be infused along with the bicarbonate, unless hyperkalemia (serum potassium above 5.5 mEq/L) is present.

57.7.1.2.3 Water and Sodium Replacement.

Dehydration and sodium loss are both corrected with IV saline. Depending on the specific needs of the patient, either 0.9% or 0.45% saline is employed. Adults usually require between 8 and 10 L of fluid during the first 12 hours of treatment. In elderly patients and patients with heart disease, central venous pressure should be monitored.

57.7.1.2.4 Potassium Replacement.

Hypokalemia of DKA is a serious problem and must be corrected. As a rule, potassium is replenished by IV administration. Because hypokalemia predisposes the patient to dysrhythmias, electrocardiographic monitoring is essential.

Treatment of potassium loss is tricky. Why? Because plasma potassium levels may be normal even though intracellular potassium is very low. When insulin is administered, causing cellular uptake of potassium to increase, severe hypokalemia can develop as plasma potassium rushes into potassium-depleted cells. Because of this relationship between insulin administration and plasma potassium levels, the following guidelines apply: (1) if plasma potassium is normal, no potassium should be administered until plasma potassium declines in response to insulin; (2) if plasma potassium is low, potassium should be given immediately (and then re-administered if potassium levels fall following insulin administration).

57.7.1.2.5 Normalization of Glucose Levels.

Treatment of ketoacidosis with insulin may convert hyperglycemia into hypoglycemia. Because cellular uptake of glucose is impaired by insulin deficiency, ketoacidosis is likely to be associated with a reduction in intracellular glucose—despite elevations in plasma glucose content. Under these conditions, insulin administration will cause plasma glucose to rush into the glucose-depleted cells, thereby causing plasma levels of glucose to drop precipitously. If insulin therapy induces hypoglycemia, plasma glucose can be restored by administering glucagon or glucose itself.

57.7.2 Hyperglycemic Hyperosmolar Nonketotic Syndrome

Hyperglycemic hyperosmolar nonketotic syndrome (HHNS), also known as hyperglycemic hyperosmolar syndrome, (HHS), is similar to DKA in some respects and different in others. As noted, the central characteristic in both disorders is severe hyperglycemia brought on by insulin deficiency. In HHNS, as in DKA, a large amount of glucose is excreted in the urine, carrying a large volume of water with it. The result is dehydration and loss of blood volume, which greatly increases the blood concentrations of electrolytes and nonelectrolytes (particularly glucose)—hence the term *hyperosmolar*. Loss of blood volume also increases the hematocrit. As a result, the blood “thickens” and blood flow becomes sluggish. How does HHNS differ from DKA? As its name indicates, HHNS is nonketotic: There is little or no change in ketoacid levels in blood, and hence little or no change in blood pH. In contrast, blood levels of ketoacids rise dramatically in DKA, causing blood pH to fall. Since ketone levels remain close to normal in HHNS, the sweet or acetone-like smell imparted to the urine and breath of the DKA patient is absent. Finally, whereas DKA occurs mainly in patients with type 1 diabetes and develops quickly (usually in association with infection, acute illness, or some other stress), HHNS occurs more often in patients with type 2 diabetes and evolves slowly: metabolic changes typically begin a month or two before signs and symptoms become apparent. If HHNS goes untreated, severe dehydration will eventually lead to coma, seizures, and death. As with DKA, management of HHNS is directed at correcting hyperglycemia and dehydration by use of intravenous insulin, fluids, and electrolytes.

57.8 GLUCAGON FOR INSULIN OVERDOSE

Insulin overdose can cause severe hypoglycemia. The preferred treatment is IV glucose. However, if this option is not available, blood glucose can be restored with glucagon.

Glucagon, a polypeptide hormone produced by alpha cells of the pancreas, has effects on carbohydrate metabolism that are opposite to those of insulin. Specifically, glucagon promotes the breakdown of glycogen to glucose, reduces conversion of glucose to glycogen, and stimulates

biosynthesis of glucose. Hence, whereas insulin acts to lower plasma glucose content, glucagon causes glucose to rise. In addition to these metabolic effects, glucagon acts on GI smooth muscle to promote relaxation.

Glucagon is used to treat hypoglycemia resulting from insulin overdose. However, in patients with severe hypoglycemia, IV glucose is preferred. Why? Because IV glucose raises blood glucose immediately, whereas responses to glucagon are somewhat delayed. Accordingly, glucagon should be used only if IV glucose is not an option. When IV glucagon is administered to unconscious patients, the subsequent rise in blood glucose usually restores consciousness in 20 minutes or so. Once consciousness is sufficient for swallowing, oral carbohydrates should be given. These will help prevent recurrence of hypoglycemia and will help replenish hepatic glycogen stores.

Glucagon cannot correct hypoglycemia resulting from starvation. Why? Because glucagon acts in large part by promoting glycogen breakdown, and people who are starved have little or no glycogen left.

Glucagon is administered parenterally (IM, subQ, and IV). The drug is supplied in powder form and must be reconstituted to a concentration of 1 mg/mL (or less) using the diluent supplied by the manufacturer. A dose of 0.5 to 1 mg is usually effective.

57.8.1

KEY POINTS

- Diabetes mellitus (diabetes) is characterized by sustained hyperglycemia.
- Initial metabolic changes involve glucose and other carbohydrates. If the disease progresses, metabolism of fats and proteins changes as well.
- Diabetes has two major forms: type 1 diabetes, formerly called insulin-dependent diabetes mellitus or juvenileonset diabetes, and type 2 diabetes, formerly called non– insulin-dependent diabetes mellitus or adult-onset diabetes.
- Symptoms of type 1 diabetes result from a complete absence of insulin. The underlying cause is autoimmune destruction of pancreatic beta cells.
- Symptoms of type 2 diabetes result primarily from cellular resistance to insulin's actions, not from insulin deficiency.
- Type 1 diabetes and type 2 diabetes share the same long-term complications: hypertension, heart disease, stroke, blindness, renal failure, neuropathy, lower limb amputations, erectile dysfunction, and gastroparesis. However, these complications are more likely in type 1 diabetes, typically develop sooner, and usually are more severe.

- Diabetes is diagnosed if (1) fasting plasma glucose is 126 mg/dL or higher, or (2) casual blood glucose is 200 mg/dL or higher, and the patient has the classic signs and symptoms of diabetes: polyuria, polydipsia, and sudden weight loss that cannot be attributed to other common causes.

683

- With type 1 and type 2 diabetes, the goal of treatment is to reduce long-term complications, including death.
- Type 1 diabetes is treated with insulin replacement. Oral hypoglycemics agents are ineffective.
- Type 2 diabetes is treated with oral hypoglycemics, or if needed, insulin or another injectable drug—but always in conjunction with a program of diet modification and exercise, and only if glycemic control cannot be maintained by diet and exercise alone.
- Self-monitoring of blood glucose (SMBG) is the standard method for day-to-day monitoring of diabetes therapy. The premeal target is 90 to 130 mg/dL, and the peak postmeal target is 180 mg/dL or lower.
- Glycated hemoglobin (HbA_{1c}) should be measured every 3 to 6 months to assess long-term glycemic control. The target value is 7% of total hemoglobin or lower.
- Insulin is an anabolic hormone. That is, it promotes conservation of energy and buildup of energy stores.
- Insulin has two basic effects: it (1) stimulates uptake of glucose, amino acids, and potassium; and (2) promotes synthesis of complex organic molecules (glycogen, proteins, triglycerides).
- Insulin deficiency puts the body into a catabolic mode. As a result, glycogen is converted to glucose, proteins are degraded to amino acids, and fats are converted to glycerol (glycerin) and free fatty acids.
- Insulin deficiency promotes hyperglycemia by increasing glycogenolysis and gluconeogenesis and decreasing glucose utilization.
- Seven types of insulin are used in the United States: regular insulin (human insulin), NPH insulin, and five human insulin analogs: insulin lispro, insulin aspart, insulin glulisine, insulin detemir, and insulin glargine.

684

- All insulins used in the United States are produced by recombinant DNA technology. Insulin extracted from beef or pork pancreas is no longer available.
- Insulin lispro, insulin aspart, and insulin glulisine have a very rapid onset and short duration.
- Regular (native) insulin, when used subQ, has a moderately rapid onset and short duration.
- NPH insulin and insulin detemir have intermediate durations.
- Insulin glargine has a prolonged duration, with no definite “peak” in either blood levels or hypoglycemic effects.
- All insulins can be administered subQ, and four preparations—regular, aspart, lispro, and glulisine insulin—can be administered IV as well. A formulation for oral inhalation [Exubera] has been withdrawn.
- One insulin preparation—NPH insulin—is a *suspension*. It looks cloudy and should be gently agitated before being drawn into a syringe. All other insulins are *solutions*. They look clear and do not require agitation.
- Insulin is used to treat all patients with type 1 diabetes and some patients with type 2 diabetes.
- When insulin therapy produces tight glucose control, it can markedly reduce the long-term complications of diabetes, as demonstrated in the Diabetes Control and Complications Trial (DCCT) and the United Kingdom Prospective Diabetes Study (UKPDS).
- To achieve tight glucose control, patients with type 1 diabetes must practice intensive insulin therapy, consisting of either (1) an evening injection of insulin glargine supplemented with mealtime injections of regular, lispro, aspart, or glulisine insulin; or (2) continuous subQ infusion of regular, lispro, aspart, or glulisine insulin supplemented with mealtime bolus doses. With both approaches, the mealtime dose is adjusted to match caloric intake. Tight glucose control cannot be achieved with conventional insulin therapy (ie, one or two injections a day).
- SMBG is an essential component of intensive insulin therapy. Blood glucose should be measured 3 to 5 times a day. (In patients with type 2 diabetes who are not using insulin,

SMBG does not improve long-term outcomes, and hence, although desirable, is not considered necessary.)

- Compared with conventional therapy, intensive insulin therapy carries a greater risk of hypoglycemia. Other drawbacks are greater cost, inconvenience, complexity, and weight gain.
- The most important and common adverse effect of insulin therapy is hypoglycemia (blood glucose below 50 mg/dL), which occurs whenever insulin levels exceed insulin needs. Symptoms include tachycardia, palpitations, sweating, headache, confusion, drowsiness, and fatigue. If hypoglycemia is severe, convulsions, coma, and death may follow.
- Beta blockers can delay awareness of hypoglycemia by masking hypoglycemia-induced signs that are caused by activation of the sympathetic nervous system (eg, tachycardia, palpitations). In addition, beta blockers inhibit the breakdown of glycogen to glucose, and can thereby impede glucose replenishment.
- Insulin-induced hypoglycemia can be treated with a fast-acting oral sugar (eg, glucose tablets, orange juice, sugar cubes), IV glucose, or parenteral glucagon. (Oral sucrose—aka table sugar—acts slowly, and will barely work at all in patients taking acarbose, a drug that prevents intestinal conversion of sucrose into glucose and fructose.)
- Oral hypoglycemic drugs—metformin, sulfonylureas, glinides, thiazolidinediones, alpha-glucosidase inhibitors, and gliptins—are indicated only for type 2 diabetes. They are not used for type 1 diabetes.
- Metformin (a biguanide) decreases glucose production by the liver and increases glucose uptake by muscle. In patients who need to lose weight, metformin can also help by reducing appetite.
- The major adverse effects of metformin are GI disturbances: decreased appetite, nausea, and diarrhea. Metformin does *not* cause hypoglycemia.
- Very rarely, metformin causes lactic acidosis, which can be fatal. The risk of lactic acidosis is greatly increased by renal impairment, which decreases metformin excretion and thereby causes levels to rise rapidly.
- Sulfonylureas stimulate release of insulin from the pancreas. They may also increase cellular sensitivity to insulin.
- The major adverse effect of sulfonylureas is hypoglycemia. They may also increase the risk of sudden cardiac death.

- Rosiglitazone, a thiazolidinedione (glitazone) for type 2 diabetes, increases insulin sensitivity of target cells, and thereby increases glucose uptake by muscle and decreases glucose production by the liver.

- Rosiglitazone promotes water retention, and can thereby cause weight gain and edema.

684

Water retention can cause heart failure, and can exacerbate symptoms in those who already have the disease.

685

- Like the sulfonylureas, and unlike metformin, rosiglitazone poses a risk of hypoglycemia.
- Acarbose, an alpha-glucosidase inhibitor for type 2 diabetes, inhibits digestion and absorption of carbohydrates, and thereby reduces the postprandial rise in blood glucose. To be effective, acarbose must be taken with every meal.
- The major adverse effects of acarbose are GI disturbances: flatulence, cramps, and abdominal distention.
- Pramlintide, an amylin mimetic, is injected subQ before meals to enhance the effects of mealtime insulin in patients with type 1 or type 2 diabetes. The drug delays gastric emptying and suppresses glucagon release, and thereby helps reduce postprandial hyperglycemia.
- The combination of pramlintide plus insulin poses a risk of severe hypoglycemia. Nausea is common.
- Exenatide, an incretin mimetic for type 2 diabetes, is injected subQ before meals to supplement the actions of metformin and/or a sulfonylurea. The drug delays gastric emptying, suppresses glucagon release, and stimulates glucose-dependent release of insulin.
- Exenatide poses a risk of hypoglycemia in patients taking a sulfonylurea, but not in those taking metformin. Nausea is common.

57.8.2 Summary of Major Nursing Implications*

57.8.... INSULIN

57.8.... Preadministration Assessment

57.8.... Therapeutic Goal

Insulin is required by all patients with type 1 diabetes and by some with type 2 diabetes. The goal of insulin therapy is to maintain plasma levels of glucose and HbA_{1c} within an acceptable range (see [Table 56-3](#)).

57.8.... Baseline Data

Assess for clinical manifestations of diabetes (eg, polyuria, polydipsia, polyphagia, weight loss) and for indications of hyperglycemia. Baseline laboratory tests may include casual plasma glucose, FPG, an OGTT, HbA_{1c}, urinary glucose and ketones, and serum electrolytes.

Assess for baseline knowledge of diabetes and readiness to learn.

57.8.... Identifying High-Risk Patients

Special care is needed in patients taking drugs that can raise or lower blood glucose levels, including sympathomimetics, beta blockers, glucocorticoids, sulfonylureas, metformin, glinides (eg, repaglinide), thiazolidinediones (eg, troglitazone), and pramlintide.

57.8.... Implementation: Administration

57.8.... Routes

All insulins may be administered subQ, and four preparations—regular, aspart, lispro, and glulisine insulin—may be administered IV as well. A formulation for oral inhalation is no longer available.

57.8.... Preparing for Subcutaneous Injection

Teach the patient to prepare for subQ injections as follows:

- Before loading the syringe, disperse insulin suspensions (ie, NPH insulin preparations) by rolling the vial gently between the palms. Vigorous agitation causes frothing and must be avoided. If granules or clumps remain after mixing, discard the vial.
- Except for NPH insulin, all preparations are formulated as clear, colorless solutions, and hence can be administered without resuspension. If a preparation becomes cloudy or discolored, or if a precipitate develops, discard the vial.
- Before loading the syringe, swab the bottle cap with alcohol.
- Eliminate air bubbles from the syringe and needle after loading.
- Cleanse the skin (with alcohol or soap and water) prior to injection.

57.8....

Sites of Injection

Provide the patient with the following instructions regarding sites of subQ injection:

- Usual sites of injection are the abdomen, upper arm, and thigh. To minimize variability in responses, make all injections in just one of these areas. Injections in the abdomen provide the most consistent insulin levels and effects.
- Rotate the injection site within the general area employed (eg, the abdomen).
- Allow about 1 inch between sites. If possible, use each site just once a month.

57.8....

Insulin Storage

Teach the patient the following about insulin storage:

- Store unopened vials of insulin in the refrigerator, but do not freeze. When stored under these conditions, insulin can be used up to the expiration date on the vial.
- The vial in current use can be stored at room temperature for up to 1 month, but must be kept out of direct sunlight and extreme heat. Discard partially filled vials after several weeks if left unused.

685

- Mixtures of insulin prepared in vials may be stored for 1 month at room temperature, and for 3 months under refrigeration.
- Mixtures of insulin in pre-filled syringes (plastic or glass) should be stored in a refrigerator, where they will be stable for at least 1 week, and perhaps 2. Store the syringe vertically (needle pointing up) to avoid clogging the needle. Gently agitate the syringe prior to administration to resuspend the insulin.

57.8....

Dosage Adjustment

The dosing goal is to maintain blood glucose levels within an acceptable range. Dosage must be adjusted to balance changes in caloric intake and other factors that can decrease insulin needs (strenuous exercise, pregnancy during the first trimester) or increase insulin needs (illness, trauma, stress, adolescent growth spurt, pregnancy after the first trimester).

Regular insulin can adsorb in varying amounts onto IV infusion sets. Dosage adjustments made to compensate for losses are based on the therapeutic response.

57.8....

Patient and Family Education

Patient and family education is an absolute requirement for safe and successful glycemic control. **Ensure that patients and their families receive thorough instruction on**

- The nature of diabetes
- The importance of tight glucose control
- The major components of the treatment routine —insulin, SMBG, diet, exercise—emphasizing the importance of proper diet and adequate exercise even though insulin is in use
- Procedures for purchasing insulin, syringes, and needles
- Methods of insulin storage
- Procedures for mixing insulins
- Calculation of dosage adjustments
- Techniques of insulin injection
- Rotation of injection sites

- Measurement of blood glucose
- Signs and management of hypoglycemia
- Signs and management of hyperglycemia
- Special problems of diabetic pregnancy
- The procedure for obtaining Medic Alert registration
- The importance of avoiding arbitrary switches between insulins made by different manufacturers

Ongoing Evaluation and Interventions

Measures to Evaluate and Enhance Therapeutic Effects

SMBG should be employed to evaluate day-to-day treatment. **Teach patients how to use the blood glucose monitor, and encourage them to measure blood glucose before meals and at bedtime.** Hemoglobin A_{1c} should be measured 2 to 4 times a year to assess long-term glycemic control. Measuring urinary glucose is not helpful.

Minimizing Adverse Effects

Hypoglycemia.

Hypoglycemia occurs whenever insulin levels exceed insulin needs. **Inform the patient about potential causes of hypoglycemia (eg, insulin overdose, reduced food intake, vomiting, diarrhea, excessive alcohol intake, unaccustomed exercise, termination of pregnancy), and teach the patient and family members to recognize the early signs and symptoms of hypoglycemia (tachycardia, palpitations, sweating, nervousness, headache, confusion, drowsiness, fatigue).**

Rapid treatment is mandatory. If the patient is conscious, oral carbohydrates are indicated (eg, glucose tablets, orange juice, sugar cubes, honey, corn syrup, nondiet soda). However, if the swallowing or gag reflex is suppressed, nothing should be administered PO. For unconscious patients, IV glucose is the treatment of choice. Parenteral glucagon is an alternative.

Hypoglycemic coma must be differentiated from coma of diabetic ketoacidosis (DKA). The differential diagnosis is made by measuring plasma or urinary glucose:

Hypoglycemic coma is associated with very low levels of glucose, whereas high levels signify DKA.

57.8... Lipohypertrophy (Lipodystrophy)

Accumulation of subcutaneous fat can occur at sites of frequent insulin injection.

Inform the patient that lipohypertrophy can be minimized by systematic rotation of the injection site within the area selected (eg, abdomen).

57.8... Systemic Allergic Reactions

Systemic reactions (widespread urticaria, impairment of breathing) are rare. If systemic allergy develops, it can be reduced through desensitization (ie, giving small initial doses of human insulin followed by a series of progressively larger doses).

57.8... Minimizing Adverse Interactions

57.8... Hypoglycemic Agents

Several drugs, including *sulfonylureas*, *glinides*, *alcohol* (used acutely), and *beta blockers*, can intensify hypoglycemia induced by insulin. When any of these drugs is combined with insulin, special care must be taken to ensure that blood glucose content does not fall too low.

57.8... Hyperglycemic Agents

Several drugs, including thiazide diuretics, glucocorticoids, and sympathomimetics, can raise blood glucose concentration and can thereby counteract the beneficial effects of insulin. When these agents are combined with insulin, increased insulin dosage may be needed.

57.8... Beta Blockers.

Beta blockade can mask sympathetic responses (eg, tachycardia, palpitations, tremors) to a steep drop in glucose levels, and can thereby delay awareness of insulin-induced hypoglycemia. Also, because beta blockade impairs hepatic conversion of glycogen to glucose (glycogenolysis), beta blockers can make insulin-induced hypoglycemia even worse, and can delay recovery from a hypoglycemic event.

686

METFORMIN

Preadministration Assessment

Therapeutic Goal

Metformin, taken alone or combined with any other antidiabetic drug, is used as an adjunct to calorie restriction and exercise to help maintain glycemic control in patients with type 2 diabetes. The drug is also used to prevent type 2 diabetes and to treat women with polycystic ovary syndrome. Metformin is not used for, nor is it effective in, type 1 diabetes.

Identifying High-Risk Patients

Metformin is *contraindicated* or should be used with great caution in patients with or at imminent risk of developing renal insufficiency, liver disease, severe infection, heart failure, a history of lactic acidosis, or shock or other conditions that can cause hypoxemia. It should not be administered to patients who consume excessive amounts of alcohol acutely or long term, until and unless alcohol consumption can be cut back markedly. Likewise, patients for whom the drug is prescribed should be cautioned and encouraged to drink alcohol in moderation.

Implementation: Administration

Route

Oral.

Administration

Advise patients to take ***immediate-release*** tablets twice daily, with the morning and evening meals.

Advise patients to take ***extended-release*** metformin once daily with the evening meal.

Ongoing Evaluation and Interventions

Minimizing Adverse Effects

Lactic Acidosis.

Rarely, metformin causes lactic acidosis, a medical emergency with a 50% mortality rate. Avoid metformin in patients with renal insufficiency and other conditions that increase acidosis risk (eg, liver disease, severe infection, shock), and use with caution in patients with heart failure. **Inform patients about early signs of lactic acidosis—hyperventilation, myalgia, malaise, and unusual somnolence—and instruct them to seek immediate medical attention if these develop.** Withhold metformin until lactic acidosis has been ruled out. If lactic acidosis is diagnosed, hemodialysis may correct the condition and remove accumulated metformin.

Gastrointestinal Effects

Metformin can cause nausea, diarrhea, and appetite reduction, which usually subside over time. If these reactions are intolerable and the drug must be stopped, suitable alternative drugs should be started.

Vitamin Deficiency

Metformin can reduce absorption of vitamin B₁₂ and folic acid. Supplements may be needed.

Minimizing Adverse Interactions

Alcohol

Inform patients that alcohol increases the risk of lactic acidosis, and therefore must be avoided or, at least, consumed in moderation.

SULFONYLUREAS

First-Generation Agents

Acetohexamide

Chlorpropamide

Tolazamide

Tolbutamide

57.8.... Second-Generation Agents (Preferred)

Glimepiride

Glipizide

Glyburide (glibenclamide)

57.8.... Preadministration Assessment

57.8.... Therapeutic Goal

Sulfonylureas—taken alone or with other hypoglycemic agents—are used as an adjunct to calorie restriction and exercise to maintain glycemic control in patients with type 2 diabetes. These drugs do not work in patients with type 1 diabetes.

57.8.... Identifying High-Risk Patients

Sulfonylureas are *contraindicated* during pregnancy and breast-feeding. Sulfonylureas should not be used in conjunction with alcohol.

Use with *caution* in patients with kidney or liver dysfunction.

57.8.... Implementation: Administration

57.8.... Route

Oral.

57.8.... Administration

Advise patients to administer with food if GI upset occurs.

Note that dosages for the second-generation agents, which are preferred, are much lower than dosages for first-generation agents (see [Table 56-12](#)).

	<p>Sulfonylureas are intended only as supplemental therapy of type 2 diabetes. Encourage patients to maintain their established program of exercise and caloric restriction.</p>

Preadministration Assessment

Therapeutic Goal

Glinides—taken alone or combined with metformin or a glitazone—are used as adjuncts to calorie restriction and exercise to maintain glycemic control in patients with type 2 diabetes. Glinides are not used for type 1 diabetes.

Identifying High-Risk Patients

Use with *caution* in patients with liver impairment and those taking gemfibrozil.

Implementation: Administration

Route

Oral.

Administration

Inform patients that dosing *must* be associated with a meal, and instruct them to take the drug 30 minutes or less before eating.

Ongoing Evaluation and Interventions

Minimizing Adverse Effects

Hypoglycemia

Inform patients about signs of hypoglycemia (palpitations, tachycardia, sweating, fatigue, excessive hunger), and instruct them to notify the prescriber if these occur.
Treat severe hypoglycemia with IV glucose.

Minimizing Adverse Interactions

Gemfibrozil

Gemfibrozil slows metabolism of glinides, and thereby increases their levels and the risk of hypoglycemia. Avoid gemfibrozil if possible.

THIAZOLIDINEDIONES (GLITAZONES)

Pioglitazone

Rosiglitazone

Preadministration Assessment

Therapeutic Goal

Glitazones—taken alone or combined with metformin, a sulfonylurea, or insulin—are used as adjuncts to calorie restriction and exercise to maintain glycemic control in patients with type 2 diabetes. Glitazones are not used for type 1 diabetes.

Identifying High-Risk Patients

Glitazones are *contraindicated* for patients with *severe* heart failure, and should be used with *caution* in those with *mild* heart failure or even heart failure risk factors. Caution is also needed in patients taking insulin or gemfibrozil.

Baseline Data

Obtain a baseline value for serum alanine aminotransferase (ALT).

Implementation: Administration

Route

Oral.

Administration

Rosiglitazone

Advise patients to take the drug twice daily, with or without food.

Pioglitazone

Advise patients to take the drug once daily, with or without food.

Ongoing Evaluation and Interventions

Minimizing Adverse Effects

Fluid Retention

Glitazones promote fluid retention, and can thereby cause edema and weight gain. Because fluid retention can exacerbate heart failure, glitazones must be used with caution in patients with *mild* heart failure or heart failure risk factors, and must be avoided in those with *severe* failure. **Inform patients about signs of heart failure (dyspnea, edema, weight gain, fatigue), and instruct them to consult the prescriber if these develop.**

Liver Injury

Rosiglitazone and pioglitazone *may* pose a risk of liver injury. Accordingly, ALT should be determined at baseline and periodically thereafter (eg, every 3 to 6 months). If ALT levels rise to more than 3 times the upper limit of normal, or if jaundice develops, glitazones should be withdrawn. **Inform patients about symptoms of liver injury (nausea, vomiting, abdominal pain, fatigue, anorexia, dark urine, jaundice), and instruct them to notify the prescriber if these develop.**

Hypoglycemia

Glitazones pose a risk of hypoglycemia when combined with insulin or gemfibrozil, but not when used alone. Use the combinations with caution.

Minimizing Adverse Interactions

Insulin.

Like the glitazones, insulin increases the risk of (1) hypoglycemia and (2) fluid retention and the associated risk of heart failure. Use the combination with caution.

Gemfibrozil

Gemfibrozil can raise plasma levels of glitazones, and may thereby increase the risk of hypoglycemia. Use the combination with caution.

* Patient education information is highlighted as **blue text**.

⁵⁸CHAPTER 57 Drugs for Thyroid Disorders

Thyroid hormones have profound effects on metabolism, cardiac function, growth, and development. These hormones stimulate the metabolic rate of most cells, and increase the force and rate of cardiac contraction. During infancy and childhood, thyroid hormones promote maturation; severe deficiency can produce extreme short stature and permanent mental impairment. Fortunately, most abnormalities of thyroid function can be effectively treated.

We begin our study of thyroid drugs by reviewing thyroid physiology. Next we review the pathophysiology of hypothyroid and hyperthyroid states. Finally, we discuss the agents used for thyroid disorders.

^{58.1}THYROID PHYSIOLOGY

^{58.1.1} Chemistry and Nomenclature

The thyroid gland produces two active hormones: triiodothyronine (T_3) and thyroxine (T_4 , tetraiodothyronine). As shown in [Figure 57-1](#), these hormones have nearly identical structures. The only difference is that T_4 contains four atoms of iodine, whereas T_3 contains three. The biologic effects of T_3 and T_4 are qualitatively similar. However, when compared on a molar basis, T_3 is much more potent.

Preparations of T_3 and T_4 employed clinically, although synthetic, are identical in structure to the naturally occurring hormones. The generic name of synthetic T_3 is *liothyronine*, and the generic name of synthetic T_4 is *levothyroxine*. A fixed-ratio mixture of T_3 plus T_4 , known as *liotrix*, is also available.

Figure 57-1 Structural formulas of the thyroid hormones.

58.1.2 Synthesis and Fate of Thyroid Hormones

58.1.2.1 Synthesis.

Synthesis of thyroid hormones takes place in four steps ([Fig. 57-2](#)). The circled numbers in the figure correspond with the steps below.

- *Step 1.* Formation of thyroid hormone begins with the active transport of *iodide* into the thyroid. Under normal conditions, this process produces concentrations of iodide within the thyroid that are 20 to 50 times greater than the concentration of iodide in plasma. When plasma iodide levels are extremely low, intrathyroid iodide content may reach levels that are more than 100 times greater than those in plasma.
- *Step 2.* Following uptake, iodide undergoes oxidation to *iodine*, the active form of iodide. Iodide oxidation is catalyzed by an enzyme called *peroxidase*.
- *Step 3.* In this step, activated iodine becomes incorporated into tyrosine residues that are bound to *thyroglobulin*, a large glycoprotein. As indicated in [Figure 57-2](#), one tyrosine molecule may receive either one or two iodine atoms, resulting in the production of moniodotyrosine (MIT) or diiodotyrosine (DIT), respectively.
- *Step 4.* In this final step, iodinated tyrosine molecules are coupled. Coupling of one DIT with one MIT forms T_3 (step 4A); coupling of one DIT with another DIT forms T_4 (step 4B).

58.1.2.2 Fate.

Thyroid hormones are released from the thyroid gland by a proteolytic process. The amount of T_4 released is substantially greater than the amount of T_3 . However, much of the T_4 that is released undergoes conversion to T_3 by enzymes in peripheral tissues. In fact, conversion of T_4 to T_3 accounts for the majority (about 80%) of the T_3 found in plasma.

689

Figure 57-2 **Steps in thyroid hormone synthesis.** The reactions at each step (circled numbers) are explained in the text. (DIT = diiodotyrosine, MIT = monoiodotyrosine, T_3 = triiodothyronine, T_4 = thyroxine, Tyr = tyrosine.)

More than 99.5% of the T_3 and T_4 in plasma is bound to plasma proteins. Consequently, only a tiny fraction of circulating thyroid hormone is free to produce biologic effects.

Thyroid hormones are eliminated primarily by hepatic metabolism. Because T_3 and T_4 are extensively bound to plasma proteins, metabolism is slow. As a result, the half-lives of these hormones are prolonged—about 1 day for T_3 and 7 days for T_4 .

58.1.3 Thyroid Hormone Actions

Thyroid hormones have three principal actions: (1) stimulation of energy use, (2) stimulation of the heart, and (3) promotion of growth and development. Stimulation of energy use elevates the basal metabolic rate, resulting in increased oxygen consumption and increased heat production. Stimulation of the heart increases both the rate and force of contraction, resulting in increased cardiac output and increased oxygen demand. Thyroid effects on growth and development are profound: Thyroid hormones are essential for normal development of the brain and other components of the nervous system, and they have a significant impact on maturation of skeletal muscle.

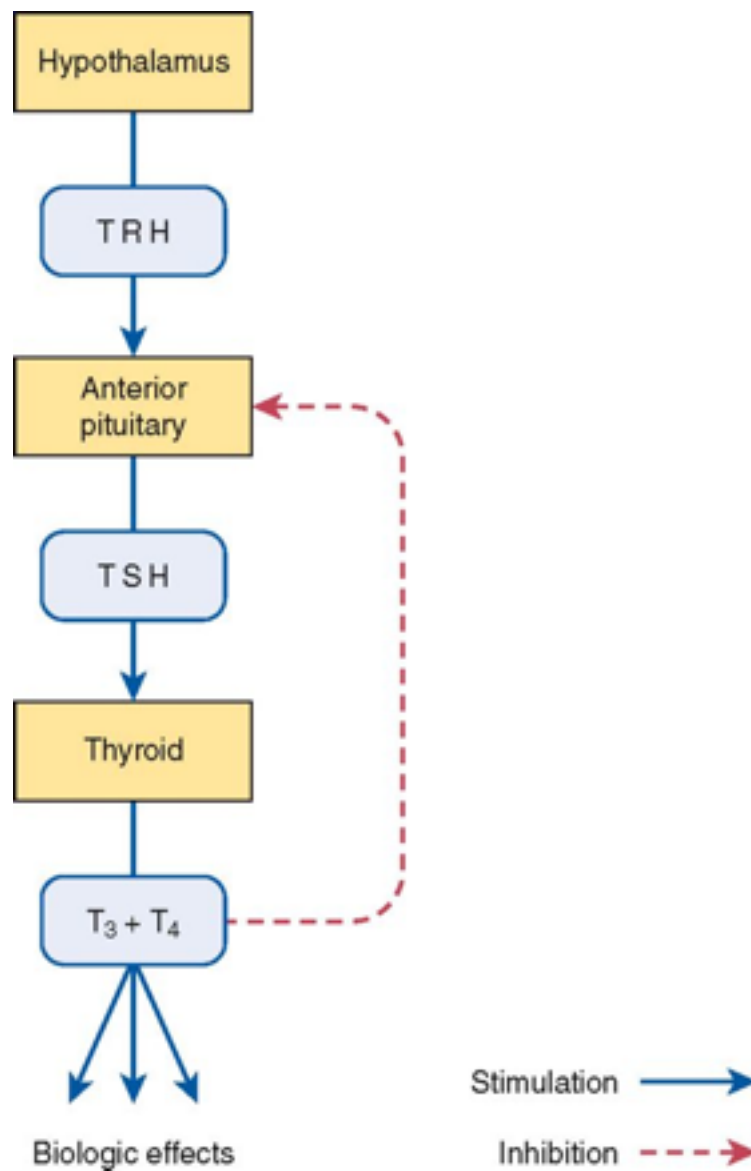

How do thyroid hormones produce their effects? By modulating the activity of specific genes. Furthermore, it appears that most, if not all, of the effects of thyroid hormones are mediated by T_3 , not T_4 . There is good evidence that T_3 penetrates to the cell nucleus and binds with high affinity to nuclear receptors, which in turn bind to specific DNA sequences. The result is modulation of gene transcription, causing production of proteins that mediate thyroid hormone effects. Although T_4 also binds with nuclear receptors, its affinity is low, and gene transcription is not altered. Hence it would seem that T_4 serves only as a source of T_3 , having no physiologic effects of its own.

58.1.4 Regulation of Thyroid Function by the Hypothalamus and Anterior Pituitary

The functional relationship between the hypothalamus, anterior pituitary, and thyroid is depicted in [Figure 57-3](#). As indicated, thyrotropin-releasing hormone (TRH), secreted by the hypothalamus, acts on the pituitary to cause secretion of thyrotropin (thyroid-stimulating hormone [TSH]). TSH then acts on the thyroid to stimulate all aspects of thyroid function: thyroid size is enlarged, iodine uptake is augmented, and synthesis and release of thyroid hormones are increased. In response to rising plasma levels of T_3 and T_4 , further release of TSH is suppressed. The stimulatory effect of TSH on the thyroid, followed by the inhibitory effect of thyroid hormones on the pituitary, constitutes a negative feedback loop.

690

Figure 57-3 **Regulation of thyroid function.** TRH from the hypothalamus stimulates release of TSH from the pituitary. TSH stimulates all aspects of thyroid function, including release of T_3 and T_4 . T_3 and T_4 act on the pituitary to suppress further TSH release. (T_3 = triiodothyronine, T_4 = thyroxine, TRH = thyrotropin-releasing hormone, TSH = thyrotropin [thyroid-stimulating hormone].)

58.1.5 Effect of Iodine Deficiency on Thyroid Function

When iodine availability is diminished, production of thyroid hormones decreases. The ensuing drop in thyroid hormone levels promotes release of TSH, which acts on the thyroid to increase its size (causing goiter) and ability to concentrate iodine. If iodine deficiency is not too severe, the increased capacity for iodine uptake will restore normal production of T_3 and T_4 .

58.2 THYROID FUNCTION TESTS

Several laboratory tests can be used to evaluate thyroid function. Three are described below. Values indicating euthyroid (normal), hypothyroid, and hyperthyroid states are summarized in [Table 57-1](#).

58.2.1 Serum TSH.

Serum TSH determinations are used primarily for screening and diagnosis of hypothyroidism, and for monitoring replacement therapy in hypothyroid patients.

Measurement of serum TSH is the most sensitive method for diagnosing hypothyroidism. Why? Because the anterior pituitary is exquisitely sensitive to changes in thyroid hormone levels. As a result, very small reductions in serum T_3 and T_4 can cause a dramatic rise in serum TSH.

Therefore, even when the degree of hypothyroidism is minimal, it will be reflected by an abnormally high level of TSH. When replacement therapy is instituted, the TSH level should return to normal.

TABLE 57-1 Serum Values for Thyroid Function Tests

Thyroid Test	Serum Values		
	Normal	Hypothyroid	Hyperthyroid
Total T_4 (mcg/dL)	4.5–12.5	Under 4.5	Over 12.5
Free T_4 (ng/dL)	0.9–2	Under 0.9	Over 2
Total T_3 (ng/dL)	80–220	Under 80	Over 220
Free T_3 (pg/dL)	230–620	Under 230	Over 620
TSH (microunits/mL)	0.3–6	Over 6	Under 0.3

Serum TSH determinations can also be used to distinguish primary hypothyroidism from secondary hypothyroidism. In primary (thyroidal) hypothyroidism, TSH levels are *high*. However, in secondary hypothyroidism (hypothyroidism resulting from anterior pituitary dysfunction), TSH levels are low, normal, or even slightly elevated—despite the presence of low levels of T_3 and T_4 .

58.2.2 Serum T₄ Test.

Testing can measure either *total T₄* (bound plus free) or *free T₄*. Measurement of free T₄ is preferred. The T₄ test can be used to monitor thyroid hormone replacement therapy, and to screen for thyroid dysfunction. However, in both cases, measurement of TSH is preferred.

58.2.3 Serum T₃ Test.

As with T₄, we can measure either total or free T₃. Measurement of free T₃ is preferred. This test is useful for diagnosing hyperthyroidism. Why? Because, in this disorder, levels of T₃ often rise sooner and to a greater extent than levels of T₄. T₃ determinations can also be used to monitor thyroid hormone replacement therapy; all thyroid preparations should increase levels of T₃.

58.3 THYROID PATHOPHYSIOLOGY

58.3.1 Hypothyroidism

Hypothyroidism can occur at any age. In adults, mild deficiency of thyroid hormone is referred to simply as *hypothyroidism*. Severe deficiency is called *myxedema*. When hypothyroidism occurs in infants, the resulting condition is called *cretinism*.

58.3.1.1 Hypothyroidism in Adults

58.3.1.1.1 Clinical Presentation.

Signs and symptoms of hypothyroidism depend on disease severity. With mild hypothyroidism, symptoms are subtle and may go unrecognized for what they are. In contrast, with moderate to severe disease, characteristic signs and symptoms emerge. The face is pale, puffy, and expressionless. The skin is cold and dry. The hair is brittle, and hair loss occurs. Heart rate and temperature are lowered. The patient may complain of lethargy, fatigue, and intolerance to cold. Mentation may be impaired. Thyroid enlargement (goiter) may occur if reduced levels of T₃ and T₄ promote excessive release of TSH.

58.3.1.1.2 Causes.

Hypothyroidism in the adult is usually due to malfunction of the thyroid itself. In iodine-sufficient countries, the principal cause is *chronic autoimmune thyroiditis* (Hashimoto's thyroiditis). Other causes are insufficient iodine in the diet, surgical removal of the thyroid,

691

692

and destruction of the thyroid by radioactive iodine. Adult hypothyroidism may also result from insufficient secretion of TSH and TRH.

58.3.1.1.3 Therapeutic Strategy.

Hypothyroidism in adults requires replacement therapy with thyroid hormones. In almost all cases, treatment must continue lifelong. Today, the standard replacement regimen consists of *levothyroxine* (T_4) alone. Combined therapy with levothyroxine plus liothyronine (T_3) is an option. However, with only one exception, all studies to date indicate that combined T_3/T_4 offers no advantage over T_4 alone. (Remember, when we give T_4 , much of it is rapidly converted to T_3 , the active form of the hormone.) When replacement doses of T_4 are adequate, they can eliminate all signs and symptoms of thyroid deficiency.

58.3.1.2 Hypothyroidism During Pregnancy

Maternal hypothyroidism can result in permanent neuropsychologic deficits in the child. We have long known that *congenital* hypothyroidism can cause mental retardation and other developmental problems (see below under *Hypothyroidism in Infants*). However, it was not until 1999 that researchers demonstrated that *maternal* hypothyroidism—in the absence of fetal hypothyroidism—can decrease IQ and other aspects of neuropsychologic function in the child. The impact of maternal hypothyroidism is limited largely to the first trimester, a time during which the fetus is unable to produce thyroid hormones of its own. By the second trimester, the fetal thyroid gland is fully functional, and hence the fetus can supply its own hormones from then on. Therefore, to help ensure healthy fetal development, maternal hypothyroidism must be diagnosed and treated very early. Unfortunately, symptoms of hypothyroidism are often nonspecific (irritability, tiredness, poor concentration, etc.) or there may be no symptoms at all. Accordingly, some authorities now recommend routine screening for hypothyroidism as soon as pregnancy is confirmed. If hypothyroidism is diagnosed, replacement therapy should begin immediately.

When women taking thyroid supplements become pregnant, dosage requirements usually increase—often by as much as 50%. The need for increased dosage begins between weeks 4 and 8 of gestation, levels off around week 16, and then remains steady until parturition. To ensure adequate hormone levels, some authorities increase T_4 dosage by 30% as soon as pregnancy is confirmed. Further adjustments are based on serum TSH levels, which should be monitored closely.

58.3.1.3 Hypothyroidism in Infants

58.3.1.3.1 Clinical Presentation.

Hypothyroidism in newborns may be permanent or transient. In either case, congenital hypothyroidism (cretinism) can cause mental retardation and derangement of growth. In the absence of thyroid hormones, the child develops a large and protruding tongue, potbelly, and dwarfish stature. Development of the nervous system, bones, teeth, and muscles is impaired.

58.3.1.3.2 Causes.

Cretinism usually results from a failure in thyroid development. Other causes include autoimmune disease, severe iodine deficiency, TSH deficiency, and exposure to radioactive iodine *in utero*.

58.3.1.3.3 Therapeutic Strategy.

Hypothyroidism in newborns requires replacement therapy with thyroid hormones. If treatment is initiated within a few days of birth, physical and mental development will be normal. However, if therapy is delayed beyond 3 to 4 weeks, some permanent retardation will be evident, although the physical effects of thyroid deficiency will reverse.

How long should replacement therapy last? In all children, treatment should continue for 3 years, after which it should be stopped for 4 weeks. The objective is to determine if thyroid deficiency is permanent or transient. If TSH rises, indicating thyroid hormone production is low, we know the deficiency is permanent, and hence replacement therapy should resume. If TSH and T₄ normalize, we know the deficiency was transient, and hence further replacement therapy is unnecessary.

58.3.2 Hyperthyroidism

There are two major forms of hyperthyroidism: *Graves' disease* and *toxic nodular goiter* (also known as *Plummer's disease*). Of the two, Graves' disease is more common. Signs and symptoms of both disorders are similar. The principal difference is that Graves' disease may cause exophthalmos, whereas toxic nodular goiter does not.

58.3.2.1 Graves' Disease

Graves' disease is the most common cause of excessive thyroid hormone secretion. This disorder occurs most frequently in women 20 to 40 years of age. The incidence in females is 6 times greater than in males.

58.3.2.1.1 Clinical Presentation.

Most clinical manifestations result from elevated levels of thyroid hormone. Heartbeat is rapid and strong, and dysrhythmias and angina may develop. The central nervous system is stimulated, resulting in nervousness, insomnia, rapid thought flow, and rapid speech. Skeletal muscles may weaken and atrophy. Metabolic rate is raised, resulting in increased heat production, increased body temperature, intolerance to heat, and skin that is warm and moist. Appetite is increased. However, despite increased food consumption, weight loss occurs if caloric intake fails to match the increase in metabolic rate. Collectively, the above signs and symptoms are referred to as *thyrotoxicosis*.

In addition to thyrotoxicosis, patients with Graves' disease often present with *exophthalmos* (protrusion of the eyeballs). The underlying cause is an immune-mediated infiltration of the extraocular muscles and orbital fat by lymphocytes, macrophages, plasma cells, mast cells, and mucopolysaccharides.

58.3.2.1.2 Cause.

Thyroid stimulation in Graves' disease is caused by thyroid-stimulating immunoglobulins (TSIs), which are antibodies produced by an autoimmune process. TSIs increase thyroid activity by stimulating receptors for TSH on the thyroid gland. That is, TSIs mimic the effects of TSH on thyroid function. TSIs are not responsible for exophthalmos.

58.3.2.1.3 Treatment.

Treatment for Graves' disease is directed at decreasing the production of thyroid hormones. Three modalities are employed: (1) surgical removal of thyroid tissue, (2) destruction of thyroid tissue with radioactive iodine, and (3) suppression of thyroid hormone synthesis with antithyroid drugs (propylthiouracil, methimazole). In the United States, radiation is the preferred treatment for adults, whereas antithyroid drugs are preferred for younger patients.

Beta blockers (eg, propranolol) and nonradioactive iodine may be used as adjunctive therapy. Beta blockers suppress tachycardia by blocking beta receptors on the heart. Nonradioactive iodine inhibits synthesis and release of thyroid hormones.

692

693

Since exophthalmos is not the result of hyperthyroidism per se, this condition is not improved by lowering thyroid hormone production. If exophthalmos is severe, it can be treated with high doses of oral glucocorticoids or surgery.

58.3.2.2 Toxic Nodular Goiter (Plummer's Disease)

Toxic nodular goiter is the result of thyroid adenoma. Clinical manifestations are much like those of Graves' disease, except exophthalmos is absent. Toxic nodular goiter is a persistent condition that rarely undergoes spontaneous remission. Treatment modalities are the same as for Graves' disease. However, if antithyroid drugs are used, symptoms return rapidly when the drugs are withdrawn. Accordingly, surgery and radiation, which provide long-term control, are often preferred.

58.3.2.3 Thyrotoxic Crisis (Thyroid Storm)

Thyrotoxic crisis can occur in patients with severe thyrotoxicosis when they undergo major surgery or develop a severe intercurrent illness (eg, infection, sepsis). The crisis is not triggered by a rise in thyroid hormones, and cannot be identified with laboratory tests. The syndrome is characterized by profound hyperthermia (105°F or even higher), severe tachycardia, restlessness, agitation, and tremor. Unconsciousness, coma, hypotension, and heart failure may ensue.

Thyrotoxic crisis can be life threatening and requires immediate treatment. High doses of potassium iodide or strong iodine solution are given to suppress thyroid hormone release. Propylthiouracil is given to suppress thyroid hormone synthesis and peripheral conversion of T₄ to T₃. A beta blocker is given to reduce heart rate. Additional measures include sedation, cooling, and giving glucocorticoids and IV fluids.

58.4 THYROID HORMONE PREPARATIONS FOR HYPOTHYROIDISM

Thyroid hormones are available as pure, synthetic compounds and as extracts of animal thyroid glands. All preparations have qualitatively similar effects. The synthetic preparations are more stable and better standardized than the animal gland extracts. As a result, the synthetics are preferred to the natural products. Properties of thyroid hormone preparations are summarized in [Table 57-2](#).

58.4.1 Levothyroxine (T₄)

Levothyroxine [Levothroid, Synthroid, others] is a synthetic preparation of thyroxine (T₄), a naturally occurring thyroid hormone. The structure of levothyroxine is identical to that of the

natural hormone. Levothyroxine is the drug of choice for most patients who require thyroid hormone replacement. Consequently, levothyroxine will serve as our prototype for the thyroid hormone preparations.

58.4.1.1 Pharmacokinetics

58.4.1.1.1 Conversion to T_3 .

Much of an administered dose of levothyroxine is converted to T_3 in the body. As a result, levothyroxine can produce nearly normal levels of both T_3 and T_4 . Hence, for most patients, there is no need to give T_3 along with levothyroxine.

58.4.1.1.2 Half-Life and Plasma Levels.

Because levothyroxine is highly protein bound (about 99.97%), the hormone has a prolonged half-life (about 7 days). From a clinical perspective, this long half-life has advantages as well as disadvantages. On the negative side, about 1 month (four half-lives) is required for plasma levels of levothyroxine to reach plateau (steady state). As a result, onset of full effects is delayed. On the positive side, a long half-life causes hormone levels to remain steady between doses. This property permits once-a-day dosing, which makes levothyroxine well suited for lifelong therapy.

58.4.1.2 Therapeutic Uses

Levothyroxine is indicated for all forms of hypothyroidism, regardless of cause. The drug is used for cretinism, myxedema coma, simple goiter, and primary hypothyroidism in adults and children. Levothyroxine is also used to treat hypothyroidism resulting from insufficient TSH (secondary to pituitary malfunction) and from insufficient TRH (secondary to hypothalamic malfunction). In addition, levothyroxine is used to maintain proper levels of thyroid hormones following thyroid surgery, irradiation, and treatment with antithyroid drugs.

Levothyroxine and other thyroid hormones should not be taken to treat obesity. These hormones will accelerate metabolism and promote weight reduction only if the dosage is high enough to establish a pathologic (hyperthyroid) state.

58.4.1.3 Adverse Effects

When administered in appropriate dosage, levothyroxine rarely causes adverse effects. With an acute overdose, *thyrotoxicosis* may result. Signs and symptoms include tachycardia, angina, tremor, nervousness, insomnia, hyperthermia, heat intolerance, and sweating. The patient should

693

694

be informed about these signs and instructed to notify the prescriber if they develop. Chronic overdosage is associated with accelerated bone loss and increased risk of atrial fibrillation.

TABLE 57-2 Thyroid Hormone Preparations

Generic Name	Trade Names	Dosage Forms	Approximate Equivalent Dosage*	Description
Levothyroxine	Levothroid, Levoxyl, Synthroid, Thyro-Tabs, Unithroid	Tablets, injection	50–60 mcg	Synthetic preparation of T ₄ identical to the naturally occurring hormone
Liothyronine	Cytomel, Triostat	Tablets, injection	15–37 mcg	Synthetic preparation of T ₃ identical to the naturally occurring hormone
Liotrix	Thyrolar	Tablets	60 mcg	Synthetic T ₄ plus synthetic T ₃ in a 4:1 fixed ratio
Thyroid	Armour Thyroid, Bio-Throid, Nature-Throid, Thyroid USP, Westhroid	Tablets, capsules	60 mg	Desiccated animal thyroid glands

* Approximate dosage needed to produce equivalent effects.

58.4.1.4 Drug Interactions

58.4.1.4.1 Drugs That Reduce Levothyroxine Absorption.

Absorption of levothyroxine can be reduced by the following drugs:

- Cholestyramine [Questran]
- Colestipol [Colestid]
- Calcium supplements (eg, Tums, Os-Cal)
- Sucralfate [Carafate]
- Aluminum-containing antacids (eg, Maalox, Mylanta)
- Iron supplements (eg, ferrous sulfate)

To ensure adequate absorption of levothyroxine, patients should separate administration of levothyroxine and these drugs by 4 hours. As noted below, food also reduces absorption.

58.4.1.4.2 Drugs That Accelerate Levothyroxine Metabolism.

Several drugs can accelerate the metabolism of levothyroxine. Among these are phenytoin [Dilantin], carbamazepine [Tegretol, Carbatrol], rifampin [Rifadin, Rimactane], sertraline [Zoloft], and phenobarbital. Accordingly, in order to maintain adequate levothyroxine levels, patients taking these drugs may need to increase their levothyroxine dosage.

58.4.1.4.3 Warfarin.

Levothyroxine accelerates the degradation of vitamin K–dependent clotting factors. As a result, effects of warfarin (an anticoagulant) are enhanced. If thyroid hormone replacement therapy is started in a patient taking warfarin, the dosage of warfarin may need to be reduced.

58.4.1.4.4 Catecholamines.

Thyroid hormones increase cardiac responsiveness to catecholamines (epinephrine, dopamine, dobutamine), thereby increasing the risk of catecholamine-induced dysrhythmias. Caution must be exercised when administering catecholamines to patients receiving levothyroxine and other thyroid preparations.

58.4.1.4.5 Other Interactions.

Levothyroxine can increase requirements for *insulin* and *digoxin*. Hence, when converting patients from a hypothyroid to a euthyroid state, dosages of insulin and digoxin may need to be increased.

58.4.1.5 Are Levothyroxine Preparations Interchangeable?

Levothyroxine is available in several brand-name and generic formulations. Whether any of these are interchangeable is in dispute.

Levothyroxine has a narrow therapeutic range, and hence tight control of plasma drug levels is important. Otherwise, symptoms of hypothyroidism or toxicity will develop. In order to maintain good control, all pills a patient takes must produce the same levothyroxine levels. Accordingly, if a patient switches from one product to another, the new product must be bioequivalent to the old one.

Whether or not any levothyroxine products—brand-name or generic—are truly equivalent is a point of contention. According to the Food and Drug Administration (FDA), certain formulations of levothyroxine are therapeutically equivalent to others. For example, the FDA maintains that generic levothyroxine made by Mylan is equivalent to three brand-name

products: Levoxyl, Synthroid, and Unithroid. However, three medical organizations—the American Association of Clinical Endocrinologists (AACE), The Endocrine Society (TES), and the American Thyroid Association (ATA)—*strongly* disagree, as expressed in a 2004 position statement. Why do they disagree? Because they believe the FDA's testing procedure was seriously flawed. First, the FDA only measured blood levels of levothyroxine; they did not measure serum TSH, the favored clinical test for assessing thyroid status. Second, and more important, testing was done in *normal* (euthyroid) volunteers. Hence, when blood levels of levothyroxine were measured, the values reflected the sum of endogenous thyroxine plus levothyroxine contributed by the drug—making it impossible to state with precision how much of the total was truly due to the drug. As a result, conclusions regarding the equivalence of levothyroxine products are questionable. Nonetheless, pharmacists have begun to switch patients from one product to another, often without the knowledge of the patient or prescriber—a practice with the potential for causing toxicity or therapeutic failure.

Given the debate about whether certain levothyroxine products are clinically interchangeable, what should the clinician do? In their position statement, the AACE, TES, and ATA recommend the following:

- Maintain patients on the same brand-name levothyroxine product.
- If a switch *is* made (from one branded product to another, from a branded product to a generic product, or from one generic product to another), retest serum TSH in 6 weeks, and adjust the levothyroxine dosage as indicated.
- Advise patients to check with their prescriber before allowing a pharmacist to switch to a different levothyroxine product.

58.4.1.6 Dosage and Administration I: General Considerations

58.4.1.6.1 Routes of Administration.

Levothyroxine is almost always administered by mouth. Oral doses should be taken on an empty stomach to enhance absorption. *Dosing is usually done in the morning, at least 30 minutes before breakfast.*

Intravenous administration is used for myxedema coma and for patients who cannot take levothyroxine orally. Intravenous doses are about 80% of the size of oral doses.

58.4.1.6.2 Evaluation.

The goal of replacement therapy is to provide a dosage that compensates precisely for the existing thyroid deficit. This dosage is determined using a combination of clinical judgment and laboratory tests. When therapy is successful in adults, clinical evaluation should reveal a reversal of the signs and symptoms of thyroid deficiency—and an absence of signs of thyroid excess. Successful therapy of infants is reflected in normalization of intellectual function and normalization of growth and development. Monthly determinations of height provide a good index of success.

Measurement of serum TSH is an important means of evaluation. Successful replacement therapy causes elevated TSH levels to fall. However, TSH will not normalize quickly, and often lags behind normalization of serum T_3 and T_4 . Hence, evaluation should not be done until 6 to 8 weeks after starting treatment. A TSH target of 0.5 to 2 microunits/mL is appropriate for most patients. Once an adequate replacement dosage is established, TSH levels will remain suppressed for the duration of treatment.

In some cases, serum T_4 must be used to evaluate therapy. Why? Because, in some patients, TSH secretion remains high even though levels of thyroid hormones have been restored to normal. When this happens, success is indicated by levels of T_4 in the normal to high-normal range—whether or not TSH values are normal.

694

695

58.4.1.6.3 Duration of Therapy.

For most hypothyroid patients, replacement therapy must be continued for life. Treatment provides symptomatic relief but does not produce cure. Patients must be made fully aware of the chronic nature of their condition. In addition, they should be forewarned that, although therapy will cause symptoms to improve, these improvements do not constitute a reason to interrupt or discontinue drug use.

58.4.1.7 Dosage and Administration II: Specific Applications.

58.4.1.7.1 Hypothyroidism in Adults.

When calculated on a body weight basis, the average adult dosage is about 1.6 mcg/kg/day. Most patients under the age of 50 or so can be started on full replacement doses. For older patients, dosage should be low initially and then gradually increased. A typical starting dosage is 25 to 50 mcg/day. For elderly patients with coronary heart disease, the starting dosage is even lower—between 12.5 and 25 mcg/day.

58.4.1.7.2 Myxedema Coma.

Myxedema coma is a rare but serious condition that requires rapid treatment. Levothyroxine is administered IV in a dose of 200 to 500 mcg. If required, an additional dose of 100 to 300 mcg can be given 1 day later. Glucocorticoids (eg, hydrocortisone) are also required.

58.4.1.7.3 Cretinism.

In cretinism, thyroid hormone dosage decreases with age. For infants less than 3 months old, the dosage is 10 to 15 mcg/kg/day; for children ages 3 to 6 months, 8 to 10 mcg/kg/day; for children ages 6 to 12 months, 6 to 8 mcg/kg/day; for children ages 1 to 5 years, 5 to 6 mcg/kg/day; and for children ages 5 to 12 years, 4 to 5 mcg/kg/day. In all cases, dosage is adjusted to normalize TSH and free T₄.

58.4.1.7.4 Simple Goiter.

In simple goiter, the thyroid is enlarged and levels of thyroid hormones are reduced. Thyroid enlargement is caused by TSH that has been released in response to low levels of thyroid hormones. When treating simple goiter, the goal is to provide full replacement doses of thyroid hormones, so as to suppress further TSH release. For many patients, this can be achieved with 100 to 200 mcg of levothyroxine daily.

58.4.2 Liothyronine (T₃)

Liothyronine [Cytomel, Triostat] is a synthetic preparation of triiodothyronine (T₃), a naturally occurring thyroid hormone. The structure of liothyronine is identical to that of thyroid-derived T₃. Since liothyronine is the active form of levothyroxine, the effects of the two drugs are identical.

58.4.2.1 Contrasts with Levothyroxine.

Liothyronine differs from levothyroxine in three important ways: (1) liothyronine has a shorter half-life and shorter duration of action, (2) liothyronine has a more rapid onset, and (3) liothyronine is more expensive. Because of its high price and relatively brief duration of action, liothyronine is less desirable than levothyroxine for long-term use. However, because its effects develop quickly, liothyronine may be superior to levothyroxine in situations that require speedy results, especially myxedema coma.

58.4.2.2 Evaluation.

As with levothyroxine, the dosage of liothyronine is adjusted on the basis of clinical evaluation and laboratory data. Two laboratory tests are useful: free serum T_3 and serum TSH. Since liothyronine is not converted into T_4 , plasma levels of T_4 remain low. Hence, T_4 levels cannot be used to assess treatment.

58.4.2.3 Dosage and Administration.

Liothyronine is usually administered by mouth, although IV administration may also be used. Dosage is about 80% of the dosage of levothyroxine. Because of its short half-life, liothyronine is taken twice daily, in contrast to levothyroxine, which is taken once daily.

58.4.3 Other Thyroid Preparations

58.4.3.1 Liotrix

Liotrix [Thyrolar] is a mixture of synthetic T_4 plus synthetic T_3 in a 4:1 fixed ratio. (This ratio is similar to the ratio of these hormones in plasma.) The rationale for using liotrix is that the mixture can produce plasma levels of T_4 and T_3 similar to those that occur naturally. However, since levothyroxine alone produces the same ratio of T_4 to T_3 , liotrix offers no advantage over levothyroxine for most indications.

58.4.3.2 Thyroid (Desiccated).

Thyroid [Armour Thyroid, others] consists of desiccated animal thyroid glands. Standardization is based on content of iodine, levothyroxine, and liothyronine. The ratio of levothyroxine to liothyronine is not less than 5:1. Thyroid is available in tablets (15 to 300 mg) and capsules (7.5 to 240 mg). For practical purposes, thyroid is obsolete: Use is limited to patients who have been taking the preparation for years. Thyroid is rarely prescribed for patients starting therapy today.

58.5 DRUGS FOR HYPERTHYROIDISM

58.5.1 Antithyroid Drugs: Thionamides

Thionamides work to suppress thyroid hormone synthesis. Two thionamides are available: propylthiouracil (PTU) and methimazole. Differences between the two drugs are primarily pharmacokinetic ([Table 57-3](#)). Methimazole requires fewer daily doses than PTU, and hence is generally preferred. However, methimazole crosses the placenta more readily than PTU, and hence PTU is preferred during pregnancy.

58.5.1.1 Propylthiouracil

Propylthiouracil is the oldest thionamide and will serve as our prototype for the family. The drug differs from methimazole in two major ways: It has a shorter half-life (and hence requires more daily doses), and it crosses the placenta poorly (and hence is safer during pregnancy).

58.5.1.1.1 Mechanism of Action.

Therapeutic responses to PTU result primarily from blocking thyroid hormone synthesis. Blockade occurs in two ways: (1) PTU prevents the oxidation of iodide, thereby inhibiting incorporation of iodine into tyrosine; and (2) PTU prevents iodinated tyrosines from coupling. Both effects result from inhibiting peroxidase, the enzyme that catalyzes both reactions. In addition to blocking thyroid hormone synthesis, PTU acts in the periphery to suppress conversion of T_4 to T_3 , the active form of thyroid hormone.

Please note that, although PTU prevents thyroid hormone synthesis, it does not destroy existing stores of thyroid hormone. Hence, once therapy has begun, it may take 3 to 12 weeks to produce a euthyroid state.

58.5.1.1.2 Pharmacokinetics.

Propylthiouracil is rapidly absorbed following oral administration. Therapeutic actions begin within 30 minutes. Plasma protein binding is moderate (75% to 80%). The half-life is short (about 90 minutes), and hence PTU must be administered several times a day. Transplacental passage is low, as is entry into breast milk.

58.5.1.1.3 Therapeutic Uses.

Propylthiouracil has four applications in hyperthyroidism:

- It can be used as the sole form of therapy for Graves' disease.
- It can be employed as an adjunct to radiation therapy until the effects of radiation become manifest.

TABLE 57-3 Pharmacokinetics of Propylthiouracil and Methimazole

	Propylthiouracil	Methimazole
Bioavailability	80–95%	80–95%
Plasma protein binding	75–80%	0
Levels in breast milk	Low	Higher
Transplacental passage	Low	Higher
Half-life	1–2 hr	6–13 hr
Dosing frequency		
Initial therapy	3 or 4 times a day	1–3 times a day
Maintenance therapy	2 or 3 times a day	Once a day

695

- It can be given to suppress thyroid hormone synthesis in preparation for thyroid gland surgery (subtotal thyroidectomy).
- It can be given to patients experiencing thyrotoxic crisis; benefits derive from suppressing thyroid hormone synthesis and from suppressing conversion of T_4 to T_3 .

696

It is important to note that not all patients respond to PTU and, among those who do respond, prolonged treatment (6 to 12 months) may be needed to normalize thyroid hormone production.

58.5.1.1.4

Adverse Effects.

Adverse responses to PTU are relatively rare. However, severe adverse effects can occur.

58.5.1.1.4.1

Agranulocytosis.

Agranulocytosis is the most serious toxicity. This reaction is rare (about 3 cases per 10,000 patients) and usually develops during the first 2 months of therapy. Sore throat and fever may be the earliest indications, and patients should be instructed to report these immediately. Because agranulocytosis often develops rapidly, periodic blood counts cannot guarantee early detection. If agranulocytosis occurs, PTU should be discontinued. Agranulocytosis will then reverse. Treatment with granulocyte colony-stimulating factor (filgrastim [Neupogen]) may accelerate recovery.

58.5.1.1.4.2 Hypothyroidism.

When given in high doses, PTU can convert the patient from a hyperthyroid state to a hypothyroid state. If this occurs, dosage should be reduced. Temporary administration of thyroid hormone may be required.

58.5.1.1.4.3 Pregnancy and Lactation.

Thionamides can cause neonatal hypothyroidism and goiter. Accordingly, these drugs must be used judiciously during pregnancy. To minimize effects on the fetus, dosage should be kept as low as possible. As an alternative, some clinicians recommend treatment with full doses combined with thyroid hormone replacement therapy. However, this practice is controversial.

Compared with methimazole, PTU crosses the placenta poorly, and hence risk to the fetus is low. Accordingly, if a thionamide is needed during pregnancy, PTU is the preferred drug.

Use of thionamides during breast-feeding should generally be avoided. However, if a thionamide must be used, PTU is preferred to methimazole.

58.5.1.1.4.4 Other Adverse Effects.

The most common undesired effect of PTU is rash. The drug may also cause nausea, arthralgia, headache, dizziness, paresthesias, and liver injury.

58.5.1.1.5 Preparations, Dosage, and Administration.

Propylthiouracil is available in 50-mg tablets for oral administration. Because of its short half-life, PTU must be given in multiple daily doses.

58.5.1.1.5.1 Treatment of Graves' Disease.

High doses (100 to 300 mg 3 times a day) are used initially. Lower doses (eg, 50 mg 3 times a day) are used for maintenance. As a rule, treatment continues for 1 to 2 years. When PTU is discontinued, some 30% to 40% of patients remain euthyroid, indicating remission. Others become hyperthyroid in 1 to 4 weeks, indicating relapse. If relapse occurs, another round of PTU can be tried. Alternatively, the patient can opt for radiation therapy or surgery.

58.5.1.2 Methimazole

Methimazole [Tapazole] is very similar to PTU. Both drugs have the same mechanism of action (inhibition of peroxidase with subsequent inhibition of thyroid hormone synthesis) and the same serious toxicity (agranulocytosis). However, the drugs do have three important differences. First, methimazole has a longer half-life (6 to 13 hours versus 90 minutes). As a result, most patients need only one dose a day, compared with 2 or 3 doses a day for PTU. Second, in contrast to PTU, methimazole does not block conversion of T_4 to T_3 in the periphery, and hence onset of effects may be slower. Third, methimazole crosses the placenta more readily than PTU, and achieves higher concentrations in breast milk. Accordingly, if a thionamide must be used during pregnancy or breastfeeding, PTU is preferred. Methimazole is supplied in 5- and 10-mg tablets. As with PTU, doses are high initially (eg, 30 to 40 mg once a day) and then decreased for maintenance (5 to 15 mg once a day). Because it requires fewer daily doses, methimazole is generally preferred to PTU, except for use by women who are pregnant or breast-feeding.

58.5.2 Radioactive Iodine (^{131}I)

58.5.2.1 Physical Properties

Iodine-131 [Iodotope], a radioactive isotope of stable iodine, emits a combination of beta particles and gamma rays. Radioactive decay of ^{131}I takes place rapidly, with a half-life of 8 days. Hence, after 56 days (seven half-lives), less than 1% of the radioactivity in a dose of ^{131}I remains.

58.5.2.2 Use in Graves' Disease

Iodine-131 can be used to destroy thyroid tissue in patients with hyperthyroidism. The objective is to produce clinical remission without causing complete destruction of the gland.

Unfortunately, delayed hypothyroidism, due to excessive thyroid damage, is a frequent complication.

58.5.2.2.1 Effect on the Thyroid.

Like stable iodine, ^{131}I is concentrated in the thyroid gland. Destruction of thyroid tissue is produced primarily by emission of beta particles. (The gamma rays from ^{131}I are relatively harmless.) Because beta particles have a very limited ability to penetrate any type of physical barrier, they do not travel outside the thyroid. Hence, damage to surrounding tissue is minimal.

Reduction of thyroid function is gradual. Initial effects become apparent in days or weeks. Full effects develop in 2 to 3 months.

Not all patients respond satisfactorily to a single treatment. About 66% of patients with Graves' disease are cured with a single exposure to ^{131}I . Others require two or more treatments.

58.5.2.2.2

Advantages and Disadvantages of ^{131}I Therapy.

The advantages of ^{131}I treatment are considerable: (1) low cost; (2) patients are spared the risks, discomfort, and expense of thyroid surgery; (3) death from ^{131}I treatment is extremely rare; and (4) no tissue other than the thyroid is injured (patients should be reassured of this).

Treatment with ^{131}I is not without drawbacks. First, the effect of treatment is delayed, taking several months to become maximal. Second, and more important, treatment is associated with a significant incidence of delayed hypothyroidism. Hypothyroidism results from excessive dosage and occurs in up to 90% of patients within the first year following ^{131}I exposure.

58.5.2.2.3

Who Should Be Treated and Who Should Not.

Patients over the age of 30 may be candidates for ^{131}I therapy. Iodine-131 also is indicated for patients who have not responded adequately to antithyroid drugs or to subtotal thyroidectomy.

As a rule, very young children are considered inappropriate candidates. The likelihood of delayed hypothyroidism is higher than in adults. Also, there is concern that administration of ^{131}I to young patients may carry a slight risk of cancer. It should be noted, however, that there is no evidence that the use of ^{131}I in Graves' disease has ever caused cancer of the thyroid or any other tissue. Although ^{131}I is generally avoided in young children, it is commonly used in postpubertal adolescents and young adults.

Iodine-131 is *contraindicated in pregnancy and lactation*. Exposure of the fetus to ^{131}I after the first trimester may damage the immature thyroid, and exposure to radiation at any point in fetal life carries a risk of generalized developmental harm. Accordingly, a negative pregnancy test is required before giving ^{131}I . Because ^{131}I enters breast milk, women receiving this agent should not breast-feed.

696

697

58.5.2.2.4 Dosage.

Dosage of ^{131}I is determined by thyroid size and by the rate of thyroidal iodine uptake. For Graves' disease, the dosage usually ranges between 4 and 10 millicuries (mCi).

58.5.2.3 Use in Thyroid Cancer.

Iodine-131 can be used to destroy malignant thyroid cells. However, since most forms of thyroid cancer do not accumulate iodine, only a small percentage of patients are candidates for ^{131}I therapy.

The doses of ^{131}I used to treat cancer are large, ranging from 50 to 150 mCi. These doses are much higher than those used in Graves' disease. Because high amounts of radioactivity are involved, body wastes must be disposed of properly. In addition, adverse effects from large doses of ^{131}I can be severe: radiation sickness may occur; leukemia may be produced; and bone marrow function may be depressed, resulting in leukopenia, thrombocytopenia, and anemia. Fortunately, these severe effects are rare.

58.5.2.4 Diagnostic Use.

Iodine-131 is employed to diagnose a variety of thyroid disorders, including hyperthyroidism, hypothyroidism, and goiter. Following ^{131}I administration, the thyroid is scanned for uptake of radioactivity; the amount and location of ^{131}I uptake reveal the extent of thyroid activity. Doses for diagnosis are minuscule (less than 1 microcurie for children and less than 10 microcuries for adults). These tracer doses pose virtually no threat to health. Please note that, although ^{131}I can be used for diagnosis, the preferred isotope is ^{123}I .

58.5.2.5 Preparations.

Iodine-131 is supplied in capsules and solution for oral administration. Both preparations are odorless and tasteless. Capsules contain between 0.8 and 100 mCi of ^{131}I . Vials of oral solution contain between 3.5 and 150 mCi of ^{131}I . Capsules and oral solutions are available generically (as sodium iodide ^{131}I) and under the trade name Iodotope.

58.5.3 Nonradioactive Iodine

Three preparations of nonradioactive iodine are available. All three have the same mechanism of action and similar pharmacologic effects, although their specific applications may differ.

58.5.3.1 Strong Iodine Solution (Lugol's Solution).

58.5.3.1.1 Description.

Lugol's solution is a mixture containing 5% elemental iodine and 10% potassium iodide. The iodine undergoes reduction to iodide within the GI tract prior to absorption.

58.5.3.1.2 Mechanism of Action.

When present in high concentrations, iodide has a paradoxical suppressant effect on the thyroid. Suppression is brought about in three ways. First, high concentrations of iodide decrease iodine uptake by the thyroid. Second, high concentrations of iodide inhibit thyroid hormone synthesis by suppressing both the iodination of tyrosine and the coupling of iodinated tyrosine residues. Third, high concentrations of iodine inhibit release of thyroid hormone into the blood. All three actions combine to decrease circulating levels of T₃ and T₄.

Unfortunately, the effects of iodide on thyroid function cannot be sustained indefinitely. With long-term iodide administration, suppressant effects become weaker. Accordingly, iodide is rarely used alone for thyroid suppression.

58.5.3.1.3 Therapeutic Use.

Strong iodine solution can be given to hyperthyroid individuals to suppress thyroid function in preparation for thyroidectomy. Initial effects develop within 24 hours. Peak effects develop in 10 to 15 days. In most cases, plasma levels of thyroid hormone are reduced with PTU before initiating strong iodine solution. Then iodine solution (along with more PTU) is administered for the last 10 days prior to surgery. In addition to its use prior to thyroidectomy, strong iodine solution is employed in thyrotoxic crisis and as an antiseptic (see [Chapter 95](#)).

58.5.3.1.4 Adverse Effects.

Chronic ingestion of iodine can produce *iodism*. Signs and symptoms include a brassy taste, a burning sensation in the mouth and throat, soreness of the teeth and gums, frontal headache, coryza (nasal inflammation and sneezing), salivation, and various skin eruptions. All of these fade rapidly upon discontinuation of iodine use.

58.5.3.1.5 Overdose.

Iodine is corrosive, and hence overdose will injure the GI tract. Symptoms include abdominal pain, vomiting, and diarrhea. Swelling of the glottis may cause asphyxiation. Treatment

consists of gastric lavage (to remove iodine from the stomach) and giving sodium thiosulfate (to reduce iodine to iodide).

58.5.3.1.6 Dosage and Administration.

When used to prepare hyperthyroid patients for thyroidectomy, strong iodine solution is administered in a dosage of 2 to 6 drops 3 times daily for 10 days immediately preceding surgery. Iodine solution should be mixed with juice or some other beverage to mask its unpleasant taste. The dosage for thyrotoxic crisis is 5 to 8 drops every 6 hours.

58.5.3.2 Sodium Iodide (IV).

Intravenous sodium iodide can be used for acute management of *thyrotoxic crisis*. Benefits derive from the ability of high concentrations of iodide to rapidly suppress thyroid hormone release. In the treatment of thyrotoxic crisis, sodium iodide is used in combination with PTU and a beta blocker. Sodium iodide for IV use is supplied as a 10% solution in 10-mL ampules. The dosage is 0.5 to 1 gm every 12 hours.

Although IV sodium iodide is generally very safe, *severe hypersensitivity reactions* have occurred. These may develop immediately or may be delayed by several hours. The most characteristic feature is angioedema. Skin eruptions, serum sickness, and edema of the larynx may also develop. Death has occurred. There is no specific antidote to these hypersensitivity reactions, and hence treatment is purely supportive.

58.5.3.3 Potassium Iodide.

58.5.3.3.1 Use in Thyroid Disease.

A concentrated solution of potassium iodide, containing 1 gm of potassium iodide per milliliter, can be used to treat Graves' disease and thyrotoxic crisis.

In Graves' disease, potassium iodide has the same effect as Lugol's solution: suppression of iodine uptake by the thyroid, inhibition of thyroid hormone synthesis, and inhibition of thyroid hormone release. All three actions reduce circulating levels of T₃ and T₄. The dosage is 1 to 3 drops of concentrated potassium iodide solution PO 3 times a day.

In patients experiencing thyrotoxic crisis, potassium iodide is given to suppress thyroid hormone release. The dosage is 5 to 8 drops PO every 6 hours.

58.5.3.3.2 Use in Radiation Emergencies.

Potassium iodide [Thyro-Block, Thyro-Shield, others] taken orally can be used to protect the thyroid gland in a radiation emergency. If a nuclear accident should release radioactive iodine into the environment, uptake by the thyroid can cause thyroid cancer. By administering large doses of nonradioactive iodide, uptake of radioactive material can be blocked. The dosage for adults is 130 mg/day. Dosages for younger people are given in [Chapter 109](#) (Potential Weapons of Biologic, Radiologic, and Chemical Terrorism). The likely duration of use is 3 to 10 days.

58.5.4 Beta Blockers

Propranolol [Inderal] and other beta blockers can suppress tachycardia and other symptoms of *Graves' disease*. Benefits derive from beta-adrenergic blockade, not from reducing levels of T₃ or T₄. One advantage of beta blockers is that they work quickly, unlike PTU, methimazole, and ¹³¹I. Dosages for hyperthyroidism are highly individualized.

Beta blockers are also beneficial in *thyrotoxic crisis*. In the absence of contraindications (eg, asthma, heart failure), all patients should receive one immediately. Administration may be oral or IV. The dosage for propranolol is 80 to 120 mg PO every 6 hours or 2 to 4 mg IV every 4 hours.

The basic pharmacology of beta blockers is discussed in [Chapter 18](#).

697

58.5.4.1

KEY POINTS

- The thyroid gland produces two active hormones: triiodothyronine (T₃), which is highly active, and thyroxine (T₄, tetraiodothyronine), which appears inactive.
- Thyroid hormones have three principal actions: stimulation of energy use, stimulation of the heart, and promotion of growth and development.
- Hormonal regulation of thyroid function occurs as follows: TRH from the hypothalamus causes the pituitary to release TSH, which causes the thyroid to make and release T₃ and T₄, which then act on the pituitary to suppress further release of TSH.
- The four steps in thyroid hormone synthesis are (1) uptake of iodide by the thyroid, (2) conversion of iodide to iodine, (3) linking of iodine to tyrosine, and (4) coupling of two iodinated tyrosines to form T₃ or T₄.
- Much of the T₄ released by the thyroid is converted to T₃ in the periphery.

698

- Low plasma levels of iodine stimulate synthesis of T₃ and T₄.
- In iodine-sufficient areas, the major cause of hypothyroidism is chronic autoimmune thyroiditis (Hashimoto's thyroiditis).
- A goiter is an enlargement of the thyroid.
- Testing serum for elevated levels of TSH is the most sensitive way to diagnose hypothyroidism.
- Most patients with hypothyroidism require lifelong replacement therapy with thyroid hormones.
- Maternal hypothyroidism during the first trimester of pregnancy can result in permanent neuropsychologic deficits in the child.
- Levothyroxine (synthetic T₄) is the drug of choice for most patients who require thyroid hormone replacement.
- There is debate as to whether certain levothyroxine preparations are interchangeable. Until the debate is resolved, it would seem best for patients to use only one product, unless the switch is approved of and monitored by the prescriber.
- Levothyroxine should be taken on an empty stomach in the morning, at least 30 minutes before breakfast.
- Cholestyramine [Questran], colestipol [Colestid], sucralfate [Carafate], aluminum-containing antacids, ferrous sulfate, and calcium supplements can significantly reduce levothyroxine absorption. At least 4 hours should separate administration of levothyroxine and these drugs.
- Levothyroxine can intensify the anticoagulant effects of warfarin.
- Graves' disease is the most common cause of excessive thyroid hormone secretion.
- Graves' disease can be treated by surgical removal of thyroid tissue, destruction of thyroid tissue with radioactive iodine (¹³¹I), or treatment with antithyroid drugs (propylthiouracil, methimazole).
- Propylthiouracil, an antithyroid drug, benefits patients with hyperthyroidism by suppressing thyroid hormone synthesis and by inhibiting conversion of T₄ to T₃ in the periphery.

- Full benefits of propylthiouracil may take 6 to 12 months to develop.
- The most serious adverse effect of propylthiouracil is agranulocytosis.
- If an antithyroid drug is required during pregnancy or breast-feeding, propylthiouracil is preferred to methimazole.
- Full effects of ^{131}I require 2 to 3 months to develop.
- Iodine-131 is contraindicated during pregnancy and lactation.
- Strong iodine solution (Lugol's solution) can be used to suppress thyroid hormone synthesis.

58.5.4.2 Summary of Major Nursing Implications*

58.5.4.2.1 LEVOTHYROXINE (T_4)

58.5.4.2... Preadministration Assessment

58.5.4.2... Therapeutic Goal

Resolution of signs and symptoms of hypothyroidism and restoration of normal laboratory values for serum TSH and free T_4 .

58.5.4.2... Baseline Data

Obtain serum levels of TSH and free T_4 .

58.5.4.2... Implementation: Administration

58.5.4.2... Routes

Oral, IV.

58.5.4.2... Administration

58.5.4.2... Oral

Instruct the patient to take levothyroxine on an empty stomach in the morning, at least 30 minutes before breakfast.

698

Make certain the patient understands that replacement therapy must continue for life. Caution patients against discontinuing treatment without consulting the prescriber.

Intravenous

Intravenous administration is reserved for treating myxedema coma and for patients who cannot take levothyroxine orally.

Ongoing Evaluation and Interventions

Evaluating Therapeutic Effects

Adults.

Clinical evaluation should reveal reversal of signs of thyroid deficiency and an absence of signs of thyroid excess (eg, tachycardia). Laboratory tests should indicate normal plasma levels of TSH and T₄.

Infants.

Clinical evaluation should reveal normalization of intellectual function, growth, and development. Monthly measurements of height provide a good index of thyroid sufficiency. Laboratory tests should show normal plasma levels of TSH and T₄. (Note: TSH levels may remain high in some children, despite adequate dosing.)

Minimizing Adverse Effects

Thyrotoxicosis

Overdose may cause thyrotoxicosis. **Inform patients about symptoms of thyrotoxicosis (tachycardia, angina, tremor, nervousness, insomnia, hyperthermia, heat intolerance, sweating), and instruct them to notify the prescriber if these develop.**

Minimizing Adverse Interactions

Drugs That Reduce Levothyroxine Absorption

Absorption of levothyroxine can be reduced by cholestyramine, colestipol, sucralfate, aluminum-containing antacids, ferrous sulfate, and calcium supplements. **Instruct patients to separate administration of levothyroxine and these drugs by 4 hours.**

58.5.4.2...

Drugs That Accelerate Levothyroxine Metabolism.

Several drugs, including carbamazepine, rifampin, phenytoin, phenobarbital, and sertraline, can accelerate metabolism of levothyroxine, and can thereby reduce its effects. An increase in levothyroxine dosage may be needed.

58.5.4.2...

Warfarin.

Levothyroxine can intensify the effects of warfarin. Warfarin dosage may need to be reduced.

58.5.4.2...

Catecholamines.

Thyroid hormones sensitize the heart to catecholamines (epinephrine, dopamine, dobutamine) and may thereby promote dysrhythmias. Exercise caution when catecholamines and levothyroxine are used together.

58.5.4.2.2

LIOTHYRONINE (T_3)

With the exceptions noted below, the nursing implications for liothyronine are the same as those for levothyroxine.

58.5.4.2...

Evaluating Therapeutic Effects

Success is indicated by resolution of the signs and symptoms of hypothyroidism and by normalization of plasma T_3 and TSH levels. T_4 levels cannot be used to evaluate therapy.

58.5.4.2.3

PROPYLTHIOURACIL

58.5.4.2...

Preadministration Assessment

58.5.4.2...

Therapeutic Goals

Propylthiouracil has four indications: (1) reduction of thyroid hormone production in Graves' disease, (2) control of hyperthyroidism until the effects of radiation on the thyroid become manifest, (3) suppression of thyroid hormone production prior to subtotal thyroidectomy, and (4) treatment of thyrotoxic crisis.

58.5.4.2...

Baseline Data

Obtain serum levels of free T_3 and free T_4 .

58.5.4.2...

Identifying High-Risk Patients

Use with *caution* during pregnancy and lactation.

58.5.4.2...

Implementation: Administration

58.5.4.2...

Route

Oral.

58.5.4.2...

Administration

Instruct the patient to take PTU at regular intervals around-the-clock (usually every 8 hours).

58.5.4.2...

Ongoing Evaluation and Interventions

58.5.4.2...

Summary of Monitoring

Evaluate treatment by monitoring for weight gain, decreased heart rate, and other indications that levels of thyroid hormone have declined. Laboratory tests should indicate a decrease in serum free T₃ and free T₄.

58.5.4.2...

Minimizing Adverse Effects

58.5.4.2...

Agranulocytosis

Inform patients about early signs of agranulocytosis (fever, sore throat), and instruct them to notify the physician if these develop. If follow-up blood tests reveal leukopenia, PTU should be withdrawn. Giving granulocyte colony-stimulating factor may accelerate recovery.

58.5.4.2...

Hypothyroidism

Propylthiouracil may cause excessive reductions in thyroid hormone synthesis. If signs of hypothyroidism develop or if plasma levels of T₃ and T₄ become subnormal, PTU dosage should be reduced. Supplemental thyroid hormone may be needed.

699

Use in Pregnancy and Lactation

Propylthiouracil can enter breast milk and can cross the placenta—albeit much less readily than methimazole. Hence, if an antithyroid drug must be used by a woman who is pregnant or breast-feeding, PTU is preferred to methimazole.

RADIOACTIVE IODINE (^{131}I)

Use in Graves' Disease

Therapeutic Goal

Suppression of thyroid hormone production.

Identifying High-Risk Patients

Iodine-131 is *contraindicated* during pregnancy and lactation.

Dosage and Administration

Iodine-131 is administered in capsules or an oral liquid. The dosing objective is to reduce thyroid hormone production without causing complete thyroid destruction. The dosage for Graves' disease is 4 to 10 mCi.

Promoting Therapeutic Effects

Responses take 2 to 3 months to develop fully. Propylthiouracil or methimazole may be required during this interval.

Minimizing Adverse Effects

Excessive thyroid destruction can cause hypothyroidism. Patients who develop thyroid insufficiency need thyroid hormone supplements.

Use in Thyroid Cancer

High doses (50 to 150 mCi) are required. These doses can cause radiation sickness, leukemia, and bone marrow depression. Monitor for these effects. Body wastes will be contaminated with radioactivity and must be disposed of appropriately.

58.5.4.2...

Diagnostic Use

Iodine-131 is used to diagnose hyperthyroidism, hypothyroidism, and goiter. Diagnostic doses are so small (less than 10 microcuries) as to be virtually harmless.

58.5.4.2.5

STRONG IODINE SOLUTION (LUGOL'S SOLUTION)

58.5.4.2...

Preadministration Assessment

58.5.4.2...

Therapeutic Goal

Suppression of thyroid hormone production in preparation for subtotal thyroidectomy. Also used to suppress thyroid hormone release in patients experiencing thyroid storm.

58.5.4.2...

Baseline Data

Obtain tests of thyroid function.

58.5.4.2...

Implementation: Administration

58.5.4.2...

Route

Oral.

58.5.4.2...

Administration

Advise patients to dilute strong iodine solution with fruit juice or some other beverage to increase palatability.

58.5.4.2...

Ongoing Evaluation and Interventions

58.5.4.2...

Minimizing Adverse Effects

58.5.4.2...

Mild Toxicity

Inform patients about symptoms of iodism (brassy taste, burning sensations in the mouth, soreness of gums and teeth), and instruct them to discontinue treatment and notify the prescriber if these occur. Symptoms fade upon drug withdrawal.

58.5.4.2...

Severe Toxicity

Iodine solution can cause corrosive injury to the GI tract. **Instruct patients to discontinue the drug and notify the prescriber immediately if severe abdominal distress develops.** Treatment includes gastric lavage and giving sodium thiosulfate.

* Patient education information is highlighted as **blue text**.

⁵⁹CHAPTER 58 Drugs Related to Hypothalamic and Pituitary Function

The hypothalamus and pituitary are intimately related both anatomically and functionally. Working together, these structures help regulate practically all bodily processes. To achieve their widespread effects, the hypothalamus and pituitary employ at least 15 hormones and regulatory factors ([Fig. 58-1](#)). As you can imagine, the endocrinology of these structures is exceedingly complex. However, rather than discussing all relevant information in depth, we will focus on just three agents: growth hormone (GH), antidiuretic hormone (ADH), and prolactin. Additional hypothalamic and pituitary hormones of therapeutic interest are considered briefly here and discussed further in other chapters.

^{59.1}OVERVIEW OF HYPOTHALAMIC AND PITUITARY ENDOCRINOLOGY

^{59.1.1}Anatomic Considerations

The pituitary sits in a depression in the skull located just below the third ventricle of the brain; the hypothalamus is located immediately above (see [Fig. 58-1](#)). The pituitary has two divisions: the *anterior pituitary* (or adenohypophysis) and *posterior pituitary* (or neurohypophysis). Both divisions are under hypothalamic control. As indicated in [Figure 58-1](#), the hypothalamus communicates with the anterior pituitary by way of release-regulating factors delivered through a system of portal blood vessels. In contrast, communication with the posterior pituitary is neuronal.

^{59.1.2}Hormones of the Anterior Pituitary

The anterior pituitary produces six major hormones. Production and release of these hormones is controlled largely by the hypothalamus. Functions of the anterior pituitary hormones are summarized briefly as follows:

- *Growth hormone* (GH) stimulates growth in practically all tissues and organs.
- *Corticotropin* (adrenocorticotrophic hormone [ACTH]) acts on the adrenal cortex to promote synthesis and release of adrenocortical hormones.
- *Thyrotropin* (thyroid-stimulating hormone [TSH]) acts on the thyroid gland to promote synthesis and release of thyroid hormones.
- *Follicle-stimulating hormone* (FSH) acts on the ovaries to promote follicular growth and development. In the testes, FSH promotes spermatogenesis.
- *Luteinizing hormone* (LH) acts in women to promote ovulation and development of the corpus luteum. In men, LH acts on the testes to promote androgen production.

- *Prolactin* stimulates milk production after parturition.

59.1.3 Hormones of the Posterior Pituitary

The posterior pituitary has only two hormones: *oxytocin* and *antidiuretic hormone* (ADH). The principal function of oxytocin is to facilitate uterine contractions at term. ADH promotes renal conservation of water.

Although oxytocin and ADH are considered hormones of the posterior pituitary, these agents are actually synthesized in the hypothalamus. The cells that make oxytocin and ADH are called neurosecretory cells. As indicated in [Figure 58-1](#), these cells originate in the hypothalamus and project their axons to the posterior pituitary. Oxytocin and ADH are produced within the bodies of these cells and then transported down the axons to the axon terminals for storage. When appropriate stimuli impinge upon the bodies of the neurosecretory cells, impulses are sent down the axon, causing hormone release.

59.1.4 Hypothalamic Release-Regulating Factors

The hypothalamus has the primary responsibility for regulating the release of hormones from the *anterior* pituitary. To accomplish this, the hypothalamus employs eight different release-regulating factors (see [Fig. 58-1](#)). Most of these factors *stimulate* the release of anterior pituitary hormones. However, two of these factors *inhibit* hormone release. As indicated in [Figure 58-1](#), the hypothalamic release-regulating factors are delivered to the anterior pituitary via portal blood vessels. Although the hypothalamic releasing factors are of

701

Figure 58-1 **Hormones and releasing factors of the hypothalamus and pituitary.** *Hypothalamic releasing factors:* GnRH = gonadotropin-releasing hormone, GH-RH = growth hormone-releasing hormone, PRF = prolactin-releasing factor, CRH = corticotropin-releasing hormone, TRH = thyrotropin-releasing hormone. *Anterior pituitary hormones:* GH = growth hormone, ACTH = adrenocorticotrophic hormone (corticotropin), TSH = thyroid-stimulating hormone, FSH = follicle-stimulating hormone, LH = luteinizing hormone.

extreme *physiologic* importance, only five of them—growth hormone–releasing hormone, thyrotropin-releasing hormone, gonadotropin-releasing hormone, corticotropin-releasing hormone, and somatostatin—have clinical applications. These are the only hypothalamic release-regulating factors discussed in this chapter.

59.1.5 Feedback Regulation of the Hypothalamus and Anterior Pituitary

With few exceptions, the release of hypothalamic and anterior pituitary hormones is regulated by a *negative feedback loop*, as illustrated in [Figure 58-2](#). In this example, the loop begins with the secretion of releasing-factor *X* from the hypothalamus. Factor *X* then acts on the anterior pituitary to stimulate release of hormone A. Hormone A then acts on its target gland to promote release of hormone B. Hormone B has two actions: (1) it produces its designated biologic effects and (2) it acts on the hypothalamus and pituitary to inhibit further release of factor *X* and hormone A. This feedback inhibition of the hypothalamus and pituitary suppresses further release of hormone B itself, thereby keeping levels of hormone B within an appropriate range.

59.2 GROWTH HORMONE

Growth hormone (GH) is a large polypeptide hormone (191 amino acids) produced by the anterior pituitary. As its name suggests, GH helps regulate growth. Childhood deficiency of GH results in *short stature*. Excessive GH results in *gigantism* (when too much is present prior to puberty) and *acromegaly* (when too much is present during adulthood).

59.2.1 Physiology

59.2.1.1 Regulation of Release

The factors that regulate GH release are summarized in [Figure 58-3](#). As indicated, the hypothalamus first releases growth hormone–releasing hormone (GH-RH), which stimulates release of GH from the pituitary. Growth hormone then acts on the liver and other tissues to cause release of *insulin-like growth factor-1* (IGF-1). IGF-1 has two actions: it (1) promotes growth and (2) acts on the hypothalamus and pituitary to suppress release of GH-RH and GH, thereby completing a negative feedback loop.

One additional hormone—*somatostatin*—helps regulate GH release. As shown in [Figure 58-3](#), somatostatin, which is produced in the hypothalamus, acts on the pituitary to inhibit GH release.

59.2.1.2 Biologic Effects

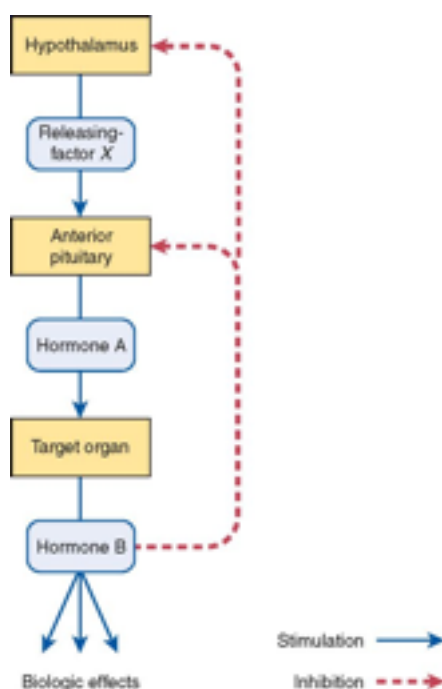

59.2.1.2.1 Promotion of Growth.

GH, acting through IGF-1, stimulates the growth of practically all organs and tissues. If administered to a GH-deficient child prior to epiphyseal closure, GH will increase bone length, producing a corresponding increase in height. The size and number of muscle cells is increased, resulting in enlargement of muscle mass, and the internal organs are stimulated to grow in proportion to overall body growth. The only structures that do not respond noticeably are the brain and eyes.

702

703

Figure 58-2 Negative feedback regulation of the hypothalamus and anterior pituitary. The feedback loop works as follows: Factor X stimulates the pituitary to release hormone A, which stimulates its target organ, causing release of hormone B. Hormone B then acts on the hypothalamus and pituitary to suppress further release of factor X and hormone A, thereby suppressing further release of hormone B itself.

59.2.1.2.2 Promotion of Protein Synthesis.

For growth to occur, cells must increase production of protein. GH facilitates this process by increasing amino acid uptake and utilization. Since amino acids have substantial nitrogen content, increased protein synthesis results in net nitrogen retention, which is reflected in reduced urinary nitrogen excretion. Increased amino acid utilization also causes blood urea nitrogen to fall.

59.2.1.2.3 Effect on Carbohydrate Metabolism.

Administration of GH reduces glucose utilization. Hence, plasma levels of glucose tend to rise. When GH is administered to nondiabetics, elevation of blood glucose stimulates release of insulin, thereby maintaining glucose levels within a normal range. In contrast, when GH is administered to patients with type 1 diabetes, insulin cannot be released. As a result, the hyperglycemic action of GH goes unopposed, allowing plasma glucose levels to rise, sometimes dramatically.

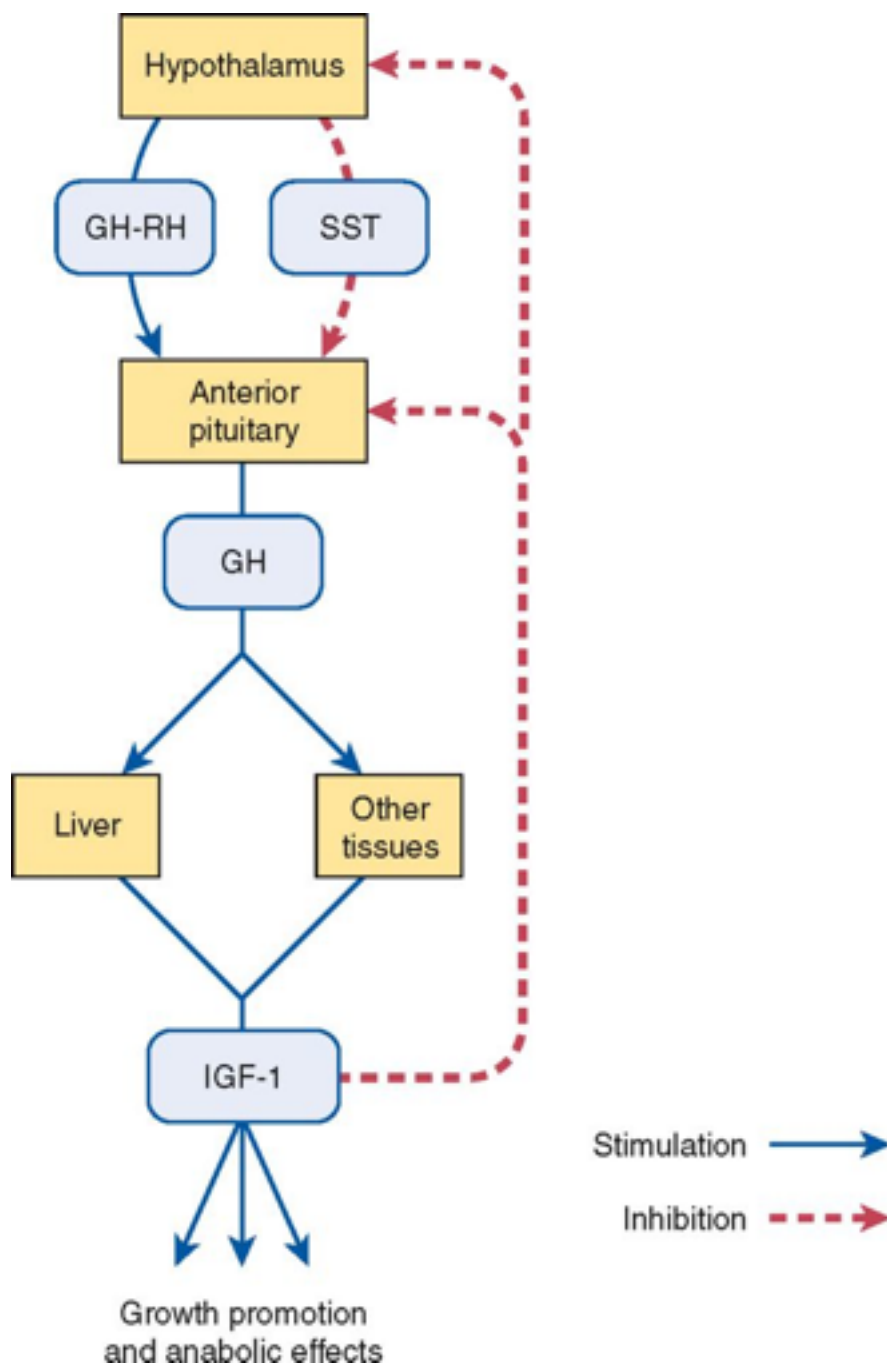

59.2.2 Pathophysiology

59.2.2.1 Growth Hormone Deficiency

59.2.2.1.1 Pediatric.

Growth hormone is essential for normal growth of children, and hence GH deficiency results in *short stature*. Growth is retarded to an equal extent in all parts of the body, and hence the child, although short, has normal proportions.

Figure 58-3 **Regulation of growth hormone release.**(GH-RH = growth hormone–releasing hormone, SST = somatostatin, GH = growth hormone, IGF-1 = insulin-like growth factor-1.)

Mental function is not impaired. The only treatment for GH deficiency is replacement therapy with human GH itself (see below under *Therapeutic Uses*).

59.2.2.1.2 Adult.

In adults, GH deficiency causes a syndrome characterized by reduced muscle mass, reduced exercise capacity, increased mortality from cardiovascular causes, and impaired psychosocial function. Onset of GH deficiency may begin in childhood or later in life.

59.2.2.2 Growth Hormone Excess

59.2.2.2.1 Consequences.

When GH excess occurs in children, the resulting syndrome is called *gigantism*, and when the excess occurs in adults, the syndrome is called *acromegaly*. The pathophysiology of both syndromes is similar. The principal difference is that GH excess causes children to grow very tall—as much as 7 to 9 feet—owing to stimulation of long bones prior to epiphyseal closure. In adults, effects on bone growth result in coarse facial features, splayed teeth, and large hands and feet. However, because the epiphyses have already closed, height is not increased. Other manifestations, seen in adults *and* children, include headache, profuse sweating, soft tissue swelling, cardiomegaly, hypertension, arthralgias, and diabetes. Levels of IGF-1 are elevated in all patients. In almost all cases, the cause of GH excess is a pituitary adenoma.

703

59.2.2.2.2 Treatment Overview.

704

Treatment of gigantism requires surgical removal of the pituitary. In contrast, acromegaly may be treated with three modalities: surgery, radiation, or drugs. Surgical excision of the pituitary adenoma is the preferred initial treatment for most patients. Radiation therapy may be used as primary treatment or as an adjunct to surgery. When used as primary treatment, radiation takes 10 to 20 years to produce a full response.

Drugs are generally reserved for patients with large tumors or residual disease despite tumor excision and/or radiation therapy. Three drugs are available: octreotide [Sandostatin, Sandostatin LAR Depot], lanreotide [Somatuline Depot], and pegvisomant [Somavert]. The pharmacology of these agents is discussed later under *Drugs for Acromegaly*.

59.2.3 Clinical Pharmacology

59.2.3.1 Therapeutic Uses

59.2.3.1.1 Pediatric Growth Hormone Deficiency.

Prior to 2003, pediatric indications for GH were limited to children with documented GH deficiency. Treatment should begin early in life and must stop prior to epiphyseal closure. To ensure timely termination of treatment, epiphyseal status should be assessed annually. When treatment is started early, adult height may be increased by as much as 6 inches. To monitor treatment, height and weight should be measured monthly. Therapy should continue until a satisfactory adult height has been achieved, until epiphyseal closure occurs, or until a response can no longer be elicited. Efficacy of therapy declines as the patient grows older and is usually lost entirely by age 20 to 24 years. If treatment fails to promote growth, GH should be discontinued and the diagnosis of GH deficiency re-evaluated. Growth hormone replacement is very expensive, costing between \$20,000 and \$40,000 a year.

59.2.3.1.2 Pediatric Non–Growth-Hormone-Deficient (NGHD) Short Stature.

In 2003, the Food and Drug Administration approved GH for treating children with NGHD short stature. These children have normal levels of GH but are nonetheless very short. To qualify for treatment, children must be 2.25 standard deviations below the mean height for their sex and age, which makes them among the shortest 1.2% of their peers. In clinical trials, children who received 6 to 7 injections a week for 4 to 6 years grew an extra 1 to 3 inches, although some did not respond at all. As with treatment of GH-deficient children, the cost is very high.

59.2.3.1.3 Pediatric Short Stature Associated with Prader-Willi Syndrome.

Prader-Willi syndrome (PWS) is a complex genetic disorder characterized by short stature, mental impairment, incomplete sexual development, behavior problems, low muscle tone, and the urge to eat constantly, which promotes obesity. Growth hormone is indicated to increase the height of PWS patients, but only if GH deficiency has been documented.

704

705

TABLE 58-1 Somatropin (Human Growth Hormone): Preparations, Indications, and Dosages

Trade Name	Approved Indications	Dosage
Accretropin	Pediatric GH deficiency	0.18–0.3 mg/kg/wk subQ, divided into 6 or 7 equal daily doses
	Turner's syndrome	0.36 mg/kg/wk subQ, divided into 6 or 7 equal daily doses
Genotropin	Pediatric GH deficiency	0.16–0.24 mg/kg/wk subQ, divided into 6 or 7 equal daily doses
	Pediatric short stature associated with PWS	0.24 mg/kg/wk subQ, divided into 6 or 7 equal daily doses
		0.33 mg/kg/wk subQ, divided into 6 or 7 equal daily doses
	Turner's syndrome	0.04–0.08 mg/kg/wk subQ, divided into 7 equal daily doses
	Adult GH deficiency	
Humatrope	Pediatric GH deficiency	0.18 mg/kg/wk subQ or IM, divided into either (a) 6 equal daily doses or (b) 3 equal doses administered every other day
	Pediatric NGHD short stature	Up to 0.37 mg/kg/wk subQ, divided into 6 or 7 equal daily doses
	Somatropin deficiency syndrome	0.006 mg/kg/day subQ initially, increased to 0.0125 mg/kg/day (max)
	Turner's syndrome	0.375 mg/kg/wk (max) subQ, divided into either (a) 7 equal daily doses or (b) 3 equal doses administered every other day
	Adult GH deficiency	0.006–0.0125 mg/kg/day subQ
Norditropin	Pediatric GH deficiency	0.024–0.034 mg/kg subQ 6–7 days/wk
	Turner's syndrome	0.067 mg/kg/day subQ
	Adult GH deficiency	0.004–0.016 mg/kg/day subQ

Nutropin, Nutropin AQ	Pediatric GH deficiency	0.3 mg/kg/wk subQ, divided into 7 equal daily doses
	Pediatric NGHD short stature	0.3 mg/kg/wk subQ, divided into 7 equal daily doses
	Chronic renal insufficiency	0.35 mg/kg/wk subQ, divided into 7 equal daily doses
	Turner's syndrome	0.375 mg/kg/wk subQ, divided into 3–7 equal daily doses
	Adult GH deficiency	0.006 mg/kg/day subQ initially, increased to 0.025 mg/kg/day (max) in patients under 35 yr, or to 0.0125 mg/kg/day (max) in patients over 35 yr
Omnitrope	Pediatric GH deficiency	0.1–0.24 mg/kg/wk subQ, divided into 6 or 7 equal daily doses
	Adult GH deficiency	0.04–0.08 mg/kg/wk subQ, divided into 7 equal daily doses
Saizen	Pediatric GH deficiency	0.06 mg/kg subQ or IM 3 days/wk
	Adult GH deficiency	0.005 mg/kg/day subQ initially, increased to no more than 0.01 mg/kg/day after 4 wk
Serostim	Cachexia or wasting in AIDS	4–6 mg subQ daily at bedtime (dose depends on patient's weight)
Tev-Tropin	Pediatric GH deficiency	0.1 mg/kg subQ 3 times a week
Zorbtive	Short-bowel syndrome	0.1 mg/kg subQ daily for 4 wk
AIDS = acquired immunodeficiency syndrome, GH = growth-hormone, NGHD = non-growth-hormone-deficient, PWS = Prader-Willi syndrome.		

59.2.3.1.4 Adult Growth Hormone Deficiency.

In adults with GH deficiency, replacement therapy can increase lean body mass, decrease adipose mass, and increase lumbar spine density. Unfortunately, GH also increases systolic blood pressure and fasting blood glucose. Furthermore, although GH increases muscle mass, it does not increase strength.

59.2.3.1.5 Other Uses.

In addition to the uses noted above, GH is approved for pediatric growth failure associated with chronic renal insufficiency, cachexia or wasting in patients with AIDS, Turner's

syndrome, and short-bowel syndrome. Individual GH preparations that are approved for these indications are listed in [Table 58-1](#).

59.2.3.2 Adverse Effects and Interactions

59.2.3.2.1 Hyperglycemia.

GH is diabetogenic. When used in patients with pre-existing diabetes, significant hyperglycemia may result. Glucose levels should be monitored and insulin dosage should be adjusted accordingly.

59.2.3.2.2 Neutralizing Antibodies.

Over the course of treatment, patients may develop neutralizing antibodies that bind with GH and thereby render the hormone inactive. If these antibodies develop, treatment with mecasermin (recombinant IGF-1) may be effective (see below).

59.2.3.2.3 Carpal Tunnel Syndrome.

Carpal tunnel syndrome can develop during treatment with *Serostim* (a somatotropin preparation). Giving fewer doses per week may reduce symptoms. If symptoms persist, *Serostim* should be discontinued.

59.2.3.2.4 Fatality in PWS Patients.

Fatalities have occurred in PWS patients treated with GH. Major risk factors are severe obesity, upper airway obstruction, sleep apnea, and respiratory infection. Growth hormone is contraindicated in PWS patients who are severely obese or have severe respiratory impairment.

59.2.3.2.5 Interaction with Glucocorticoids.

Glucocorticoids can oppose the growth-promoting effects of GH. Glucocorticoid replacement doses must be carefully adjusted to avoid growth inhibition.

59.2.3.3 Preparations and Dosage

59.2.3.3.1 Somatotropin.

Somatotropin [Humatrope, Nutropin, others] is a form of GH produced by recombinant DNA technology. The structure and actions of somatotropin are identical to those of GH produced by

the human pituitary. At this time, 10 preparations of somatropin are available. As indicated in [Table 58-1](#), they differ with respect to approved indications and dosages.

59.2.3.3.2 Somatrem.

Somatrem [Protropin] is a form of GH produced by recombinant DNA technology. With the exception of one amino acid, the structure of somatrem is identical to that of GH produced by the human pituitary. The biologic activity of somatrem is indistinguishable from that of naturally occurring GH. In 2005, somatrem was removed from the market.

59.2.3.4 Administration

Administration is parenteral—IM or subQ. Subcutaneous administration is preferred because it is less painful than IM while being just as safe and effective. Subcutaneous administration can be done using either (1) a traditional syringe and needle, or (2) for some products, a needle-free device.

59.3 MECASERMIN (INSULIN-LIKE GROWTH FACTOR-1)

Mecasermin [Increlex], produced by recombinant DNA technology, is identical to naturally occurring IGF-1, the compound that mediates the effects of GH. Mecasermin is approved for long-term therapy of growth failure in children with severe primary deficiency of IGF-1, a rare condition seen in about 10,000 children worldwide. The drug may also be used in children with GH deficiency who can no longer be treated with GH itself, owing to development of neutralizing antibodies. In children with GH deficiency who are still responsive to GH, treatment with GH is preferred to treatment with IGF-1. Mecasermin should not be used after epiphyseal closure or by children with secondary forms of IGF-1 deficiency.

Mecasermin can cause a variety of adverse effects. The most common is hypoglycemia, which develops in nearly 50% of patients, usually during the first weeks of treatment. Hypertrophy of the tonsils develops in 15% of patients, and can be managed by tonsillectomy if needed. Other adverse effects include intracranial hypertension, vomiting, arthralgia, otitis media, elevation of serum aminotransferases and lipids, and overgrowth of fat, facial bones, and the kidneys. Like all other foreign proteins, mecasermin can trigger allergic reactions, both local and systemic.

Mecasermin is supplied in solution (10 mg/mL) in 40-mL multi-use vials. Administration is by subQ injection. The initial dosage is 40 to 80 mcg/kg twice daily. If treatment is well tolerated for at least 1 week, the dosage may be increased by 40 mcg/kg/dose up to a maximum of 120 mcg/kg twice daily. Higher doses, which have not been evaluated, will increase the risk of hypoglycemia.

Pharmacology for Nursing Care, 7th Edition

To minimize hypoglycemia, all injections should be made about 20 minutes before or after eating. If hypoglycemia develops despite adequate food intake, the dosage should be reduced. If the patient is unable to eat when a dose is scheduled, that dose should be withheld; subsequent doses should not be increased to make up for the dose that was missed. Treatment is expensive: a regimen of 120 mcg/kg twice daily costs about \$29,000 a year.

59.4 PROLACTIN

Prolactin is a polypeptide hormone produced by the anterior pituitary. The principal function of prolactin is stimulation of milk production after parturition. Prolactin deficiency is generally without symptoms, except for disturbance of lactation. In contrast, overproduction of prolactin causes multiple adverse effects.

59.4.1 Regulation of Release

Regulation of prolactin release is predominantly *inhibitory*. Under the influence of dopamine released from the hypothalamus, release of prolactin by the pituitary is *suppressed*. When release of dopamine declines, release of prolactin is allowed to increase. Another hypothalamic factor, known as prolactin-releasing factor (PRF), *promotes* prolactin release. However, the stimulatory influence of PRF is usually dominated by dopamine-mediated inhibition. The most powerful stimulus to prolactin release is suckling, an action that presumably suppresses release of dopamine from the hypothalamus.

59.4.2 Prolactin Hypersecretion

Excessive secretion of prolactin produces adverse effects in males and females. Women may experience amenorrhea, galactorrhea (excessive milk flow), and infertility. In men, libido and potency are reduced; galactorrhea occurs on occasion. Puberty may be delayed in boys and girls. Causes of prolactin hypersecretion include pituitary adenoma, injury to the hypothalamus, and certain drugs (eg, antipsychotic drugs, estrogens).

59.4.3 Suppressing Prolactin Release with Dopamine Agonists

Excessive secretion of prolactin can be reduced with two dopamine agonists: cabergoline [Dostinex] and bromocriptine [Parlodel]. These drugs bind with dopamine receptors in the pituitary, and thereby exert the same inhibitory influence on prolactin release as does dopamine released from the hypothalamus. Cabergoline is better tolerated than bromocriptine, and dosing is more convenient. As a result, cabergoline is generally preferred. The pharmacology of both drugs and their use in hyperprolactinemia is discussed in [Chapter 62](#) (Drug Therapy of Infertility). The

705

706

use of cabergoline and bromocriptine (and other dopamine agonists) in Parkinson's disease is discussed in [Chapter 21](#).

59.5 THYROTROPIN

Thyrotropin (thyroid-stimulating hormone [TSH]) is produced by the anterior pituitary. The physiologic role of thyrotropin is stimulation of thyroid gland function. Specifically, thyrotropin promotes (1) thyroidal uptake of iodine, (2) synthesis and release of thyroid hormones, and (3) thyroid growth. Clinical application of thyrotropin is limited to diagnostic evaluation of patients with thyroid cancer.

59.6 CORTICOTROPIN

Corticotropin (adrenocorticotrophic hormone [ACTH]) is a polypeptide hormone produced by the anterior pituitary. This hormone acts on the adrenal cortex to stimulate production and release of adrenocortical hormones (eg, cortisol, aldosterone). The principal use of corticotropin is diagnosis of adrenocortical dysfunction. A synthetic analog of corticotropin, called cosyntropin, is available. Corticotropin and cosyntropin, along with the hormones of the adrenal cortex, are discussed in [Chapter 59](#).

59.7 GONADOTROPINS

The anterior pituitary produces two gonadotropic hormones: *folliclestimulating hormone* (FSH) and *luteinizing hormone* (LH). (Note: LH is also known as *interstitial cell–stimulating hormone*, a term that is not widely used.) LH and FSH are produced by the pituitaries of males and females and serve to regulate gonadal function in both sexes. In women, FSH acts on the ovaries to promote follicular growth and development. In men, FSH supports sperm production. The role of LH in women is to promote ovulation and formation of the corpus luteum. In men, LH stimulates testosterone synthesis by Leydig cells of the testicular interstitium. Plasma levels of LH and FSH are relatively stable in males. In females, levels of both hormones vary with the phase of the menstrual cycle. The physiology of LH and FSH in females is discussed further in [Chapter 60](#).

LH and FSH are employed clinically to treat infertility in men and women. In women, fertility is increased by promoting follicular development and ovulation. In men, fertility is increased through enhanced spermatogenesis.

Four preparations of gonadotropins are used clinically: menotropins, urofollitropin, follitropin alfa, and follitropin beta. Menotropins [Pergonal, Repronex] is a 50:50 mixture of LH and FSH. Urofollitropin [Fertinex, Metrodin] is primarily FSH. Follitropin alfa [Gonal-F] and follitropin beta

[Follistim] are human FSH preparations produced by recombinant DNA technology. The use of gonadotropins to treat infertility is discussed in [Chapter 62](#).

59.8 ANTIDIURETIC HORMONE

Antidiuretic hormone, also known as *vasopressin*, is a nine-peptide hormone that acts on the kidney to cause reabsorption (conservation) of water. Deficiency of ADH produces *hypothalamic diabetes insipidus*, a condition in which large volumes of dilute urine are produced.

59.8.1 Physiology

59.8.1.1 Actions.

ADH promotes renal conservation of water. How? ADH acts on the collecting ducts of the kidney to increase their permeability to water, which results in increased water *reabsorption*. Because water is withdrawn from the tubular urine (back into the extracellular space), urine that entered the collecting ducts in a relatively dilute state becomes highly concentrated by the time it leaves.

In addition to its renal actions, ADH can stimulate contraction of vascular smooth muscle and smooth muscle of the GI tract. Because of its ability to cause vasoconstriction, ADH is also known as vasopressin. It should be noted that the plasma levels of ADH required to cause smooth muscle contraction are higher than those that occur physiologically.

59.8.1.2 Production, Storage, and Release.

ADH is produced in neurosecretory cells of the hypothalamus, transported down their axons, and then stored in their terminals until released. Release is regulated by the hypothalamus—the brain center responsible for maintaining body fluids at their proper osmolality. When the hypothalamus senses that osmolality has risen too high, it instructs the posterior pituitary to release ADH. The resultant increase in water reabsorption dilutes body fluids, causing osmolality to decline. Release of ADH can also be stimulated by hypotension and by reduced plasma volume.

59.8.2 Pathophysiology: Hypothalamic Diabetes Insipidus

Hypothalamic diabetes insipidus is a syndrome caused by partial or complete deficiency of ADH. The syndrome is characterized by polydipsia (excessive thirst) and excretion of large volumes of dilute urine. Deficiency of ADH may be inherited or may result from head trauma, neurosurgery, cancer, and other causes. The best treatment is replacement therapy with ADH. (In contrast to

hypothalamic diabetes insipidus, *nephrogenic diabetes insipidus* results from a failure of the kidney to produce concentrated urine despite adequate levels of ADH.)

59.8.3 Antidiuretic Hormone Preparations

Two preparations with ADH activity are available: *vasopressin* and *desmopressin*. Vasopressin is identical in structure to naturally occurring ADH; desmopressin is a structural analog of natural ADH. The preparations differ with respect to route of administration, duration of action, and therapeutic applications ([Table 58-2](#)). They also differ in their ability to cause vasoconstriction.

59.8.4 Adverse Effects

59.8.4.1 Water Intoxication.

Excessive water retention can cause water intoxication. Early signs include drowsiness, listlessness, and headache. Severe intoxication progresses to convulsions and terminal coma. Patients experiencing early symptoms of intoxication should notify the prescriber. Treatment includes restriction of fluid intake and diuretic therapy.

A major cause of intoxication is failure to reduce water intake once ADH therapy has begun. Since treatment prevents continued fluid loss, failure to decrease fluid intake will result in water buildup. Hence, at the onset of treatment, patients should be instructed to reduce their accustomed fluid intake.

The risk of water intoxication is also increased by renal impairment. Accordingly, if creatinine clearance is below 50 mL/min, ADH should not be used.

59.8.4.2 Excessive Vasoconstriction.

Because of its powerful vasoconstrictor actions, *vasopressin* can cause severe adverse cardiovascular effects. (Desmopressin is a weak pressor agent, and hence does not adversely affect hemodynamics.) By constricting arteries of the heart, vasopressin can cause angina pectoris and even myocardial infarction—especially in patients with coronary insufficiency. In addition, vasopressin may cause gangrene by decreasing blood flow in the periphery. Because it can reduce cardiac perfusion, vasopressin must be used with extreme caution in patients with coronary artery disease. This warning does not apply to desmopressin. Despite its potential for adverse effects on cardiac circulation, vasopressin can be lifesaving in people experiencing cardiac arrest (see below).

706

707

TABLE 58-2 ADH Preparations

Generic Name [Trade Name]	Routes	Duration of Antidiuretic Action (hr)	Therapeutic Uses	Usual Dosage
Desmopressin [DDAVP, Stimate, Minirin]	Intranasal, subQ, IV, PO	8–20	Diabetes insipidus	<i>Adults:</i> 0.1 mL (10 mcg) intranasally 2 times/day or 0.25–0.5 mL subQ or IV twice daily or 0.1–1.2 mg PO daily in 2 or 3 doses <i>Children:</i> 0.05–0.3 mL intranasally daily either as a single dose or in 2 doses
			Hemophilia	See Chapter 53
			Nocturnal enuresis	0.2–0.6 mg PO at bedtime (intranasal therapy of enuresis is now contraindicated)
Vasopressin [Pitressin]	IM, subQ*	2–8	Diabetes insipidus	5–10 units IM or subQ 3–4 times/day
			Postoperative abdominal distention	5 units IM initially; then 10 units IM every 3–4 hr
			Abdominal radiography (to dispel gas shadows)	10 units 2 hr before and again 30 min before the procedure
			Cardiac resuscitation	40 units

* Sometimes administered intranasally or IV.

59.8.5 Therapeutic Uses

59.8.5.1 Diabetes Insipidus.

Diabetes insipidus may be treated with either desmopressin or vasopressin. However, *desmopressin* is the agent of choice. Why? Because desmopressin has a long duration of action, is easy to administer (by mouth or intranasal spray), and lacks significant side effects, especially vasoconstriction. The response to treatment is rapid, and urine volume quickly drops to normal.

Because desmopressin is expensive, and because excessive dosing can result in water intoxication, the smallest effective dosage should be employed.

59.8.5.2 Cardiac Arrest.

For patients in cardiac arrest, vasopressin is used to enhance cardiopulmonary resuscitation (CPR). Benefits derive from vasopressin-induced vasoconstriction, which, in people receiving CPR, increases blood flow to the heart and brain, improves neurologic outcome, and increases the chances of successful resuscitation.

59.8.5.3 Other Uses.

Vasopressin is indicated for postoperative abdominal distention and preparation for abdominal radiography.

Desmopressin is indicated for nocturnal enuresis (bedwetting), hemophilia A, and von Willebrand's disease. The drug decreases enuresis by reducing urine production, and helps patients with hemophilia A and von Willebrand's disease by promoting release of clotting factor VIII (see [Chapter 53](#)).

59.9 CONIVAPTAN, AN ANTIDIURETIC HORMONE ANTAGONIST

Conivaptan [Vaprisol], an antagonist of ADH, is indicated for short-term IV therapy of hyponatremia (low sodium in blood) in euvolemic and hypervolemic hospitalized patients. How does the drug work? In patients with euvolemic or hypervolemic hyponatremia, levels of circulating ADH are usually high, causing retention of water by the kidney. Conivaptan blocks ADH receptors in renal collecting ducts, and thereby promotes renal excretion of free water, leaving sodium behind for reabsorption into the blood. As a result, the concentration of sodium in blood rises, thereby correcting the hyponatremia. Infusion-site reactions are common, occurring in 32% to 51% of patients. Other common reactions include hypokalemia, orthostatic hypotension, headache, fever, constipation, diarrhea, and vomiting. Dosing consists of an initial IV infusion (20 mg over 30 minutes) followed by a more prolonged infusion (20 mg over 24 hours). A maximum of three additional infusions (20 or 40 mg over 24 hours each) may be done as needed. If blood sodium rises too fast (more than 12 mEq/24 hr), serious neurologic sequelae can result. Accordingly, blood sodium should be monitored often and, if the rise is too rapid, conivaptan should be discontinued.

59... OXYTOCIN

Oxytocin is produced by neurosecretory cells of the hypothalamus and is then transported down the axons of these cells for storage in the posterior pituitary. Oxytocin has two physiologic roles: (1) promotion of uterine contractions during labor and (2) stimulation of milk ejection during breast-feeding. The principal therapeutic application of the drug is induction of labor near term. The physiology, pharmacology, and applications of oxytocin are discussed in [Chapter 63](#).

59... DRUGS FOR ACROMEGALY

As discussed above, acromegaly results from excessive production of GH by a pituitary tumor, and can be treated with three modalities: surgical excision of the pituitary, irradiation of the pituitary, and drug therapy. As a rule, drugs are reserved for patients who did not respond adequately to surgery and/or radiation, or for whom these modalities are not options. Two types of drugs are available: somatostatin analogs and GH receptor antagonists. Drug therapy is both prolonged and expensive.

59.11.1 Somatostatin Analogs.

The somatostatin analogs—octreotide and lanreotide—are our most effective drugs for suppressing GH release. Benefits derive from mimicking the suppressant actions of somatostatin on the pituitary (see [Fig. 58-3](#)). The somatostatin analogs can be used as primary therapy for acromegaly or as an adjunct to surgery and/or radiation. In both cases, the objective is to normalize levels of GH and IGF-1.

Octreotide is available in two formulations: an immediate-release product, sold as *Sandostatin*, and a sustained-release product, sold as *Sandostatin LAR Depot*. The usual maintenance dosage is 100 mcg subQ 3 times a day (for *Sandostatin*) or 10 to 30 mg IM once a month (for *Sandostatin LAR Depot*). Gastrointestinal side effects (nausea, cramps, diarrhea, flatulence) are common initially, but subside in 1 to 2 weeks. Within a year, cholesterol gallstones develop in about 25% of patients, although they are usually asymptomatic.

Lanreotide [Somatuline Depot] is supplied in single-use, pre-filled syringes (60, 90, and 120 mg) for deep subQ injection into the buttocks. Dosages range from 60 to 120 mg every 4 weeks. The most common side effect is diarrhea, which develops in 31% to 48% of patients. Other common reactions include gallstones, bradycardia, injection-site reactions, and hypo- or hyperglycemia.

59.11.2 Pegvisomant, a Growth Hormone Receptor Antagonist.

Pegvisomant [Somavert], a GH receptor antagonist, may be our most effective drug for acromegaly. The goal of therapy is to normalize serum levels of IGF-1. In clinical trials, treatment for 12 months or longer greatly reduced symptoms and normalized IGF-1 levels in nearly all patients (97%). Pegvisomant is generally well tolerated. The most common side effects are injection-site reactions, nausea, diarrhea, chest pain, and flu-like symptoms. In a few patients, serum levels of hepatic transaminases rise, indicating liver injury. Monitoring of hepatic function is recommended. The only known drug interaction is an apparent reduction in pegvisomant effects by opioid analgesics. Why this occurs is a mystery. Pegvisomant is available as a powder (10, 15, and 20 mg) that must be reconstituted with sterile water prior to use. Administration is by subQ injection. Treatment consists of an initial 40-mg loading dose (given by the prescriber), followed by 10-mg doses injected once daily by the patient. Every 4 to 6 weeks, the level of IGF-1 is measured, and dosage is increased by 5 mg (if the IGF-1 level is still above normal) or decreased by 5 mg (if the IGF-1 level is below normal). Treatment should continue indefinitely, which can be hugely expensive—ranging from \$50,000 to \$100,000 a year.

707

708

59... DRUGS RELATED TO HYPOTHALAMIC FUNCTION

Of the seven regulatory factors found in the hypothalamus, only four—growth hormone–releasing hormone (GH-RH), gonadotropin-releasing hormone (GnRH), corticotropin-releasing hormone (CRH), and somatostatin—have clinical applications. GH-RH is used to diagnose the cause of growth hormone deficiency. GnRH and its synthetic analogs are used to treat prostate cancer and endometriosis, and to induce ovulation. CRH is used to diagnose adrenal disorders. As discussed above, somatostatin is used for acromegaly.

59.12.1 Sermorelin (Growth Hormone–Releasing Factor).

Sermorelin [Geref] is a synthetic *growth hormone–releasing factor* that acts just like natural GH-RH. That is, sermorelin acts on the pituitary to stimulate release of GH, which in turn causes release of insulin-like growth factor-1. The structure of sermorelin is identical to the final 29-amino acid sequence of GH-RH. Sermorelin has only one clinical application: diagnosing the pituitary's ability to secrete GH.

59.12.2 Gonadotropin-Releasing Hormone.

Gonadotropin-releasing hormone is produced by the hypothalamus and promotes release of gonadotropins (LH and FSH) from the pituitary. Four preparations of GnRH are available:

leuprolide, *goserelin*, *nafarelin*, and *gonadorelin*. Leuprolide and goserelin are discussed in [Chapter 102](#) (Anticancer Drugs II). Nafarelin is discussed in [Chapter 62](#) (Drug Therapy of Infertility). Gonadorelin is used to evaluate anterior pituitary function.

59.12.2.1

KEY POINTS

- Release of hormones from the anterior pituitary is stimulated by releasing factors from the hypothalamus and inhibited by negative feedback loops.
- The growth-promoting actions of growth hormone (GH) are mediated by insulin-like growth factor-1 (IGF-1).
- Pediatric GH deficiency causes short stature.
- Adult GH deficiency causes reduced muscle mass, reduced exercise capacity, increased mortality from cardiovascular causes, and impaired psychosocial function.
- Pediatric GH excess causes gigantism.
- Adult GH excess causes acromegaly.
- Among pediatric patients, GH is approved for growth promotion in children who are GH deficient as well as children who are very short despite having normal GH levels.
- Exogenous glucocorticoids can inhibit responses to GH.
- GH can elevate glucose levels in patients with diabetes.
- Acromegaly can be treated with three drugs: pegvisomant (a GH receptor antagonist) and two analogs of somatostatin—octreotide and lanreotide—that suppress GH release.
- Prolactin stimulates milk production after delivery.
- Excessive production of prolactin can be suppressed with cabergoline and bromocriptine, drugs that mimic the inhibitory action of hypothalamic dopamine on the pituitary.
- Antidiuretic hormone (ADH) acts on the kidney to cause reabsorption (conservation) of water.
- ADH deficiency results in hypothalamic diabetes insipidus.

- Hypothalamic diabetes insipidus can be treated by replacement therapy with desmopressin, a synthetic form of ADH.
- When initiating ADH replacement therapy, warn the patient to decrease water intake, because failure to do so can cause water intoxication.
- Vasopressin, a drug identical to natural ADH, can cause profound vasoconstriction.
- By promoting vasoconstriction, vasopressin can be lifesaving in patients with cardiac arrest.

59.12.2.2 Summary of Major Nursing Implications*

59.12.2.... SOMATROPIN (HUMAN GROWTH HORMONE)

The nursing implications summarized here apply only to the use of GH in *pediatric* patients.

59.12.2.... Preadministration Assessment

59.12.2.... Therapeutic Goal

Normalization of growth and development in children with (1) proven GH deficiency and (2) very short stature despite normal GH levels.

59.12.2.... Baseline Data

Assess developmental status (height, weight, etc.), and obtain laboratory data on thyroid function and GH levels.

59.12.2.... Identifying High-Risk Patients

GH is *contraindicated* during and after epiphyseal closure, and in children with PWS who are severely obese or have severe respiratory impairment.

708

Use with *caution* in children with diabetes mellitus and hypothyroidism.

709

59.12.2.... Implementation: Administration

59.12.2.... Routes

SubQ (preferred) or IM.

59.12.2....

Administration

For powdered preparations, reconstitute with the appropriate volume of diluent. *Mix gently; do not shake.* Do not inject if the preparation is cloudy or contains particulate matter.

59.12.2....

Ongoing Evaluation and Interventions

59.12.2....

Evaluating Treatment

Monitor height and weight monthly. Continue therapy until a satisfactory adult height has been achieved, until epiphyseal closure occurs, or until a response can no longer be elicited (usually by age 20 to 24).

If no stimulation of growth occurs, discontinue treatment and re-evaluate the diagnosis of GH deficiency.

59.12.2....

Minimizing Adverse Effects and Interactions

59.12.2....

Hyperglycemia

GH can elevate plasma glucose levels in diabetics. Increase insulin dosage as needed.

59.12.2....

Hypothyroidism

GH may suppress thyroid function. Assess thyroid function before treatment and periodically thereafter. If levels of thyroid hormone fall, institute replacement therapy.

59.12.2....

Carpal Tunnel Syndrome.

Serostim (a form of somatropin) can cause carpal tunnel syndrome. If symptoms do not resolve after reducing the dosing frequency, Serostim should be discontinued.

59.12.2....

Fatality in PWS Patients

Owing to a risk of death, do not give GH to pediatric patients with PWS who are severely obese or have severe respiratory impairment.

59.12.2....

Interaction with Glucocorticoids

Glucocorticoids can oppose the growth-stimulating effects of GH. Carefully adjust glucocorticoid replacement dosage to avoid growth inhibition.

59.12.2....

Neutralizing Antibodies

Development of neutralizing antibodies can inactivate exogenous GH. If these antibodies develop, mecasermin (recombinant IGF-1) may be an effective alternative to GH.

59.12.2....

ANTIDIURETIC HORMONE

Desmopressin

Vasopressin

The nursing implications summarized here apply only to the use of ADH preparations for *hypothalamic diabetes insipidus*.

59.12.2....

Preadministration Assessment

59.12.2....

Therapeutic Goal

Normalization of urinary water excretion in patients with hypothalamic diabetes insipidus.

59.12.2....

Baseline Data

Determine creatinine clearance and fluid and electrolyte status.

59.12.2....

Identifying High-Risk Patients

Use *vasopressin* with *caution* in patients with coronary artery disease and other vascular diseases.

59.12.2.... Implementation: Administration

59.12.2.... Routes

59.12.2.... Desmopressin

Intranasal, PO, subQ, IV.

59.12.2.... Vasopressin

IM, subQ.

59.12.2.... Administration

Teach the patient the technique for intranasal administration. To promote adherence, make certain the patient understands that treatment is lifelong.

59.12.2.... Ongoing Evaluation and Interventions

59.12.2.... Evaluating Therapeutic Effects

Teach the patient to monitor and record daily intake and output of fluid. If ADH dosage is correct, urine volume should rapidly drop to normal.

59.12.2.... Minimizing Adverse Effects

59.12.2.... Water Intoxication

Excessive retention of water can produce water intoxication—most often at the beginning of therapy. **Instruct patients to decrease their accustomed fluid intake at the start of treatment. Inform patients about early signs of water intoxication (drowsiness, listlessness, headache), and instruct them to notify the prescriber if these occur.** Treatment includes fluid restriction and diuretic therapy. Avoid ADH in patients with creatinine clearance below 50 mL/min.

59.12.2.... Cardiovascular Effects.

Vasopressin, but not desmopressin, is a powerful vasoconstrictor. Excessive vasoconstriction can produce angina pectoris, myocardial infarction, and gangrene

(from extravasation of IV vasopressin). Use vasopressin with caution, especially in patients with coronary insufficiency.

* Patient education information is highlighted as **blue text**.

⁶⁰CHAPTER 59 Drugs for Disorders of the Adrenal Cortex

The hormones of the adrenal cortex affect multiple physiologic processes, including maintenance of glucose availability, regulation of water and electrolyte balance, development of sexual characteristics, and life-preserving responses to stress. As you might guess, when production of adrenal hormones goes awry, the consequences can be profound. The two most familiar forms of adrenocortical dysfunction are *Cushing's syndrome*, caused by adrenal hormone excess, and *Addison's disease*, caused by adrenal hormone deficiency.

In approaching the drugs for treating disorders of the adrenal cortex, we begin by reviewing adrenocortical endocrinology. After that, we discuss the disease states associated with adrenal hormone excess and adrenal hormone insufficiency. Having established this background, we discuss the agents used for diagnosis and treatment of adrenocortical disorders.

^{60.1}PHYSIOLOGY OF THE ADRENOCORTICAL HORMONES

The adrenal cortex produces three classes of steroid hormones: *glucocorticoids*, *mineralocorticoids*, and *androgens*. Glucocorticoids influence carbohydrate metabolism and other processes; mineralocorticoids modulate salt and water balance; and adrenal androgens contribute to expression of sexual characteristics. When referring to either the glucocorticoids or the mineralocorticoids, three terms may be used: *corticosteroids*, *adrenocorticoids*, or simply *corticoids*. These terms are not used in reference to adrenal androgens.

^{60.1.1} Glucocorticoids

Glucocorticoids are so named because they increase the availability of glucose. Of the several glucocorticoids produced by the adrenal cortex, *cortisol* is the most important. The structural formula of cortisol is shown in [Figure 59-1](#).

When considering the glucocorticoids, we need to distinguish between *physiologic effects* and *pharmacologic effects*. *Physiologic effects* occur at *low* levels of glucocorticoids (ie, the levels produced by release of glucocorticoids from healthy adrenals, or by administering glucocorticoids in low doses). *Pharmacologic effects* occur at *high* levels of glucocorticoids. These are the levels achieved when glucocorticoids are administered in the large doses required to treat disorders unrelated to adrenocortical function (eg, allergic reactions, asthma, inflammation, cancer). In this chapter, discussion is limited to the *physiologic* role of glucocorticoids. The use of glucocorticoids for nonendocrine purposes is discussed in [Chapter 71](#).

60.1.1.1 Physiologic Effects

60.1.1.1.1 Carbohydrate Metabolism.

Supplying the brain with glucose is essential for survival. Glucocorticoids help meet this need. Specifically, they promote glucose availability in four ways: (1) stimulation of gluconeogenesis, (2) reduction of peripheral glucose utilization, (3) inhibition of glucose uptake by muscle and adipose tissue, and (4) promotion of glucose storage (in the form of glycogen). All four actions increase glucose availability during fasting, and thereby help ensure the brain will not be deprived of its primary source of energy.

The effects of glucocorticoids on carbohydrate metabolism are opposite to those of insulin. That is, whereas insulin lowers plasma levels of glucose, glucocorticoids raise them. When present chronically in high concentrations, glucocorticoids produce symptoms much like those of diabetes.

60.1.1.1.2 Protein Metabolism.

Glucocorticoids promote protein catabolism (breakdown). This action, which is opposite to that of insulin, provides amino acids for glucose synthesis. If present at high levels for a prolonged time, glucocorticoids will cause muscle wasting, thinning of the skin, and negative nitrogen balance.

60.1.1.1.3 Fat Metabolism.

Glucocorticoids promote lipolysis (fat breakdown). When present at high levels for an extended time, as occurs in Cushing's syndrome, glucocorticoids cause fat redistribution, giving the patient a potbelly, “moon face,” and “buffalo hump” on the back.

710

Figure 59-1 Structural formulas of representative adrenocortical hormones.

CORTISOL [Hydrocortisone]
(a glucocorticoid)

ALDOSTERONE
(a mineralocorticoid)

ANDROSTENEDIONE
(an androgen)

60.1.1.1.4 Cardiovascular System.

Glucocorticoids are required to maintain the functional integrity of the vascular system. When levels of glucocorticoids are depressed, capillary permeability is increased, the ability of vessels to constrict is reduced, and blood pressure falls.

Glucocorticoids have multiple effects on blood cells. These hormones increase red blood cell counts and hemoglobin levels. Of the white blood cells, only the polymorphonuclear leukocytes increase. In contrast, lymphocytes, eosinophils, basophils, and monocytes decrease.

60.1.1.1.5 Skeletal Muscle.

Glucocorticoids support function of striated muscle, primarily by maintaining circulatory competence. In the absence of sufficient levels of glucocorticoids, muscle perfusion decreases, causing work capacity to decrease as well.

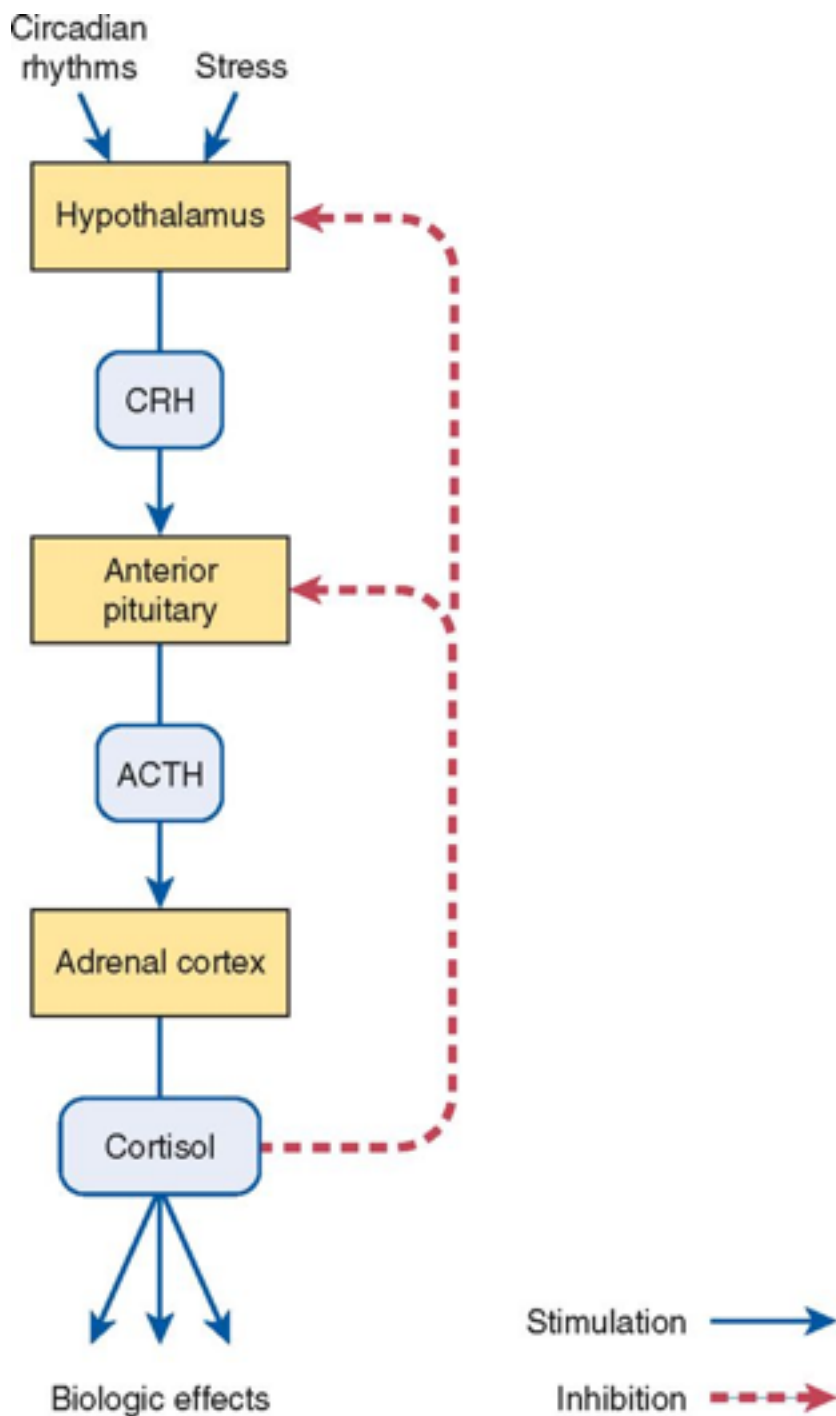

60.1.1.1.6 Central Nervous System.

Glucocorticoids affect mood, central nervous system (CNS) excitability, and the electroencephalogram. Glucocorticoid insufficiency is associated with depression, lethargy, and irritability. Rarely, outright psychosis occurs. In contrast, when present in excess, glucocorticoids can produce generalized excitation and euphoria.

60.1.1.1.7 Stress.

In response to stress (eg, anxiety, exercise, trauma, infection, surgery), the adrenal cortex secretes increased amounts of glucocorticoids, and the adrenal medulla secretes

Figure 59-2 **Negative feedback regulation of glucocorticoid synthesis and secretion.**(ACTH = adrenocorticotrophic hormone, CRH = corticotropin-releasing hormone.)

increased amounts of epinephrine. Working together, glucocorticoids and epinephrine serve to maintain blood pressure and blood glucose content. If glucocorticoid levels are inadequate, hypotension and hypoglycemia can occur. If the stress is extreme (eg, trauma, surgery, severe infection), glucocorticoid deficiency can result in circulatory collapse and death. Accordingly, it is imperative that patients with adrenal insufficiency receive glucocorticoid supplements when severe stress occurs.

60.1.1.1.8 Respiratory System in Neonates.

During labor and delivery, the adrenals of the full-term fetus release a burst of glucocorticoids. Within hours, these steroids act on the lungs to accelerate their maturation. In the premature infant, the adrenals produce only small amounts of glucocorticoids. As a result, preterm infants experience a high incidence of respiratory distress syndrome.

60.1.1.2 Regulation of Synthesis and Secretion

Adrenal storage of glucocorticoids is minimal. Accordingly, the amount of glucocorticoid released from the adrenals per unit time closely approximates the amount being made.

Glucocorticoid synthesis and release are regulated by a negative feedback loop ([Fig. 59-2](#)). The loop begins with release of corticotropin-releasing hormone (CRH) from the hypothalamus.

CRH acts on the anterior pituitary to promote release of adrenocorticotrophic hormone (ACTH), which stimulates the zona fasciculata of the adrenal cortex, causing synthesis and release of cortisol and other glucocorticoids. Following release, cortisol acts in two ways: (1) it promotes its designated biologic effects and (2) it acts on the hypothalamus and pituitary to suppress further release of CRH and ACTH. Hence, as cortisol levels rise, they act to suppress further stimulation of glucocorticoid production, thereby keeping glucocorticoid levels within an appropriate range.

The hypothalamic-pituitary-adrenal system is activated by signals from the CNS. These signals turn the system on by causing the hypothalamus to release CRH. As indicated in [Figure 59-2](#), two modes of activation are involved. One provides a basal level of stimulation; the other increases stimulation at times of stress. Basal stimulation follows a circadian rhythm: Cortisol levels are lowest near bedtime, rise during sleep, reach a peak just before waking, and then decline through the day. (Note that this cycle is linked to one's *sleep pattern*, and not to the clock. Hence, for some people, cortisol may peak in the morning, and for others it may peak in the afternoon or evening, depending on when they normally sleep.) When stress occurs, glucocorticoid production goes up. Stressful events that can activate the loop include injury,

infection, and surgery. The signals generated by stress produce intense stimulation of the hypothalamus. The resultant release of CRH and ACTH can cause plasma levels of cortisol to increase 10-fold. Because stress is such a powerful stimulus, it overrides feedback inhibition by cortisol.

How much cortisol do the adrenals produce? Basal production ranges between 5 and 10 mg/m²/day (the equivalent of 20 to 30 mg/day of hydrocortisone or 5 to 7 mg/day of prednisone). When severe stress occurs, production increases 5- to 10-fold—to a maximum of 100 mg/m²/day.

60.1.2 Mineralocorticoids

The mineralocorticoids influence renal processing of sodium, potassium, and hydrogen. In addition, they have direct effects on the heart and blood vessels. Of the mineralocorticoids made by the adrenal cortex, *aldosterone* is the most important.

60.1.2.1 Physiologic Effects.

60.1.2.1.1 Renal Actions.

Aldosterone promotes sodium and potassium hemostasis, and helps maintain intravascular volume. Specifically, the hormone acts on the collecting ducts of the nephron to promote sodium reabsorption in exchange for secretion of potassium and hydrogen. The total amount of hydrogen and potassium lost equals the amount of sodium reabsorbed. It should be noted that, as sodium is reabsorbed, water is reabsorbed along with it. In the absence of aldosterone, renal excretion of sodium and water is greatly increased, whereas excretion of potassium and hydrogen is reduced. As a result, aldosterone insufficiency causes hyponatremia, hyperkalemia, acidosis, cellular dehydration, and reduction of extracellular fluid volume. Left uncorrected, the condition can lead to renal failure, circulatory collapse, and death.

60.1.2.1.2 Cardiovascular Actions.

Until recently, we believed that aldosterone acted only on the kidneys. However, we now know that it acts on the heart and blood vessels as well. When aldosterone levels are high, cardiovascular effects are *harmful*, increasing the risk of heart failure and hypertension. Specific cardiovascular effects include (1) promotion of myocardial remodeling (which can impair pumping); (2) promotion of myocardial fibrosis (which increases the risk of dysrhythmias); (3) activation of the sympathetic nervous system and suppression of norepinephrine uptake in the heart (both of which can promote dysrhythmias and ischemia);

(4) promotion of vascular fibrosis (which decreases arterial compliance); and (5) disruption of the baroreceptor reflex.

60.1.2.2 Control of Secretion.

Secretion of aldosterone is regulated by the renin-angiotensin-aldosterone system (RAAS), not by ACTH. The mechanisms by which the RAAS regulates aldosterone are discussed in [Chapter 43](#). It is important to note that, because aldosterone is not regulated by ACTH, conditions that alter secretion of ACTH do not alter secretion of aldosterone.

60.1.3 Adrenal Androgens

The adrenal cortex produces several steroids that have androgenic properties. *Androstenedione* is representative. Under normal conditions, physiologic effects of adrenal androgens are minimal. In adult males, the influence of adrenal androgens is overshadowed by the effects of testosterone produced by the testes. In adult females, a metabolite of the adrenal androgens (testosterone) contributes to development of sexual hair and maintenance of normal libido. Although adrenal androgens normally have very little effect, when production is excessive, as occurs in congenital adrenal hyperplasia, virilization can result.

60.2 PATHOPHYSIOLOGY OF THE ADRENOCORTICAL HORMONES

60.2.1 Adrenal Hormone Excess

60.2.1.1 Cushing's Syndrome

60.2.1.1.1 Causes.

Signs and symptoms of Cushing's syndrome result from excess levels of circulating glucocorticoids. Principal causes are (1) hypersecretion of ACTH by pituitary adenomas (Cushing's disease), (2) hypersecretion of glucocorticoids by adrenal adenomas and carcinomas, and (3) administering glucocorticoids in the large doses used to treat arthritis and other nonendocrine disorders (see [Chapter 71](#)).

60.2.1.1.2 Clinical Presentation.

Cushing's syndrome is characterized by obesity, hyperglycemia, glycosuria, hypertension, fluid and electrolyte disturbances, osteoporosis, muscle weakness, myopathy, hirsutism, menstrual irregularities, and decreased resistance to infection. The skin is weakened, resulting in striae (stretch marks) and increased susceptibility to injury. Fat undergoes redistribution to

the abdomen, face, and upper back, giving the patient a characteristic potbelly, “moon face,” and “buffalo hump.” Psychiatric changes are common.

60.2.1.1.3 Treatment.

Treatment is directed at the cause. The treatment of choice for adrenal adenoma and carcinoma is surgical removal of the diseased adrenal gland. If bilateral adrenalectomy is required, replacement therapy with glucocorticoids and mineralocorticoids will be needed. For patients with inoperable adrenal carcinoma, treatment with *mitotane* may be indicated. Mitotane is an anticancer drug that produces selective destruction of adrenocortical cells. The pharmacology of mitotane is discussed in [Chapter 101](#).

When Cushing's syndrome is caused by pituitary adenoma, surgery is the preferred intervention. Partial removal of the pituitary often lowers ACTH secretion to safe levels, while leaving other pituitary functions intact. If partial adenectomy is unsuccessful, the remainder of the pituitary may be removed. As an alternative, pituitary irradiation may be employed.

712

713

The role of drugs in treating Cushing's syndrome is limited. Most commonly, drugs are employed as adjuncts to radiation and surgery; drugs are rarely the primary intervention. When drugs *are* used, they can help by suppressing corticosteroid synthesis. Two drugs that do this—*aminoglutethimide* and *ketoconazole*—are discussed below.

60.2.1.2 Primary Hyperaldosteronism

60.2.1.2.1 Clinical Presentation, Causes, and Diagnosis.

Hyperaldosteronism (excessive secretion of aldosterone) causes hypokalemia, metabolic alkalosis, and hypertension, and can increase the risk of heart failure. Muscle weakness and changes in the electrocardiogram develop secondary to hypokalemia. Hyperaldosteronism is frequently caused by an aldosterone-producing adrenal adenoma. The condition may also result from bilateral adrenal hyperplasia. Primary hyperaldosteronism can be diagnosed by determining the ratio of plasma aldosterone concentration to plasma renin activity (as discussed in [Chapter 43](#), renin is an enzyme that plays a critical role in the RAAS).

60.2.1.2.2 Treatment.

Management of hyperaldosteronism depends on the cause. When an adrenal adenoma is responsible, surgical resection of the adrenal gland is usually curative. When bilateral adrenal

hyperplasia is the cause, an *aldosterone antagonist* is the preferred treatment. The antagonist employed most frequently is *spironolactone*, a drug we normally think of as a potassium-sparing diuretic. Under the influence of spironolactone, potassium levels may normalize in 2 weeks. To achieve full control of hypertension, an additional diuretic may be required. The basic pharmacology of spironolactone is discussed in [Chapter 40](#) (Diuretics). Alternatives to spironolactone include *amiloride* (another potassium-sparing diuretic [see [Chapter 40](#)]) and *eplerenone* (a highly selective aldosterone antagonist [see [Chapter 43](#)]).

60.2.2 Adrenal Hormone Insufficiency

60.2.2.1 General Therapeutic Considerations

Adrenal hormone insufficiency can result from multiple causes, including destruction of the adrenals, inborn deficiencies of the enzymes required for corticosteroid synthesis, and reduced secretion of ACTH and CRH. Regardless of the cause, adrenal insufficiency requires lifelong replacement therapy with appropriate corticosteroids. All patients require a *glucocorticoid*. Some may require a *mineralocorticoid* as well. Of the glucocorticoids available, *hydrocortisone*, *prednisone*, and *dexamethasone* are drugs of choice. When a mineralocorticoid is indicated, *fludrocortisone* is the drug of choice.

Replacement therapy should mimic normal patterns of corticosteroid secretion. To accomplish this goal, some clinicians give the entire daily dose at bedtime (which produces glucocorticoid levels that rise during sleep and reach a peak near the waking hour); others divide the daily dose, giving two-thirds in the morning and one-third in the afternoon. Mineralocorticoids can be administered once a day. Doses of glucocorticoids and mineralocorticoids should approximate the amounts normally secreted by the adrenals. It is important to note that, when glucocorticoids are employed for replacement therapy, doses are much smaller than the doses employed for nonendocrine disorders.

At times of stress, patients must increase their glucocorticoid dosage. I cannot overemphasize the importance of doing so: *Failure to increase the dosage can be fatal.* Recall that healthy adrenals increase their output of glucocorticoids in response to stress. For patients with adrenal insufficiency, the extra glucocorticoids that would normally be supplied by the adrenals must instead be supplied through supplemental dosing. Dosing guidelines related to specific medical conditions and surgical procedures are summarized in [Table 59-1](#). For mild or febrile illness, the “3 by 3 rule” applies: Take 3 times the usual dosage for 3 days.

To ensure availability of glucocorticoids in emergencies, patients should carry an adequate supply at all times. This supply should include an injectable preparation plus an oral preparation. Furthermore, the patient should wear some form of identification (eg, Medic Alert bracelet) to inform emergency personnel about his or her glucocorticoid needs.

60.2.2.2 Addison's Disease (Primary Adrenocortical Insufficiency)

60.2.2.2.1 Clinical Presentation and Causes.

Addison's disease is characterized by weakness, emaciation, hypoglycemia, and increased pigmentation of the skin and mucous membranes. Hyperkalemia, hyponatremia, and hypotension are present as well. These symptoms result from a deficiency of glucocorticoids and mineralocorticoids that occurs secondary to adrenal atrophy. Potential causes include carcinoma, infection, and autoimmune disease.

60.2.2.2.2 Treatment.

Replacement therapy with adrenocorticoids is required. *Hydrocortisone*, which has both glucocorticoid and mineralocorticoid activity, is a drug of choice. If additional mineralocorticoid activity is needed, *fludrocortisone*, the only mineralocorticoid available, can be added to the regimen.

60.2.2.3 Secondary and Tertiary Adrenocortical Insufficiency

Secondary adrenocortical insufficiency results from decreased secretion of ACTH, while tertiary insufficiency results from decreased secretion of CRH. In both cases, adrenal secretion of glucocorticoids is diminished, whereas secretion of mineralocorticoids is usually normal. Glucocorticoid insufficiency produces a characteristic set of symptoms: hypoglycemia, malaise, loss of appetite, and reduced capacity to respond to stress. For secondary and tertiary insufficiency, treatment consists of replacement therapy with a glucocorticoid (eg, hydrocortisone). Rarely, a mineralocorticoid is needed too.

60.2.2.4 Acute Adrenal Insufficiency (Adrenal Crisis)

60.2.2.4.1 Clinical Presentation.

Acute adrenal insufficiency is characterized by hypotension, dehydration, weakness, lethargy, and GI symptoms (eg, vomiting, diarrhea). Left untreated, the syndrome progresses to shock and then death.

60.2.2.4.2 Causes.

Adrenal crisis may be brought on by adrenal failure, pituitary failure, or failure to provide patients receiving replacement therapy with adequate doses of corticosteroids. Adrenal crisis may also be triggered by abrupt withdrawal from chronic, high-dose glucocorticoid therapy.

60.2.2.4.3 Treatment.

Patients require rapid replacement of fluid, salt, and glucocorticoids. They also need glucose for energy. These needs are met by injecting 100 mg of hydrocortisone (as an IV bolus) followed by IV infusion of normal saline with dextrose. Additional hydrocortisone is given by infusion at a rate of 100 mg every 8 hours.

713

714

TABLE 59-1 Guidelines for Giving Supplemental Doses of Glucocorticoids at Times of Stress Related to Medical Conditions and Surgical Procedures

Medical Condition or Surgical Procedure	Supplemental Glucocorticoid Dosage
Minor	
Inguinal hernia repair	25 mg of hydrocortisone (or 5 mg of methylprednisolone) IV on day of procedure.
Colonoscopy	
Mild febrile illness	
Mild to moderate nausea/vomiting	
Gastroenteritis	
Moderate	
Open cholecystectomy	50–75 mg of hydrocortisone (or 10–15 mg of methylprednisolone) IV on day of procedure.
Hemicolectomy	
Significant febrile illness	Taper quickly over 1–2 days to usual replacement dose.
Pneumonia	
Severe gastroenteritis	
Severe	
Major cardiothoracic surgery	100–150 mg of hydrocortisone (or 20–30 mg of methylprednisolone) IV on day of procedure.
Whipple procedure	
Liver resection	Rapidly taper to usual replacement dose over next 1–2 days.
Pancreatitis	
Critically Ill	
Sepsis-induced hypotension or shock	50–100 mg of hydrocortisone IV every 6–8 hr (or 0.18 mg/kg/hr as continuous infusion) <i>plus</i> 50 mg of fludrocortisone until shock resolves, which may take several days to a week or more. Then gradually taper to usual replacement dose, following vital signs and serum sodium.
Adapted from Coursin DB, Wood KE: Corticosteroid supplementation for adrenal insufficiency. JAMA 287:236–240, 2002.	

60.2.2.5 Congenital Adrenal Hyperplasia

60.2.2.5.1 Clinical Presentation and Causes.

Congenital adrenal hyperplasia results from an inborn deficiency of enzymes needed for glucocorticoid synthesis. The ability to make glucocorticoids is reduced, but not eliminated. In an attempt to enhance glucocorticoid synthesis, the pituitary releases large amounts of ACTH, which act on the adrenal to cause growth of adrenal tissue (hyperplasia) and increased synthesis of glucocorticoids and androgens. (Synthesis of mineralocorticoids is minimally affected.) Frequently, stimulation of glucocorticoid synthesis may be sufficient to bring levels of cortisol up to normal. Unfortunately, the amounts of ACTH required to normalize glucocorticoid production are so large that synthesis of adrenal androgens becomes excessive. In girls, increased androgen levels cause masculinization of the external genitalia, but the ovaries, uterus, and fallopian tubes are not affected. Increased androgen levels in boys may cause precocious penile enlargement. In children of both sexes, linear growth is accelerated. However, because androgens cause premature closure of the epiphyses, adult height is usually diminished.

60.2.2.5.2 Treatment.

The objective is to ensure adequate levels of glucocorticoids while preventing excessive production of adrenal androgens. This goal is achieved through lifelong administration of glucocorticoids. *Hydrocortisone*, *dexamethasone*, and *prednisone* are preferred agents. By supplying glucocorticoids exogenously, we can suppress secretion of ACTH. As a result, the adrenals are no longer stimulated to produce excessive quantities of androgens. As a rule, ACTH suppression can be achieved with daily doses of hydrocortisone equivalent to twice the amount secreted by normal adrenals. To assess treatment, children should be monitored every 3 months for growth rate and signs of virilization.

60.3 AGENTS FOR REPLACEMENT THERAPY IN ADRENOCORTICAL INSUFFICIENCY

Patients with adrenocortical insufficiency require replacement therapy with corticosteroids. A glucocorticoid is always required; some patients require a mineralocorticoid too. The principal glucocorticoids employed are *hydrocortisone*, *dexamethasone*, and *prednisone*. *Fludrocortisone* is the only mineralocorticoid available.

Please note that classification of a drug as a “glucocorticoid” or “mineralocorticoid” may be an oversimplification. That is, a drug that we classify as a glucocorticoid may also exhibit salt-retaining (mineralocorticoid) activity. Conversely, a drug that we classify as a mineralocorticoid may also display typical glucocorticoid activity.

714

715

60.3.1 Hydrocortisone

Hydrocortisone is a synthetic steroid whose structure is identical to that of cortisol, the principal glucocorticoid produced by the adrenal cortex (see [Fig. 59-1](#)). Hydrocortisone is a preferred drug for adrenocortical insufficiency and will serve as our prototype of the glucocorticoids employed clinically. It should be noted that, despite its classification as a glucocorticoid, hydrocortisone also has mineralocorticoid actions.

60.3.1.1 Therapeutic Uses

60.3.1.1.1 Replacement Therapy.

Hydrocortisone is a preferred drug for all forms of adrenocortical insufficiency. Oral hydrocortisone is ideal for chronic replacement therapy. Parenteral administration is used for acute adrenal insufficiency and to supplement oral doses at times of stress. Because of its mineralocorticoid actions, hydrocortisone may suffice as sole therapy for adrenal insufficiency, even when salt loss is a symptom.

60.3.1.1.2 Nonendocrine Applications.

Hydrocortisone and other glucocorticoids are used to treat a broad spectrum of nonendocrine disorders, ranging from allergic reactions to inflammation to cancer. The doses required are considerably higher than those employed for replacement therapy. The use of glucocorticoids for nonendocrine diseases is discussed in [Chapter 71](#).

60.3.1.2 Adverse Effects

When given in the low doses required for replacement therapy, hydrocortisone and other glucocorticoids are devoid of adverse effects. In contrast, when taken chronically in the large doses employed to treat nonendocrine disorders, glucocorticoids are highly toxic. The adverse effects of chronic, high-dose therapy include adrenal suppression and production of Cushing's syndrome. These and other adverse effects are discussed in [Chapter 71](#).

60.3.1.3 Preparations, Dosage, and Administration.

Dosages presented here are for oral and parenteral therapy of adrenal insufficiency. Dosages for nonendocrine disorders are presented in [Chapter 71](#).

60.3.1.3.1 Oral Therapy.

Hydrocortisone base [Cortef, Hydrocortone] is used for oral therapy of chronic adrenal insufficiency. The total daily dose is 8 to 15 mg/m². For adults, this translates to 15 to 25 mg/day. In an effort to mimic normal cortisol secretion, some clinicians give the total daily dose at bedtime; others divide the daily dose, giving two-thirds in the morning and one-third in the early afternoon.

60.3.1.3.2 Parenteral Therapy.

Hydrocortisone sodium succinate [A-Hydrocort, Solu-Cortef] and *hydrocortisone sodium phosphate* [Hydrocortone Phosphate] are used for parenteral therapy. For emergency treatment, IV doses of 50 to 100 mg are employed (see [Table 59-1](#)). When IV injections can't be used, IM doses of 100 to 250 mg may be given instead.

60.3.2 Prednisone, Dexamethasone, and Cortisone

Like hydrocortisone, prednisone and dexamethasone are preferred drugs for oral therapy of chronic adrenal insufficiency. Both may be given once daily at bedtime. For dexamethasone, the dosage is 0.25 to 0.75 mg, and for prednisone the dosage is 5 to 10 mg. In addition to its use for replacement therapy, dexamethasone is used to diagnose adrenal dysfunction (see below).

Cortisone is a prodrug that undergoes conversion to hydrocortisone (its active form) in the body. The drug has both glucocorticoid and mineralocorticoid activity. For management of chronic adrenal insufficiency, the total daily oral dosage is 12 to 15 mg/m².

60.3.3 Fludrocortisone

Fludrocortisone, formerly available as Florinef, is a potent mineralocorticoid that also possesses significant glucocorticoid activity. Fludrocortisone is the only mineralocorticoid available and is the drug of choice for chronic mineralocorticoid replacement.

60.3.3.1 Therapeutic Uses.

Fludrocortisone is a preferred drug for treating Addison's disease, primary hypoaldosteronism, and congenital adrenal hyperplasia (when salt wasting is a feature of the syndrome). In most cases, fludrocortisone must be used in combination with a glucocorticoid (eg, hydrocortisone).

60.3.3.2 Adverse Effects.

Adverse effects are a direct consequence of mineralocorticoid actions. When dosage is too high, salt and water are retained in excess, while excessive amounts of potassium are lost. These effects on salt and water can result in expansion of blood volume, hypertension, edema, cardiac enlargement, and hypokalemia. Patients should be monitored for weight gain, elevation of blood pressure, and hypokalemia. If these changes occur, fludrocortisone should be temporarily withdrawn. Fluid and electrolyte imbalance should resolve spontaneously in a few days.

60.3.3.3 Preparations, Dosage, and Administration.

Fludrocortisone acetate is available in 0.1-mg tablets. The dosage is 0.1 mg/day. If excessive salt retention occurs, the daily dose should be cut to 0.05 mg.

60.4 AGENTS FOR DIAGNOSTIC TESTING OF ADRENOCORTICAL FUNCTION

60.4.1 Corticotropin and Cosyntropin

Corticotropin and cosyntropin mimic the effects of human ACTH. That is, both compounds act on the adrenal cortex to stimulate synthesis and secretion of cortisol and other adrenal corticosteroids. Corticotropin is prepared from animal pituitary glands and is nearly identical in structure to human ACTH. Cosyntropin is a synthetic polypeptide whose structure corresponds to the first 24 amino acids of ACTH. Because corticotropin, cosyntropin, and ACTH all produce equivalent stimulation of the adrenal cortex, we will use the term *ACTH* in reference to all three compounds.

60.4.1.1 Clinical Applications

ACTH is used primarily for diagnosis. For reasons discussed below, ACTH has only limited utility as a medication.

60.4.1.1.1 Diagnosis of Adrenal Insufficiency.

Suspected adrenal insufficiency can be assessed by administering ACTH and then measuring plasma cortisol content. In patients with primary adrenocortical insufficiency, ACTH is unable to promote cortisol synthesis. Hence, plasma levels of the hormone will not rise. If ACTH succeeds in elevating cortisol levels, primary adrenal insufficiency can be ruled out.

60.4.1.1.2 Therapeutic Uses.

Because of its ability to stimulate glucocorticoid production, ACTH can, in theory, be used to treat a variety of conditions that respond to glucocorticoids. In practice, however, ACTH is rarely used for treatment. Why? Because (1) responses to ACTH are highly variable; (2) ACTH cannot be given orally, whereas glucocorticoids can; (3) ACTH can produce undesired side effects by stimulating production of adrenal androgens, and possibly aldosterone; (4) since the therapeutic effects of ACTH derive from enhanced glucocorticoid production, ACTH is only useful in patients with functioning adrenal glands; and (5) there is no evidence that treatment with ACTH offers any benefit over treatment with glucocorticoids themselves. Consequently, in most cases where ACTH might be employed, it is preferable to treat with a glucocorticoid directly.

715

60.4.1.2 Preparations, Dosage, and Administration.

716

Repository corticotropin injection [H.P. Acthar Gel] is available in solution (80 units/mL) in 5-mL multidose vials. The usual dose to assess adrenal function is 80 units injected IM or subQ.

Cosyntropin [Cortrosyn] is available as a powder (0.25 mg) to be reconstituted for IM or IV administration. A dose of 0.25 mg, injected IM, is effective for assessing adrenal function in adults.

60.4.2 Dexamethasone

Dexamethasone is a synthetic steroid that has pronounced glucocorticoid properties and very little mineralocorticoid activity. The drug is used for replacement therapy, treating nonendocrine disorders, and diagnosis of adrenal dysfunction.

60.4.2.1 Overnight Dexamethasone Suppression Test

The overnight dexamethasone suppression test is used to diagnose Cushing's syndrome. The test is performed by administering 1 mg of dexamethasone at 11:00 PM followed by measurement

of plasma cortisol levels at 8:00 the following morning. In normal individuals, dexamethasone acts on the pituitary to suppress release of ACTH, thereby suppressing synthesis and release of cortisol. If the patient has Cushing's syndrome, little or no suppression of cortisol production will occur.

60.4.2.2 Prolonged Dexamethasone Suppression Test.

Once Cushing's syndrome has been diagnosed, the prolonged dexamethasone suppression test can be used to distinguish between excessive ACTH release as the cause versus dysfunction of the adrenal cortex as the cause. The test is performed as follows: (1) baseline measurement of urinary 17-hydroxycorticosteroids is made (these compounds provide an index of adrenal corticosteroid production); (2) dexamethasone is administered in 2-mg doses every 6 hours for 48 hours; and (3) 24-hour urine is collected and assessed for 17-hydroxycorticosteroids. If primary adrenal dysfunction is responsible for the symptoms of Cushing's syndrome, no suppression of 17-hydroxycorticosteroid production will occur. In contrast, if excessive ACTH release underlies Cushing's syndrome, prolonged administration of dexamethasone should produce some suppression of ACTH secretion, and therefore should cause a small but measurable reduction in urinary 17-hydroxycorticosteroids.

It should be noted that the dexamethasone suppression test is not the best method for determining the underlying cause of Cushing's syndrome. The preferred procedure is to measure plasma ACTH and cortisol content directly. If plasma cortisol levels are high and ACTH levels are normal, adrenal dysfunction is responsible for the observed signs. If levels of both ACTH and cortisol are high, excessive ACTH secretion is the likely underlying problem.

60.5 INHIBITORS OF CORTICOSTEROID SYNTHESIS

Several drugs have been employed to inhibit excessive corticosteroid synthesis in patients with Cushing's disease. Two of these—ketoconazole and aminoglutethimide—are discussed below. Although these agents can help relieve hypercortisolism, they are not a preferred form of therapy. Instead, they are used primarily as adjuncts to radiation therapy during the period required for irradiation of the pituitary to produce its effects (usually several months).

60.5.1 Ketoconazole

Ketoconazole [Nizoral] is an antifungal drug that also inhibits glucocorticoid synthesis. In fact, ketoconazole is the most effective inhibitor of glucocorticoid synthesis available. In patients with Cushing's syndrome, the drug may be used as an adjunct to surgery or radiation, but not as primary treatment. The dosage for suppression of steroid synthesis is 600 to 800 mg/day—much

higher than doses employed for antifungal therapy. At these doses, ketoconazole can cause significant liver dysfunction. The basic pharmacology of ketoconazole is discussed in [Chapter 91](#) (Antifungal Agents).

60.5.2 Aminoglutethimide

Aminoglutethimide [Cytadren] blocks the conversion of cholesterol to pregnenolone, the first step in the synthesis of all adrenal steroids. As a result, production of glucocorticoids, mineralocorticoids, and androgens declines.

Aminoglutethimide has been employed as temporary therapy to decrease excessive corticosteroid production in patients awaiting more definitive therapy (eg, surgery). Duration of treatment is seldom greater than 3 months. In patients with adrenal adenoma, adrenal carcinoma, and ectopic ACTH-secreting tumors, morning plasma levels of cortisol are reduced by about 50%.

Aminoglutethimide does not affect the underlying disease process. Hence, if therapy is stopped, overproduction of adrenal corticoids will resume.

Untoward effects are common. The most frequent are drowsiness, nausea, anorexia, and morbilliform rash. Additional effects include headache, dizziness, hematologic abnormalities, hypothyroidism, muscle pain, and fever. Masculinization may occur in females. Precocious sexual development may occur in males.

Aminoglutethimide [Cytadren] is available in 250-mg tablets for oral use. The initial dosage is 250 mg every 6 hours. If steroid synthesis remains excessive, dosage may be gradually increased, but should not exceed 2 gm/day.

60.5.2.1

KEY POINTS

- The adrenal cortex produces three classes of steroid hormones: glucocorticoids, mineralocorticoids, and androgens.
- Glucocorticoids influence the metabolism of carbohydrates, proteins, and fats. In addition, they affect skeletal muscle, the cardiovascular system, and the CNS. At times of stress, glucocorticoids are essential for survival.
- Synthesis and release of glucocorticoids is regulated by a negative feedback loop involving CRH from the hypothalamus, ACTH from the pituitary, and cortisol from the adrenal cortex.

- Aldosterone, the major mineralocorticoid, acts on the kidney to promote retention of sodium and water and excretion of potassium and hydrogen. Aldosterone also acts directly on the heart and blood vessels, causing harm when its levels are high.
- Glucocorticoid excess causes Cushing's syndrome.
- The principal treatment for Cushing's syndrome is surgical removal of the adrenals (if adrenal adenoma or carcinoma is the cause) or part of the pituitary (if pituitary adenoma is the cause).
- Ketoconazole can be used to suppress synthesis of adrenal steroids in patients with Cushing's syndrome. However, this drug is employed only as an adjunct to surgery or radiation.
- Adrenal insufficiency causes Addison's disease.
- Adrenal insufficiency is treated by replacement therapy with glucocorticoids (eg, hydrocortisone). Fludrocortisone, a pure mineralocorticoid, may be added if the mineralocorticoid actions of hydrocortisone are inadequate.
- In patients with adrenal insufficiency, it is absolutely essential to increase glucocorticoid doses at times of stress (eg, surgery, infection, trauma). Failure to do so may be fatal.
- When used in the low (physiologic) doses needed for replacement therapy, glucocorticoids have no adverse effects. In contrast, when used chronically in the high (pharmacologic) doses needed to treat nonendocrine diseases (eg, arthritis), glucocorticoids can cause severe adverse effects (see [Chapter 71](#)).
- Corticotropin and cosyntropin are drugs that act like ACTH (ie, they stimulate the synthesis and release of corticosteroids).
- Corticotropin and cosyntropin are used only for diagnosis of adrenal insufficiency—not for treatment.

716

717

60.5.2.2 Summary of Major Nursing Implications*

60.5.2.2.1 GLUCOCORTICOIDS: HYDROCORTISONE AND CORTISONE

The nursing implications summarized here apply only to the use of glucocorticoids for *replacement therapy*. Nursing implications that apply to use of glucocorticoids for *nonendocrine disorders* are summarized in [Chapter 71](#).

60.5.2.2... Use in Addison's Disease

60.5.2.2... Administration

Instruct patients to follow the prescribed dosing schedule. Some clinicians recommend taking the entire daily dose at bedtime; others recommend dividing the daily dose, taking two-thirds in the morning and one-third in the afternoon.

Make certain the patient understands that replacement therapy must continue lifelong.

60.5.2.2... Emergency Preparedness

Warn patients that dosage must be increased at times of stress (eg, infection, surgery, trauma). For mild or febrile illness, the “3 by 3 rule” applies: Take 3 times the usual dosage for 3 days. Advise the patient to carry an emergency supply of glucocorticoids—oral and injectable—at all times. Advise patients to wear identification (eg, Medic Alert bracelet) to inform emergency medical personnel of their glucocorticoid requirements.

60.5.2.2... Monitoring

Determine electrolyte and glucocorticoid levels at baseline and periodically thereafter.

60.5.2.2... Use in Congenital Adrenal Hyperplasia

To assess therapy, monitor the child at 3-month intervals for signs of excess androgen production (eg, excessive growth rate, virilization in girls, precocious penile enlargement in boys). Suppression of these effects indicates success.

60.5.2.2...

Minimizing Adverse Effects

Excessive doses can produce symptoms of Cushing's syndrome. Observe the patient for signs of Cushing's syndrome and notify the prescriber if these develop.

60.5.2.2.2

FLUDROCORTISONE (A MINERALOCORTICOID)

60.5.2.2...

Route

Oral.

60.5.2.2...

Minimizing Adverse Effects

Excessive doses cause retention of sodium and water and excessive excretion of potassium, resulting in expansion of blood volume, hypertension, cardiac enlargement, edema, and hypokalemia. Evaluate patients periodically for clinical status and electrolyte levels. **Inform patients about signs of salt and water retention (eg, unusual weight gain, swelling of the feet or lower legs) and hypokalemia (eg, muscle weakness, irregular heartbeat), and instruct them to notify the prescriber if these occur.**

Treatment consists of temporary withdrawal of fludrocortisone; fluid and electrolyte balance should normalize within days.

* Patient education information is highlighted as **blue text**.

⁶¹CHAPTER 60 Estrogens and Progestins: Basic Pharmacology and Noncontraceptive Applications

MARILYNN FREDERIKSEN

RICH LEHNE

Estrogens and progestins are hormones with multiple actions: They promote female maturation, and help regulate the ongoing activity of female reproductive organs. In addition, estrogens affect bone mineralization and lipid metabolism. The principal endogenous estrogen is estradiol. The principal endogenous progestational hormone is progesterone. Both hormones are produced by the ovaries. During pregnancy, large amounts are produced by the placenta. In addition, small amounts of estrogens and progestins are produced in peripheral tissues.

Clinical applications of the female sex hormones fall into two major categories: contraceptive and noncontraceptive applications. In this chapter, we focus on noncontraceptive uses. Contraception is discussed in [Chapter 61](#). The principal noncontraceptive application of estrogens and progestins is postmenopausal hormone replacement therapy (HRT): estrogens are given to replace estrogens that are lost following menopause; progestins are given to oppose estrogen-mediated stimulation of the endometrium.

^{61.1}THE MENSTRUAL CYCLE

Because much of the clinical pharmacology of the estrogens and progestins is related to their actions during the menstrual cycle, understanding the menstrual cycle is central to understanding these hormones. Accordingly, we begin by reviewing the menstrual cycle. The anatomic and hormonal changes that take place during the cycle are summarized in [Figure 60-1](#). As indicated, the first half of the cycle (days 1 through 14) is called the *follicular phase*, and the second half is called the *luteal phase*. One full cycle typically takes 28 days.

^{61.1.1} Ovarian and Uterine Events.

The menstrual cycle consists of a coordinated series of ovarian and uterine events. In the ovary, the following sequence occurs: (1) several ovarian follicles ripen; (2) one of the ripe follicles ruptures, causing ovulation; (3) the ruptured follicle evolves into a corpus luteum; and (4) if fertilization does not occur, the corpus luteum atrophies. As these ovarian events are taking place, parallel events take place in the uterus: (1) while ovarian follicles ripen, the endometrium prepares for nidation (implantation of a fertilized ovum) by increasing in thickness and vascularity; (2)

following ovulation, the uterus continues its preparation by increasing secretory activity; and (3) if nidation fails to occur, the thickened endometrium breaks down, causing menstruation, and the cycle begins anew.

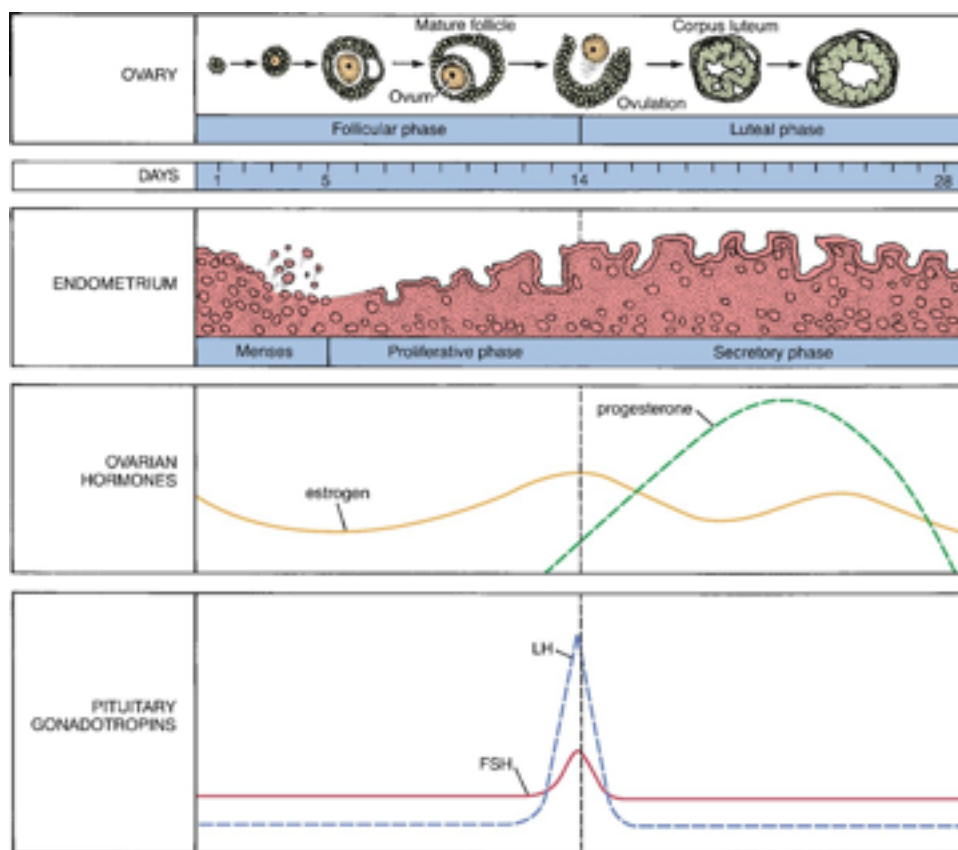

61.1.2 The Roles of Estrogens and Progesterone.

The uterine changes that occur during the cycle are brought about under the influence of estrogens and progesterone produced by the ovaries. During the first half of the cycle, estrogens are secreted by the maturing ovarian follicles. As suggested by [Figure 60-1](#), these estrogens act on the uterus to cause proliferation of the endometrium. At midcycle, one of the ovarian follicles ruptures and then evolves into a corpus luteum. For most of the second half of the cycle, estrogens and progesterone are produced by the newly formed corpus luteum. These hormones maintain the endometrium in its hypertrophied state. At the end of the cycle, the corpus luteum atrophies,

718

719

Figure 60-1 The menstrual cycle: anatomic and hormonal changes.(FSH = follicle-stimulating hormone, LH = luteinizing hormone.)

causing production of estrogens and progesterone to decline. In response to the diminished supply of ovarian hormones, the endometrium breaks down.

61.1.3 The Role of Pituitary Hormones.

Two anterior pituitary hormones—follicle-stimulating hormone (FSH) and luteinizing hormone (LH)—play central roles in regulating the menstrual cycle. During the first half of the cycle, FSH acts on the developing ovarian follicles, causing them to mature and secrete estrogens. The resultant rise in estrogen levels exerts a negative feedback influence on the pituitary, thereby suppressing further FSH release. At midcycle, LH levels rise abruptly (see [Fig. 60-1](#)). This LH surge causes the dominant follicle to swell rapidly, burst, and release its ovum into the abdominal cavity. Following ovulation, the ruptured follicle becomes a corpus luteum and, under the influence of LH, begins to secrete progesterone.

From the foregoing, it is clear that precisely timed alterations in the secretion of FSH and LH are responsible for coordinating the structural and secretory changes that occur throughout the menstrual cycle. The mechanisms that regulate secretion of FSH and LH are complex and beyond the scope of this book.

61.2 ESTROGENS

61.2.1 Biosynthesis and Elimination

61.2.1.1 Females.

In premenopausal women, the ovary is the principal source of estrogen. During the follicular phase of the menstrual cycle, estrogens are synthesized by ovarian follicles; during the luteal phase, estrogens are synthesized by the corpus luteum. The major estrogen produced by the ovaries is *estradiol*. In the periphery, some of the estradiol secreted by the ovaries is converted into *estrone* and *estriol*, hormones that are less potent than estradiol itself. Estrogens are eliminated by a combination of hepatic metabolism and urinary excretion.

During pregnancy, large quantities of estrogens are produced by the placenta. Excretion of these hormones results in high levels of estrogens in the urine. (The urine of pregnant mares is extremely rich in estrogens and serves as a commercial source of these hormones.)

719

720

61.2.1.2 Males.

Estrogen production is not limited to females. In the human male, small amounts of testosterone are converted into estradiol and estrone by the testes. Enzymatic conversion of testosterone in peripheral tissues (eg, liver, fat, skeletal muscle) results in additional estrogen production.

61.2.2 Mechanism of Action

Unlike most regulatory molecules, which act through receptors on the cell surface, estrogen acts primarily through receptors in the cell nucleus. Hence, to produce its effects, estrogen must diffuse into cells, migrate to the nucleus, and then bind with an estrogen receptor (ER). The estrogen-ER complex then binds with an *estrogen response element* on a target gene, thereby altering the rate of gene transcription. It is important to note that not all ERs are found in the nucleus: some ERs are found on cell membranes. Activating these surface receptors produces a rapid response—more rapid than can be produced by activating nuclear receptors.

There are two forms of ERs, termed *ER alpha* and *ER beta*. ER alpha is highly expressed in the vagina, uterus, ovaries, mammary glands, vascular epithelium, and hypothalamus. ER beta is expressed in the ovary and prostate, and to a lesser extent in the lungs, brain, bones, and blood vessels. Some cells have both types of ER receptor.

61.2.3 Physiologic and Pharmacologic Effects

61.2.3.1 Effects on Primary and Secondary Sex Characteristics of Females

Estrogens support the development and maintenance of the female reproductive tract and secondary sex characteristics. These hormones are required for the growth and maturation of the uterus, vagina, fallopian tubes, and breasts. In addition, estrogens direct pigmentation of the nipples and genitalia.

Estrogens have a profound influence on physiologic processes related to reproduction. During the follicular phase of the menstrual cycle, estrogens promote (1) ductal growth in the breast, (2) thickening and cornification of the vaginal epithelium, (3) proliferation of the uterine epithelium, and (4) copious secretion of thickened mucus from endocervical glands. In addition, estrogens increase vaginal acidity (by promoting local deposition of glycogen, which is then acted upon by lactobacilli and corynebacteria to produce lactic acid). At the end of the menstrual cycle, a decline in estrogen levels can bring on menstruation. However, it is the fall in progesterone levels at the end of the cycle that normally causes breakdown of the endometrium

and resultant menstrual bleeding. Following menstruation, estrogens promote endometrial restoration.

During pregnancy, the placenta produces estrogen in large amounts. This estrogen stimulates uterine blood flow and growth of uterine muscle. In addition, it acts on the breast to continue ductal proliferation. However, final transformation of the breast for milk production requires the combined influence of estrogen, progesterone, and human placental lactogen.

61.2.3.2 Metabolic Actions

Estrogens can affect various nonreproductive tissues. Important among these are bone, blood vessels, the heart, liver, and central nervous system (CNS).

61.2.3.2.1 Bone.

Estrogens have a positive effect on bone mass. Under normal circumstances, bone undergoes continuous remodeling, a process in which bone mineral is resorbed and deposited in equal amounts. The principal effect of estrogens on the process is to block bone resorption, although estrogens may also promote mineral deposition.

During puberty, the long bones grow rapidly under the combined influence of growth hormone, adrenal androgens, and *low* levels of ovarian estrogens. When estrogen levels grow high enough, they promote epiphyseal closure, and thereby bring linear growth to a stop.

After menopause, more bone is resorbed than is deposited, and hence bone mass declines. Why does this occur? Because the braking influence of estrogen on bone resorption is gone. Although estrogen replacement can help preserve bone mass, other drugs—raloxifene, bisphosphonates, calcitonin, and teriparatide—are safer, and hence are preferred (see [Chapter 74](#), Drugs Affecting Calcium Levels and Bone Mineralization).

61.2.3.2.2 Cholesterol.

Estrogens have favorable effects on cholesterol levels: levels of low-density lipoprotein (LDL) cholesterol are reduced, while levels of high-density lipoprotein (HDL) cholesterol are elevated. These beneficial effects result from actions in the liver. There is speculation, but no proof, that effects on cholesterol metabolism may explain the low incidence of myocardial infarction in premenopausal women.

Estrogens alter cholesterol excretion. Specifically, they increase the amount of cholesterol in bile and decrease the amount of bile acids in bile.

61.2.3.2.3 Blood Coagulation.

Estrogens both promote and suppress blood coagulation. Estrogens promote coagulation by (1) increasing levels of coagulation factors (eg, factors II, VII, IX, X, and XII) and by (2) decreasing levels of factors that suppress coagulation (eg, antithrombin). Estrogens suppress coagulation by increasing the activity of factors that promote breakdown of fibrin, a protein that reinforces blood clots. The net effect—increased or decreased coagulation—may be determined by a hereditary defect in one of these targets.

61.2.4 Clinical Pharmacology

61.2.4.1 Adverse Effects

The principal concerns with estrogen therapy are the potential for endometrial hyperplasia, endometrial cancer, breast cancer, and cardiovascular events. Other adverse effects are more of a nuisance than a concern.

61.2.4.1.1 Endometrial Hyperplasia and Carcinoma.

Prolonged use of estrogens *alone* by postmenopausal women is associated with an increased risk of endometrial carcinoma. However, when estrogens are used in combination with a progestin, there is little or no risk of uterine cancer. Why? When used alone, estrogens act on the endometrium to cause proliferation and hyperplasia. In a few cases, hyperplasia progresses to carcinoma. Concurrent use of a progestin greatly reduces cancer risk by antagonizing estrogen-mediated endometrial proliferation and by reversing hyperplasia. Accordingly, whenever estrogens are given to postmenopausal women who have an intact uterus, progestins should be given as well. During the first 3 to 6 months of treatment, about 30% of women experience benign, irregular bleeding. If bleeding persists, or if it starts after prolonged therapy, the possibility of endometrial carcinoma should be evaluated (eg, by endometrial biopsy).

61.2.4.1.2 Breast Cancer.

Does estrogen use *cause* breast cancer? Yes—but primarily in *postmenopausal* women who are using estrogen *combined* with a progestin. In *younger* women, and in women using estrogen *without* a progestin, the risk, if any, is very low. Results of the Women's Health Initiative (WHI) indicate that treatment of postmenopausal women with estrogen plus a progestin produces a small increase in the risk of breast cancer—but treatment with estrogen

720

721

alone apparently does not (see below under *Menopausal Hormone Replacement Therapy*). In contrast, the Women's Contraceptive and Reproductive Experience study has shown that, when estrogen plus a progestin is used in younger women for contraception, there is *no* increase in the risk of breast cancer (see [Chapter 61](#), Birth Control). How can we explain these contradictory results? The best explanation is that risk is a function of age—being relatively high in older women and very low in younger women. In either population—old or young—the risk of breast cancer from estrogen *alone* has not been established. Of note, after the results of the WHI were published, there was a dramatic decline in postmenopausal estrogen use, followed by a significant decline in the incidence of breast cancer. This observation reinforces the conclusion that postmenopausal hormone replacement therapy increases breast cancer risk.

In addition to *causing* breast cancer, estrogens can *promote* the growth of a cancer that already exists, provided the cancer is estrogen receptor–positive. Accordingly, estrogen-dependent breast cancer must be ruled out before initiating estrogen treatment. Furthermore, because all women are at potential risk for breast cancer, and because estrogens may slightly increase that risk, women taking estrogens should have a yearly breast exam by a health professional. For women older than 40, an annual mammogram is recommended.

61.2.4.1.3 Ovarian Cancer.

In postmenopausal women, therapy with estrogen alone—but not with estrogen plus a progestin—increases the risk of ovarian cancer. Details are presented below under *Menopausal Hormone Replacement Therapy*.

61.2.4.1.4 Cardiovascular Events.

In *postmenopausal* women, estrogen, used either alone or combined with a progestin, increases the risk of pulmonary embolism, venous thromboembolism (VTE), and stroke. In addition, estrogen *alone* increases the risk of myocardial infarction. The risk of VTE is greatest during the first years of treatment, and is greater with oral dosing than with transdermal or intravaginal dosing. These effects are discussed further under *Menopausal Hormone Replacement Therapy*.

In *premenopausal* women, use of combination estrogen/progestin oral contraceptives increases the risk of VTE. Although the risk is dose dependent, even low-dose formulations cause an estimated 15 to 30 cases per 100,000 woman-years of use. The cardiovascular risk associated with oral contraceptives is discussed further in [Chapter 61](#).

61.2.4.1.5 Nausea.

Nausea is the most frequent undesired response to the estrogens. Fortunately, nausea diminishes with continued use, and is rarely so severe as to necessitate treatment cessation. Nausea can be minimized by administering estrogens with food, initiating therapy at low doses, and, when appropriate, using a topical estrogen formulation (eg, gel, spray, patch, vaginal ring).

61.2.4.1.6 Adverse Effects from Use During Pregnancy.

Most estrogens are safe when used during pregnancy. However, there is one important exception: *diethylstilbestrol* (DES), a nonsteroidal estrogen. Between 1948 and 1971, DES was used extensively during pregnancy to prevent miscarriage. Sadly, this use caused clear cell adenocarcinoma (CCA) of the vagina in many women who were exposed to DES during fetal life. What about other estrogens? Recent studies indicate there is no risk of birth defects when pregnancy occurs inadvertently while a woman is taking an estrogen-based oral contraceptive. These data suggest that fetal harm associated with DES does not apply to other estrogens. DES is no longer available in the United States.

61.2.4.1.7 Other Adverse Effects.

Estrogens have been associated with *gallbladder disease*, *jaundice*, *headache*, and *chloasma* (patchy brown facial pigmentation that may develop in pregnancy). Use during menopause may produce or uncover gallbladder disease. Jaundice may develop in women with pre-existing liver dysfunction, especially those who experienced cholestatic jaundice of pregnancy. Estrogens can increase the risk of headache, especially migraine.

61.2.4.2 Therapeutic Uses

Estrogens have contraceptive and noncontraceptive applications. In this chapter, discussion is limited to the noncontraceptive applications. Use of estrogens for contraception is discussed in [Chapter 61](#).

61.2.4.2.1 Menopausal Hormone Replacement Therapy.

Hormone therapy in postmenopausal women is the most common noncontraceptive use of estrogens. This use is discussed separately below.

61.2.4.2.2 Female Hypogonadism.

In the absence of ovarian estrogens, pubertal transformation will not take place. Causes of estrogen deficiency include primary ovarian failure, hypopituitarism, bilateral oophorectomy (ie, removal of both ovaries), and Turner's syndrome (a genetic disorder that impairs gonadal function). In girls with estrogen insufficiency, puberty can be induced by administering exogenous estrogens. This treatment promotes breast development, maturation of the reproductive organs, and development of pubic and axillary hair. To simulate normal patterns of estrogen secretion, the regimen should consist of continuous low-dose therapy (for about a year) followed by cyclic administration of estrogen in higher doses.

61.2.4.2.3 Acne.

Estrogens, in the form of oral contraceptives, can help control acne. Treatment is limited to females at least 15 years old who want contraception. The use of estrogen for acne is discussed in [Chapter 104](#) (Drugs for the Skin).

61.2.4.3 Routes of Administration.

61.2.4.3.1 Oral.

Because of convenience, the oral route is used more than any other. The most active estrogenic compound—estradiol—is available alone and in combination with progestins. Estrogen itself is available in conjugated and esterified forms.

61.2.4.3.2 Transdermal.

Transdermal estradiol is available in four formulations: an emulsion [Estrasorb], a spray [Evamist], gels [EstroGel, Elestrin, Divigel], and transdermal patches [Alora, Climara, Esclim, Estraderm, Menostar, Vivelle]. The emulsion is applied once daily to the top of both thighs and the back of both calves. The spray is applied once daily to the forearm, never to the breasts or vaginal area. The gel is applied once daily to one arm, from the shoulder to the wrist. The patches are applied to the skin of the trunk (but not the breasts), allowing estrogen to be absorbed through the skin and then directly into the bloodstream. Compared with oral formulations, the transdermal formulations have three advantages: (1) the total dose of estrogen is greatly reduced (because the liver is bypassed), (2) serum levels more closely resemble those seen in healthy premenopausal women, and (3) there is less nausea and

vomiting. Rates of estrogen absorption range from 14 to 60 mcg/24 hr, depending on the product employed.

61.2.4.3.3 Intravaginal.

Estrogens for intravaginal administration are available as tablets, creams, and vaginal rings. The tablets [Vagifem], creams [Estrace Vaginal, Premarin Vaginal, Ogen Vaginal], and one of the two available vaginal rings [Estring] are used only for local effects, primarily treatment of vulval and vaginal atrophy associated with menopause. The other vaginal ring [Femring] is used for systemic effects (eg, control of hot flushes and night sweats) in addition to local effects (eg, treatment of vulval and vaginal atrophy).

61.2.4.3.4 Parenteral.

Although estrogens are formulated for intravenous and intramuscular administration, use of these routes is rare. Intravenous administration is generally limited to acute, emergency control of heavy uterine bleeding.

61.3 SELECTIVE ESTROGEN RECEPTOR MODULATORS (SERMs)

SERMs are drugs that activate estrogen receptors in some tissues and block them in others. These drugs were developed in an effort to provide the benefits of estrogen (eg, protection against osteoporosis, maintenance of the urogenital tract, reduction of LDL cholesterol) while avoiding its drawbacks (eg, promotion of breast cancer, uterine cancer, and thromboembolism). Three SERMs are available: tamoxifen [Nolvadex], toremifene [Fareston], and raloxifene [Evista]. None of these offers all of the benefits of estrogen, and none avoids all of the drawbacks.

Tamoxifen was the first SERM to be widely used. By blocking estrogen receptors, tamoxifen (and its active metabolite, endoxifen) can inhibit cell growth in the breast. As a result, the drug is used extensively to prevent and treat breast cancer. Unfortunately, blockade of estrogen receptors also produces hot flushes. By activating estrogen receptors, tamoxifen protects against osteoporosis and has a favorable effect on serum lipids. However, receptor activation also increases the risk of endometrial cancer and thromboembolism. The pharmacology of tamoxifen and toremifene (a close relative of tamoxifen) is discussed at length in [Chapter 102](#) (Anticancer Drugs II).

Raloxifene is very similar to tamoxifen. The principal difference is that raloxifene does not activate estrogen receptors in the endometrium, and hence does not pose a risk of uterine cancer. Like tamoxifen, raloxifene protects against breast cancer and osteoporosis, promotes thromboembolism, and induces hot flushes. Raloxifene is approved only for prevention and treatment of osteoporosis,

and for prevention of breast cancer in high-risk women. Raloxifene is discussed at length in [Chapter 74](#) (Drugs Affecting Calcium Levels and Bone Mineralization).

61.4 PROGESTINS

Progestins are compounds that have actions like those of progesterone, the principal endogenous gestational hormone. As their name implies, the progestins act prior to gestation to prepare the uterus for implantation of a fertilized ovum. In addition, progestins help maintain the uterus throughout pregnancy.

61.4.1 Biosynthesis

Progesterone is produced by the ovaries *and* the placenta. Ovarian production occurs during the second half of the menstrual cycle. During this period, progesterone is synthesized by the corpus luteum, in response to LH released from the anterior pituitary. If implantation of a fertilized ovum does not occur, progesterone production by the corpus luteum ceases, and menstrual flow begins. However, if implantation *does* take place, the developing trophoblast will produce its own luteotropic hormone—human chorionic gonadotropin (hCG)—that will stimulate the corpus luteum to continue making progesterone. For the first 7 weeks of gestation, the placenta depends entirely on progesterone from the corpus luteum. However, between weeks 7 and 10, production of progesterone is shared between the corpus luteum and placenta. After 10 weeks of gestation, progesterone made by the placenta is sufficient to support pregnancy, and hence ovarian progesterone production declines. Placental synthesis of progesterone and estrogen continues throughout the pregnancy.

61.4.2 Mechanism of Action

As with estrogen, receptors for progesterone are found in the cell nucleus. Hence, to produce an effect, progesterone must diffuse across the cell membrane, migrate to the nucleus, and then bind with a progesterone receptor (PR). The progesterone-PR complex then binds with a *progesterone regulatory element* on a target gene, thereby rapidly increasing gene transcription. As with estrogen, there are two types of receptors for progesterone, designated PR-A and PR-B. In general, the *stimulatory* actions of progesterone are mediated by PR-B, whereas *inhibitory* actions are mediated by PR-A.

61.4.3 Physiologic and Pharmacologic Effects

61.4.3.1 Effects During the Menstrual Cycle.

Progesterone secreted during the second half of the menstrual cycle converts the endometrium from a proliferative state into a secretory state. If implantation does not occur, progesterone production by the corpus luteum declines. The resultant fall in progesterone levels is the principal stimulus for the onset of menstruation.

In addition to affecting the endometrium, progesterone affects the endocervical glands, breasts, body temperature, respiration, and mood. Under the influence of progesterone, secretions from endocervical glands become scant and viscous. (In contrast, estrogen makes these secretions profuse and watery.) In addition, progesterone causes the epithelium of the breast to divide and grow. Actions in the CNS may cause depression and sleepiness. By increasing the sensitivity of the respiratory center to CO_2 , progesterone causes the partial pressure of carbon dioxide (pCO_2) in blood to fall. At midcycle, when ovulation occurs, progesterone raises body temperature by 0.6°C (1°F).

61.4.3.2 Effects During Pregnancy.

As noted, progesterone levels increase during pregnancy. These high levels suppress contraction of *uterine smooth muscle*, and thereby help sustain pregnancy. Unfortunately, progesterone also suppresses contraction of *GI smooth muscle*, which leads to prolonged transit time and constipation. In the *breast*, progesterone promotes growth and proliferation of alveolar tubules (acini), the structures that produce milk. Metabolic effects include suppression of arterial pCO_2 , altered serum bicarbonate content, and elevation of serum pH. Lastly, progesterone may help suppress the maternal immune system, thereby preventing immune attack on the fetus.

61.4.3.3 Other Effects.

Pharmacologic doses of progesterone can suppress release of pituitary gonadotropins (LH and FSH). This prevents follicular maturation and ovulation. Also, individual progestin preparations display varying degrees of estrogenic, androgenic, and anabolic activity.

61.4.4 Clinical Pharmacology

61.4.4.1 Adverse Effects

61.4.4.1.1 Teratogenic Effects.

High-dose therapy during the first 4 months of pregnancy has been associated with an increased incidence of birth defects (limb reductions, heart defects, masculinization of the female fetus). Accordingly, use of progestins during early pregnancy is not recommended.

61.4.4.1.2 Gynecologic Effects.

When used continuously for birth control, progestins greatly decrease production of cervical mucus and cause involution of the endometrial layer. Effects on the endometrium lead to spotting, breakthrough bleeding, and irregular menses.

61.4.4.1.3 Breast Cancer.

Progestins appear to increase the risk of breast cancer from estrogens (see below under *Menopausal Hormone Replacement Therapy*).

722

61.4.4.1.3.1 BOX 60-1 Special Interest Topic

723

61.4.4.1.3.1.1 PREMENSTRUAL SYNDROME (PMS)

PMS consists of a constellation of psychologic and physical symptoms that consistently and predictably develop during the luteal phase of the menstrual cycle, and then resolve a few days after the onset of menses. Common psychologic symptoms include irritability, depression, mood lability, crying spells, and social withdrawal. Common physical symptoms include breast tenderness, abdominal bloating, and increased appetite, especially for carbohydrates. Additional symptoms are listed in the table below. The psychologic symptoms are much more disabling than the physical symptoms. PMS is among the most common disorders in women of reproductive age.

Common Symptoms of PMS

Affective Symptoms	Somatic Symptoms
<ul style="list-style-type: none">• Irritability• Depression• Mood lability: alternating sadness and anger• Hypersensitivity to trivial events• Loneliness and social withdrawal• Angry outbursts• Confusion	<ul style="list-style-type: none">• Breast tenderness• Abdominal bloating• Ankle edema• Weight gain (from water retention)• Headache• Backache• Constipation or diarrhea

61.4.4.1.3.1.1.1

Etiology

Although PMS is clearly of neuroendocrine origin, the exact cause has not been established. At one time, abnormal hormone levels were suspected. However, we now know that hormone levels in women who experience PMS are identical to those in women who do not. Hence abnormal levels can't be the cause. Nonetheless, because symptoms are synchronized with the menstrual cycle, it would seem that hormones are in some way involved—even if levels *are* normal. One reasonable hypothesis is that women who experience PMS are sensitive to hormonal changes in a way that other women are not. Because of this altered sensitivity, normal hormonal changes are able to trigger PMS. Current evidence points to altered responsiveness in the brain. In particular, the ability of selective serotonin reuptake inhibitors (SSRIs) to relieve psychologic symptoms—as well as some physical symptoms—suggests an abnormality in circuits that use serotonin as their transmitter.

61.4.4.1.3.1.1.2

Diagnosis

To make a diagnosis of PMS, symptoms must be *intense* and *intermittent*. That is, symptoms should be prominent in the luteal phase of the menstrual cycle, and minimal or absent in the follicular phase. Practically all women experience some PMS-like symptoms in the late luteal phase. However, in the majority of women, symptoms are relatively mild, and hence do not constitute PMS. Only 20% to 30% of women have symptoms that are strong enough to be considered PMS. An even smaller number—3% to 5%—have symptoms that constitute *premenstrual dysphoric*

disorder (PMDD), an especially severe form of PMS described in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition*.

Timing of symptoms is critical. On days 4 through 12 of the menstrual cycle, symptoms should be absent—or at least no greater than would be expected in the population at large. Symptoms should begin following ovulation (around day 14 of the cycle) and then become most intense in the fourth week of the cycle, that is, late in the luteal phase. To make a diagnosis, total symptom severity in the fourth week must be at least twice the intensity of any symptoms present in the second week. Daily charting of symptoms for at least two menstrual cycles is needed to establish whether symptoms occur in the appropriate pattern and are of sufficient intensity to permit a diagnosis of PMS or PMDD.

When diagnosing PMS, it is essential to rule out conditions whose symptoms can intensify in the late luteal phase or menstrual phase, a phenomenon known as “menstrual magnification.” Common conditions subject to menstrual magnification include depression, migraine headaches, chronic fatigue syndrome, and irritable bowel syndrome. The differential diagnosis is relatively easy to make, in that, unlike PMS, these disorders are symptomatic *throughout* the cycle—they simply can become more intense as menstruation approaches.

61.4.4.1.3.1.1.3

Treatment Guidelines

In 2000, the American College of Obstetricians and Gynecologists (ACOG) issued guidelines for the diagnosis and treatment of PMS (“Clinical Management Guidelines for Premenstrual Syndrome,” *ACOG Practice Bulletin* No. 15). For women with a positive diagnosis of PMS, the guidelines recommend stepwise intervention, beginning with lifestyle changes and then progressing to drug therapy if needed.

For women with mild symptoms, lifestyle changes may provide relief. Regular aerobic exercise can reduce depressive symptoms and has numerous other health benefits. Eating foods rich in complex carbohydrates can enhance mood and reduce food cravings. Getting enough sleep can also help. In addition, small clinical trials have shown that dietary supplements (200 to 400 mg of magnesium/day and 1200 mg of calcium/day) can improve symptom scores.

If lifestyle changes fail to suppress symptoms, drug therapy may be needed. Two types of drugs are recommended: SSRIs and ovulation suppressants. SSRIs are the

initial drugs of choice, especially for women with severe PMS. According to the guidelines, ovulation suppressants should be used only if SSRIs are inadequate.

Agents that are *ineffective* should be avoided. Among these are progesterone and various supplements, including black cohosh, red clover, dong quai, and evening primrose oil. Progesterone has been used for years on the theory that it may produce a favorable hormonal balance. However, we now know that progesterone is no more effective than placebo, and in fact may exacerbate some symptoms (bloating, breast tenderness, and emotional lability).

723

724

61.4.4.1.3.1.1.4

Selective Serotonin Reuptake Inhibitors

SSRIs such as fluoxetine [Prozac, Sarafem] and sertraline [Zoloft] are the most effective treatment for the psychologic symptoms of PMS or PMDD, and hence are considered first-line therapy. These drugs, which were developed as antidepressants (see [Chapter 32](#)), can significantly reduce depression, anger, irritability, tension, dysphoria, fatigue, and confusion. Success rates range from 50% to 75%. Moreover, benefits develop quickly—within 2 to 3 days, compared with 2 to 4 weeks when SSRIs are used for depression. Why were SSRIs ever tried for PMS? Because the psychologic symptoms of PMS are much like those of depression. Interestingly, although SSRIs are most effective at reducing affective symptoms of PMS, they can also reduce physical symptoms, such as breast tenderness, bloating, and headaches.

In clinical trials, about 15% of women discontinued treatment because of side effects. The most prominent are sexual dysfunction (anorgasmia and decreased libido), sleep disturbances (insomnia or hypersomnia), and GI distress (nausea and diarrhea). If side effects are intolerable, dosage can be reduced.

Most research on using SSRIs for PMS has been conducted with either fluoxetine or sertraline. However, other SSRIs—paroxetine [Paxil], fluvoxamine [Luvox], citalopram [Celexa], and escitalopram [Lexapro]—are probably effective too. Hence, if a patient fails to respond to fluoxetine or sertraline, a trial with a different SSRI may be merited. It should be noted that, although the SSRIs are highly effective in PMS, none of these drugs is *approved* for PMS. However, three SSRIs—fluoxetine, sertraline, and paroxetine—are approved for PMDD.

With fluoxetine, sertraline, and paroxetine, dosing may be done either (1) every day throughout the menstrual cycle or (2) just during the luteal phase, the time when symptoms are present. With the second option, dosing is begun on day 14 of the cycle

and stopped on day 2 of the following cycle (ie, the day after menstruation begins). The intermittent schedule has two obvious advantages: it's cheaper than continuous dosing and side effects are minimized. Hence, unless a woman has depression in addition to PMS, intermittent dosing may be preferred. Specific dosages for three SSRIs are as follows:

- *Fluoxetine*—The usual dosage is 20 mg/day, given continuously or just during the luteal phase.
- *Sertraline*—The usual dosage is 50 to 150 mg/day, given continuously or just during the luteal phase.
- *Paroxetine*—The usual dosage is 12.5 to 25 mg/day, given continuously or just during the luteal phase.

61.4.4.1.3.1.1.5

Ovulation Suppressants

Two classes of drugs—gonadotropin-releasing hormone (GnRH) agonists and oral contraceptives (OCs)—can suppress ovulation, and may thereby suppress both menstrual cycling and associated symptoms of PMS. Of note, these drugs reduce physical symptoms better than psychologic symptoms. Ovulation suppressants are considered second-line drugs for PMS, and hence should be used only if first-line agents are ineffective or intolerable.

GnRH agonists (eg, leuprolide) can reduce physical and psychologic symptoms of PMS. Treatment can relieve breast tenderness, bloating, depression, nervous tension, anxiety, and loss of control. These agents act by suppressing release of LH and FSH from the pituitary, and thereby cause levels of estrogen and progesterone to fall to postmenopausal concentrations. Unfortunately, although GnRH agonists are effective, these drugs are expensive. In addition, with prolonged treatment (more than 6 months), there is a risk of osteoporosis (owing to loss of estrogen). The risk of osteoporosis can be overcome by giving supplemental estrogen and progestin. Nonetheless, because of the expense and need for supplemental estrogen and progestin, use of GnRH agonists is limited.

Oral contraceptives can reduce physical symptoms of PMS (eg, bloating, breast tenderness), but are generally less effective at reducing emotional symptoms. However, in 2005, investigators reported that Yasmin—an OC composed of 30 mcg ethinyl estradiol plus 3 mg drospirenone—could reduce emotional symptoms as

effectively as SSRIs. Two years later, a similar combination OC (20 mcg ethinyl estradiol plus 3 mg drospirenone), sold as YAZ, became the only OC actually approved for PMDD.

61.4.4.1.3.1.1.6

Other Remedies

Calcium supplements (1000 to 1200 mg/day) have been shown to reduce symptoms of mild to moderate PMS. In one study, 2 to 3 months of daily calcium therapy decreased depression and mood swings by 45% (vs. 28% with placebo), generalized aches and pains by 54% (vs. a 15% *increase* with placebo), food cravings by 54% (vs. 35% with placebo), and water retention by 36% (vs. 24% with placebo). Calcium did not reduce fatigue or insomnia. These data are the first clear indication that a dietary supplement can significantly reduce symptoms of PMS. Moreover, the required dosage is low—about equal to the recommended dietary intake for preventing osteoporosis (1300 mg/day for teenagers and 1000 mg/day for women ages 19 to 40). Hence, women now have two good reasons for ensuring adequate calcium intake: alleviation of PMS and protection against osteoporosis.

Spironolactone, a diuretic and aldosterone antagonist, can counteract water retention and can thereby relieve bloating and water weight gain. In addition, several well-controlled trials have shown the drug can relieve affective symptoms as well. For women with PMS, the usual dose is 100 mg/day during the luteal phase of the menstrual cycle. Of note, spironolactone is similar to drospirenone, the progestin in YAZ, an OC discussed above.

Analgesics, such as ibuprofen and naproxen, have no effect on mood, but can reduce headache, dysmenorrhea, cramps, and muscle and joint pain.

724

61.4.4.1.4

Other Adverse Effects.

Common side effects are breast tenderness, bloating, and depression.

725

61.4.4.2

Therapeutic Uses

Discussion in this chapter is limited to the noncontraceptive uses of progestins. Use for contraception is considered in [Chapter 61](#).

61.4.4.2.1 Postmenopausal Hormone Replacement Therapy.

The primary noncontraceptive use of progestins is to counteract the adverse effects of estrogen on the endometrium in women undergoing HRT. This application is discussed below.

61.4.4.2.2 Dysfunctional Uterine Bleeding.

This condition, characterized by heavy irregular bleeding, occurs when progesterone levels are insufficient to balance the stimulatory influence of estrogen on the endometrium. In the absence of sufficient progesterone, estrogen puts the endometrium in a state of continuous proliferation. Since progesterone is unavailable to induce monthly endometrial breakdown, the excessively proliferative endometrium undergoes spontaneous sloughing at irregular intervals. The result is periodic episodes of severe menstrual bleeding. Dysfunctional uterine bleeding is typically associated with anovulatory cycles. The disorder occurs most commonly in adolescents and women approaching menopause. Obese women and those with polycystic ovary syndrome are also susceptible.

Treatment has two objectives: the initial goal is cessation of hemorrhage; the long-term goal is to establish a regular monthly cycle. Excessive bleeding can be stopped by administering a progestin for 10 to 14 days. When dosing is stopped, withdrawal bleeding takes place. Bleeding is likely to be profuse and associated with cramping. Giving an oral contraceptive twice daily for 5 to 7 days can help stabilize the endometrium and thereby reduce bleeding duration.

Cyclic therapy is employed to establish a regular monthly cycle. In one regimen, oral dosing is started 10 to 14 days after the onset of each menstrual period and continued for the next 10 days. Alternatively, a progestin can be given for the first 10 days of each month. Both approaches can promote regular endometrial breakdown and menstruation.

61.4.4.2.3 Amenorrhea.

Progestins can induce menstrual flow in selected women who are experiencing amenorrhea. If endogenous estrogen levels are adequate, treatment with a progestin for 5 to 10 days will be followed by withdrawal bleeding when the progestin is stopped. If estrogen levels are low, it may be necessary to induce endometrial proliferation with an estrogen prior to giving the progestin.

61.4.4.2.4 Infertility.

Progestins are used to support an early pregnancy in women with corpus luteum deficiency syndrome and in women undergoing *in vitro* fertilization (IVF).

61.4.4.2.5 Prematurity Prevention.

In women who have delivered preterm infants, giving a progestin (17-hydroxyprogesterone caproate [Gestiva]) IM weekly from 16 to 36 weeks' gestation can reduce the incidence of preterm birth in singleton gestations, but not in multiple gestations.

61.4.4.2.6 Endometrial Carcinoma and Hyperplasia.

Progestins can provide palliation in women with metastatic endometrial carcinoma, but these drugs do not prolong life. Several months of treatment may be required for a response. The progestins employed are *medroxyprogesterone acetate* (MPA) and *megestrol acetate*. MPA is given once weekly by IM injection; megestrol acetate is administered daily by mouth.

Endometrial hyperplasia, a potentially precancerous condition, can be suppressed with progestins. Benefits derive from counteracting the proliferative effects of estrogen. Treatment options include oral therapy with megestrol acetate [Megace] or medroxyprogesterone acetate [Provera], and local delivery of a levonorgestrel using the Mirena IUD.

61.4.4.3 Preparations and Routes.

Progestins are available in oral, IM, subQ, intravaginal, intrauterine, and transdermal formulations. Older oral progestins include *medroxyprogesterone acetate* [Provera], *norethindrone* [Micronor, Nor-QD] *norethindrone acetate* [Aygestin], *megestrol acetate* [Megace], *levonorgestrel* [Plan B], and a micronized formulation of *progesterone* [Prometrium]. Newer oral progestins—*norgestimate* and *drospirenone*—are available in fixed-dose combinations with estradiol sold as Prefest and Angeliq, respectively. Intramuscular progestins are *medroxyprogesterone acetate* [Depo-Provera] and *progesterone* (in oil). *Medroxyprogesterone acetate* is also available in a formulation for subQ injection [Depo-subQ Provera 104]. *Micronized progesterone* for intravaginal use is available as progesterone gel [Crinone] and a vaginal insert [Endometrin]. Transdermal products are limited to *norethindrone* (formulated with estradiol under the name *CombiPatch*) and *levonorgestrel* (formulated with estradiol under the name *ClimaraPro*). A second-generation progestin—*etonogestrel*—used for

contraception is available by itself as a subQ implant [Implanon] and combined with estradiol in a vaginal ring [NuvaRing].

61.5 MENOPAUSAL HORMONE REPLACEMENT THERAPY

Menopausal hormone replacement therapy (HRT) consists of physiologic doses of estrogen (with or without a progestin) taken to manage symptoms caused by the loss of estrogen that occurs during menopause. Why is estrogen lost? Because ovarian follicles, which are the primary source of estrogen, decline as women grow older. Menopause typically begins around age 50, but can begin as early as 48 and as late as 55. During the initial phase, the menstrual cycle becomes irregular, anovulatory cycles may occur, and periods of amenorrhea may alternate with menses. Eventually, ovulation and menstruation cease entirely. Production of ovarian estrogens decreases gradually, coming to a complete stop several years after menstruation has ceased.

Loss of estrogen has multiple effects. Prominent among these are vasomotor symptoms (manifesting as hot flushes, also known as hot flashes and night sweats), sleep disturbances, urogenital atrophy (manifesting as vaginal dryness, itching, and burning), bone loss (manifesting as osteoporosis and increased fracture risk), and altered lipid metabolism (manifesting as increased levels of LDL cholesterol and reduced levels of HDL cholesterol). HRT can prevent or attenuate these consequences.

There are two basic regimens for HRT: (1) estrogen alone and (2) estrogen plus a progestin. The purpose of estrogen in both regimens is to replace estrogen that was lost because of menopause, and thereby control menopausal symptoms. The progestin is present for one reason only: to counterbalance estrogen-mediated stimulation of the endometrium, which can lead to endometrial hyperplasia and cancer. Accordingly, in women who no longer have a uterus, the progestin is unnecessary, and hence is omitted. It should be noted that, although progestins can protect against estrogen-induced cancer of the *uterus*, progestins appear to *increase* the risk of estrogen-induced cancer of the *breast*. In addition, progestins appear to increase the risk of adverse cardiac events.

Use of HRT has declined sharply in recent years. Why? Because evidence from two major studies has shown that the benefits of HRT are more limited than previously believed, and the risks are greater than previously appreciated. Accordingly, authorities now agree that, for most women, the benefits of *long-term* HRT to *prevent chronic disorders* do not justify the risks. However, use of *short-term* HRT to *manage menopausal symptoms* is still considered appropriate, provided the smallest effective dosage is used for the shortest time needed.

A note on nomenclature: In the discussion below, HRT that consists of *estrogen plus a progestin* is abbreviated EPT (for estrogen/progestin therapy), and HRT that consists of *estrogen alone* is

abbreviated ET (for estrogen therapy). These distinctions are needed because, as we shall see, the benefits and risks of EPT and ET are not identical.

725

61.5.1 Landmark Studies: WHI and HERS

726

The results of two trials—the Women's Health Initiative (WHI) and the Heart and Estrogen/progestin Replacement Study and its follow-up (HERS and HERS II)—have led to major changes in recommendations regarding menopausal HRT. Both trials were large, prospective, randomized, double-blind, placebo-controlled studies of the effects of HRT in menopausal women. Although these trials have limitations—for example, the results may not apply to perimenopausal women—they are nonetheless the most informative studies on HRT to date.

The WHI was designed to assess the benefits of HRT as *primary prevention* against heart disease and other disorders in *healthy* postmenopausal women. More than 27,000 women were enrolled. The study had two arms. In one arm, women with an intact uterus were given either a daily placebo or daily EPT. The specific preparation used was Prempro, a combination of conjugated estrogens (0.625 mg) and medroxyprogesterone acetate (2.5 mg). In the other arm of the trial, women who had undergone a hysterectomy received either a daily placebo or daily ET. The preparation used was Premarin, containing 0.625 mg of conjugated estrogens.

The WHI was originally scheduled to end in 2005, but both arms were terminated early. The EPT arm was stopped in July 2002, when the data showed that the risks of treatment—cardiovascular events and invasive breast cancer—exceeded any benefits. The ET arm was stopped in February 2004, when the data showed that ET conferred no protection against coronary heart disease but did increase the risk of stroke. [Table 60-1](#) summarizes the impact of EPT and ET on the incidence of major clinical events, both beneficial and adverse. Of note, neither regimen increased the incidence of death.

In contrast to the WHI, which was a *primary prevention* trial, HERS was designed to assess the benefits of HRT as *secondary prevention* in women with *established* coronary heart disease (CHD). The study enrolled 2763 postmenopausal women with an intact uterus. Participants received either placebo or daily Prempro (the same EPT regimen used in the WHI). The outcome? EPT failed to protect against myocardial infarction (MI). Worse yet, during the first few years of treatment, the risk of MI actually increased.

61.5.2 Benefits and Risks of HRT

Our understanding of the benefits and risks of HRT continues to evolve. The principal benefits of postmenopausal EPT and ET are suppression of menopausal symptoms and prevention of

osteoporosis. In addition, EPT (but not ET) can protect against colorectal cancer. Known risks of EPT include CHD, stroke, thromboembolic events, breast cancer, and dementia. ET appears safer than EPT, but still can cause stroke, deep vein thrombosis, and other undesired effects. The benefits and risks of postmenopausal EPT and ET are summarized in [Table 60-2](#).

61.5.2.1 Benefits of HRT

Treatment with estrogen plus progestin confers four primary benefits: suppression of vasomotor symptoms, prevention of urogenital atrophy, prevention of osteoporosis and related fractures, and prevention of colorectal cancer. Treatment with estrogen alone confers the first three benefits, but not the fourth. To prevent urogenital atrophy, osteoporosis, and colorectal cancer, HRT must continue lifelong. Despite long-held hopes, there is no proof that HRT improves cardiovascular health.

TABLE 60-1 Results of the Women's Health Initiative: Impact of Hormone Replacement Therapy on the Incidence of Major Adverse Clinical Events

Benefits/Harms	Events Prevented or Caused*	
	Estrogen Plus Progestin†	Estrogen Alone†
Adverse Events Prevented		
Hip fractures	5	6
Colorectal cancer	6	No effect
Adverse Events Caused		
Myocardial infarction	7	No effect
Stroke	8	12
Pulmonary embolism	8	No effect
Deep vein thrombosis	10	6
Breast cancer	8	No effect?‡
Dementia	23	No effect?§
Death	No effect	No effect

* The data represent the number of events prevented or caused each year for every 10,000 women using hormone therapy, compared with women taking placebo.

- † Estrogen plus progestin therapy is used for women who have a uterus; estrogen alone is used for women who have undergone a hysterectomy.
- ‡ Estrogen alone did not increase the incidence of breast cancer, and may have caused a slight decrease. However, the decrease was not statistically significant, and was probably due to chance.
- § Estrogen alone increases the *combined* risk of mild cognitive impairment and dementia, but the increase in dementia by itself is not statistically significant.

61.5.2.1.1 Relief of Vasomotor Symptoms.

Vasomotor symptoms (hot flashes) develop in about 70% of postmenopausal women. Episodes are characterized by sudden skin flushing, sweating, and a sensation of uncomfortable warmth. These episodes can occur at night, resulting in drenching sweats. Severe episodes can cause sleep disturbances, fatigue, and irritability. In most women, hot flashes abate within a few months to a few years; in others, they may persist for a decade or more. HRT is the most effective way to suppress symptoms.

61.5.2.1.2 Management of Urogenital Atrophy.

In the absence of estrogen, urogenital degeneration is inevitable. Of all structures in the body, the urethra and vagina have the highest concentrations of estrogen receptors. Activation of these receptors maintains the functional integrity of the urethra and vaginal epithelium. Hence, when estrogen levels decline during menopause, these structures undergo degenerative change. Atrophy of the urethra causes urge incontinence and urinary frequency. Urethritis and urinary tract infections can also occur. Atrophy of the vaginal epithelium can lead to dryness and pain with intercourse. In addition, vaginal changes can encourage the growth of pathogenic bacteria, resulting in vaginal infections. HRT, either oral or topical, can reduce some of these undesirable outcomes.

726

TABLE 60-2 Benefits and Risks of Menopausal Hormone Replacement Therapy

Benefits and Risks	Estrogen Plus Progestin	Estrogen Alone
Benefits		
Suppression of vasomotor symptoms	Yes	Yes
Preservation of urogenital integrity	Yes	Yes
Preservation of bone mineral density and prevention of osteoporotic fractures	Yes	Yes
Decreased risk of colorectal cancer	Yes	No
Risks		
Myocardial infarction	Yes	No
Stroke	Yes	Yes
Deep vein thrombosis	Yes	Yes
Pulmonary embolism	Yes	No
Breast cancer	Yes	No?*
Ovarian cancer	No	Yes
Uterine cancer	No	Yes†
Gallbladder disease	Yes	Yes
Urinary incontinence	Yes	Yes
Dementia	Yes	No?‡

* In the Women's Health Initiative (WHI), there were fewer cases of breast cancer among women using estrogen alone, compared with women taking placebo. However, the apparent decrease in risk was not statistically significant.

† Uterine cancer is a risk only for a woman with a uterus (obviously), and only if she uses estrogen in the absence of progestin, which should not be done.

‡ In the Women's Health Initiative Memory Study (WHIMS), estrogen alone increased the *combined* risk of mild cognitive impairment and dementia, but the increase in dementia by itself was not statistically significant.

61.5.2.1.3 Prevention of Osteoporosis and Related Fractures.

Osteoporosis is characterized by bone demineralization, altered bone architecture, and reduced bone strength. Compression fractures of the vertebrae are common, and can decrease height and produce a “dowager's hump.” In osteoporotic women, fractures of the hip and wrist can be caused by minimal trauma. Osteoporosis occurs in a majority (about 70%) of elderly white females; the incidence in males and black females is much lower. The condition develops following surgical removal of the ovaries as well as after natural menopause. Estrogen deficiency is the principal cause: In the absence of estrogen, bone resorption accelerates, leading to a 12% loss of bone density shortly after menopause.

In menopausal women, HRT can reduce bone resorption and slow the development of osteoporosis. More importantly, HRT can decrease the risk of osteoporotic fractures, an effect demonstrated for the first time in the WHI. It should be noted that, although HRT can indeed reduce fracture risk, the *absolute* reduction is relatively small: for every 10,000 women using HRT, there would be only 5 or 6 fewer hip fractures per year. Like the WHI, HERS showed a reduction in fracture risk. However, in the HERS study the reduction was not statistically significant. It must be stressed that HRT is primarily prophylactic: estrogen does little to reverse bone loss that has already occurred. Furthermore, beneficial effects on bone are not permanent: Following cessation of therapy, 12% of bone mass is quickly lost.

The physiology of bone, as well as the management of osteoporosis, are discussed at length in [Chapter 74](#).

61.5.2.1.4 Prevention of Colorectal Cancer.

Cancer of the colon is the fourth most common cancer in the United States and the second leading cause of cancer deaths. A meta-analysis of the results of 18 observational studies indicated that, compared with women who have never used HRT, current users have a 34% decreased risk of colon cancer. However, protection appears to decline after HRT is discontinued. The WHI was the first controlled trial to report similar outcomes.

Unfortunately, the WHI also showed something else: When colorectal cancer *is* diagnosed in women undergoing HRT, the cancer is likely to be more advanced than in women taking placebo. Furthermore, protection is limited to women using estrogen and progestin; those using estrogen alone are not helped. How might HRT confer protection? At least two mechanisms are possible: (1) reduced production of bile acids and (2) inhibited growth of colon cancer cells.

61.5.2.1.5 Improved Quality of Life?

There is a widely held belief that HRT can improve mood and make women feel more youthful and vibrant. However, data from HERS and the WHI indicate that quality-of-life (QOL) benefits are minimal. In the WHI, estrogen therapy failed to improve general health, physical function, vitality, mood, cognition, sexual satisfaction, or any other health-related QOL parameter. In HERS, QOL benefits were seen only in women with significant vasomotor symptoms. For these women, HRT was associated with improved mental health, including a reduction in depressive symptoms—with no significant change in energy level or physical function.

61.5.2.1.6 Other Benefits.

Postmenopausal HRT appears to have a positive effect on wound healing, tooth retention, and glycemic control. After menopause, a woman's skin becomes thinner and wounds heal more slowly. However, among women taking HRT, the rate of wound healing is close to that of premenopausal women. There is a direct correlation between duration of HRT and prevention of tooth loss: for every 4.2 years of HRT use, one additional tooth is retained. HRT greatly decreases the risk of developing type 2 diabetes and, among women who already have type 2 diabetes, HRT can improve glycemic control.

61.5.2.2 Adverse Effects of HRT

61.5.2.2.1 Cardiovascular Events.

The results of HERS and the WHI dramatically changed our understanding of the cardiovascular effects of HRT. In the past, we believed that HRT conferred significant cardioprotection. Why? First, estrogen has beneficial effects: It reduces levels of LDL cholesterol, raises levels of HDL cholesterol, decreases oxidation of LDL, and improves vascular endothelial function. Second, in observational studies, HRT was associated with a decreased incidence of CHD. Unfortunately, HERS and the WHI failed to demonstrate any cardiovascular benefit for HRT—but did reveal significant cardiovascular risk.

Early results of HERS, published in 1998, raised serious doubts about the cardioprotective effects of HRT. During the first year, women taking HRT experienced 50% *more* coronary events than those taking placebo. However, over the next 3 years, women taking HRT experienced 40% *fewer* coronary events. As in other studies, HRT lowered LDL cholesterol (by 11%) and raised HDL cholesterol (by 10%). The increase in coronary events during the

727

first year of HRT was both unexpected and disturbing. After all, HRT was supposed to protect against heart disease. The authors speculated that the initial increase in events was due to thrombogenic effects of HRT, whereas the subsequent decrease was due to antiatherogenic effects. If their theory was correct, then longer use of HRT should have revealed a net benefit. Unfortunately, in HERS II, a 2.7-year follow-up to the original HERS trial, the hoped-for net benefit did not materialize: The incidence of coronary events in women using HRT for the longer time was no lower than in those taking placebo. In support of this observation, the Estrogen Replacement and Atherosclerosis Trial showed that neither ET nor EPT reduces the progression of atherosclerosis, as measured by angiography. Similarly, the Women's Estrogen for Stroke Trial demonstrated that, among women with a prior ischemic stroke, ET does not reduce the incidence of stroke recurrence.

Data from the WHI indicate that, rather than protecting against cardiovascular events, both ET and EPT increase risk—although ET is somewhat safer than EPT. After 5.2 years of follow-up, women using EPT experienced a higher incidence of MI, stroke, pulmonary embolism, and deep vein thrombosis (DVT) compared with women taking placebo. Fortunately, the *absolute* increase was relatively small: For every 10,000 women using EPT, there would be 7 more heart attacks each year, 8 more strokes, 8 more pulmonary emboli, and 10 more cases of DVT. As for HRT using estrogen alone, treatment increases the risk of DVT and stroke, but not the risk of pulmonary embolism or MI. Because of increased cardiovascular risk, both arms of the WHI were terminated early.

61.5.2.2.2 Endometrial Cancer.

Estrogens increase the risk of endometrial hyperplasia and endometrial cancer, *but only when used alone*. When estrogens are combined with a progestin, the risk of endometrial cancer is reduced to the background risk. Accordingly, in women with an intact uterus, it is now standard practice to use EPT, rather than ET.

61.5.2.2.3 Breast Cancer.

Observational studies have shown that HRT using EPT increases the risk of breast cancer. Furthermore, the risk climbs with increased duration of use. The WHI was the first large, randomized controlled trial to confirm these observations: Among women using EPT for 5 or more years, the risk of invasive breast cancer was 26% higher than among women taking placebo. In absolute terms, this means that, for every 10,000 women using EPT, there would be 8 more cases of breast cancer per year. Fortunately, the increase in risk appears to fall off rapidly when EPT is discontinued.

Does therapy with estrogen alone increase risk? Apparently not. In the ET arm of the WHI, the incidence of breast cancer was *lower* among women taking estrogen compared with women taking placebo (although the decrease was not statistically significant). The seeming failure of estrogen to *promote* breast cancer was a surprise. Why? Because (1) data from laboratory studies as well as observational studies suggest that estrogen *supports* growth of breast cancer and (2) antiestrogens have been shown to *reduce* the risk of breast cancer in healthy women. Given these data, it seems unlikely that estrogen actually protected against breast cancer in the WHI, although it clearly did not increase the risk.

61.5.2.2.4 Ovarian Cancer.

In 2001, researchers reported that long-term replacement therapy with estrogen alone increases the risk of death from ovarian cancer. Specifically, among postmenopausal women using ET for 10 or more years, the mortality rate from ovarian cancer is 2.2 times the rate among nonusers. When ET is discontinued, the increased risk declines very gradually, and may still be evident after 29 years. In a separate large study, sponsored by the National Cancer Institute, researchers confirmed these results and made an additional important observation: Long-term use of estrogen *plus progestin* does *not* increase the risk of ovarian cancer. This is good news for the 8.6 million American women who use EPT—but not for the 12 million women who, because of having undergone a hysterectomy, use estrogen alone. It should be noted that ovarian cancer is relatively rare: The average woman has a 1 in 60 lifetime chance of developing the disease, compared with a 1 in 9 lifetime chance of developing breast cancer. However, even though ovarian cancer is rare, it still kills 14,000 American women each year. Women using ET should undergo regular pelvic examinations. Unfortunately, there are no proven screening strategies for ovarian cancer that will detect early disease.

61.5.2.2.5 Gallbladder Disease.

Several studies, including the WHI, HERS, and the Nurses' Health Study (NHS), have shown that use of postmenopausal ET and EPT increases the risk of cholecystitis, an inflammatory condition of the gallbladder caused by chronic gallstones. Cholecystectomy (removal of the gallbladder) is the usual remedy. In the NHS, the risk of cholecystitis depended on duration of HRT use, being highest among women using HRT for 5 or more years. In the HERS trial, the incidence of cholecystectomy among HRT users was 48% higher than among nonusers. In the WHI, both ET and EPT increased the risk of gallbladder disease.

61.5.2.2.6 Dementia.

Data from the estrogen plus progestin arm of the Women's Health Initiative Memory Study (WHIMS), released in 2003, indicate that EPT *increases* the risk of dementia, primarily Alzheimer's disease. The WHIMS evaluated 4532 subjects from the WHI, 2229 of whom were receiving EPT and 2303 of whom were receiving placebo. After a mean follow-up of 4 years, the incidence of dementia in the EPT group was twice that in the placebo group. Fortunately, although the relative risk was high (a twofold increase over placebo), the absolute risk was still relatively low: for every 10,000 women using EPT for 1 year, there would be 23 additional cases of dementia.

What about estrogen alone? According to the WHIMS data released in 2004, ET does not protect against dementia, and probably increases the risk. Among women using ET, there were more cases of mild cognitive impairment (MCI) and outright dementia than among women taking placebo—but neither increase was statistically significant. However, although ET did not increase the risk of MCI or dementia *individually*, pooling the data for MCI and dementia showed that ET *did* increase the risk for MCI plus dementia combined. Hence, like EPT, ET increases the risk of cognitive decline, although ET may not increase the risk of dementia *per se*.

61.5.2.2.7 Urinary Incontinence.

Oral estrogen is often prescribed to treat urinary incontinence in postmenopausal women. However, data from the WHI indicate that estrogen confers no benefit, whether taken alone or combined with progestin. In fact, the WHI showed that HRT *increases* the risk of incontinence in women who are not incontinent, and makes incontinence worse in women who already are. These results are unexpected, given there are biologically plausible mechanisms by which estrogen might be expected to improve urinary tract health. It may be that *intravaginal* estrogen could succeed where oral therapy has failed. However, there is a paucity of research in this area.

728

61.5.2.2.8 Minor Adverse Effects.

Minor adverse effects are common. Nausea occurs in up to 20% of women during the first 2 to 3 months of HRT. Fluid retention may result in weight gain and breast tenderness. With cyclic regimens, menstrual bleeding occurs.

729

61.5.3 Warnings

After reviewing the WHI results, the FDA ruled that *all* products intended for HRT, whether they contain estrogen alone or estrogen combined with a progestin, must carry strengthened warnings. Although only one estrogen/progestin product [Prempro] was studied in the WHI, until data on other products become available, all estrogen-containing products are assumed to carry similar risks. Accordingly, product labels must now have a *black-box warning* (the highest level of warning in drug labeling) that contains statements similar to these:

- Estrogens and progestin should not be used to prevent cardiovascular disease.
- The use of unopposed estrogens in women with intact uteri increases the risk of endometrial cancer.
- If undiagnosed persistent or recurrent abnormal vaginal bleeding occurs, rule out malignancy with endometrial sampling or other tests.
- The Women's Health Initiative (WHI) reported that postmenopausal women treated for 5 years with conjugated estrogens combined with medroxyprogesterone acetate experienced increased risks of myocardial infarction, stroke, pulmonary emboli, deep vein thrombosis, and invasive breast cancer.
- The Women's Health Initiative Memory Study (WHIMS) reported that postmenopausal women more than 65 year old treated for 4 to 5 years with conjugated estrogens combined with medroxyprogesterone acetate experienced an increased risk of developing probable dementia.
- In the absence of comparable data, products that contain other doses of other estrogens and other progestins should be assumed to have similar risks.
- There is no evidence that “natural” estrogens are more or less hazardous than “synthetic” estrogens at equiestrogenic doses.
- Prescribers should order estrogens and progestins at the lowest effective doses and for the shortest duration consistent with treatment goals and risks for the individual woman.

A warning is also included not to use estrogens during pregnancy. However, this warning is present because there is no therapeutic reason to use estrogens during pregnancy. This warning does not apply to the use of estrogens during IVF cycles.

To further minimize risks, the new labeling advises women who use HRT to perform monthly breast self-examinations, have yearly breast exams by a healthcare provider, and undergo periodic mammograms (scheduled on the basis of the patient's age and risk factors). In addition, healthcare providers should advise women on ways to reduce the risk of osteoporosis (eg, taking calcium and vitamin D supplements, performing weight-bearing exercise) and heart disease (eg, treating hypertension, maintaining a healthy weight, reducing dietary fat, avoiding smoking).

Women at high risk of complications should not use HRT. Among these are women with undiagnosed postmenopausal vaginal bleeding and women who have experienced blood clots, breast cancer, stroke, or MI.

61.5.4 Recommendations on HRT Use

Given our current understanding of the risks and benefits of HRT, the question arises: Should *any* woman use HRT? The answer is “Yes”—provided the benefits for the individual outweigh the risks. To make this assessment, risk factors for the individual must be inventoried, and the hoped-for benefits should be clearly defined. For women with significant baseline risks (eg, personal or family history of breast cancer, cardiovascular disease), the risk of harm from HRT goes up.

Over the last few years, several expert sources issued revised recommendations on HRT. The recommendations below represent a composite of those offered by three groups: the North American Menopause Society, the FDA, and the U.S. Preventive Services Task Force (USPSTF). These recommendations are based in large part on data from the WHI and HERS.

The recommendations below are based on studies using Premarin and Prempro. In the absence of data proving otherwise, we must assume that all other estrogen and estrogen/progestin products carry similar risks. Likewise, until proof is available, we cannot assume that ET is significantly safer than EPT.

61.5.4.1 General Recommendations

In order to balance benefits and risks, an individual risk profile should be compiled for every woman considering HRT. All candidates for HRT should be informed of known risks. Women with multiple risk factors should consider alternative therapies. For most women, the benefits of *long-term* HRT for disease prevention do not outweigh the risks, and hence long-term HRT should generally be avoided. Conversely, the benefits of short-term therapy (less than 4 years) to treat menopausal symptoms often *do* justify the risks. To keep risk as low as possible, HRT

should be used in the lowest dosage and for the shortest time needed to accomplish treatment goals.

61.5.4.2 Use for Approved Indications

HRT has only three approved indications:

- Treatment of moderate to severe vasomotor symptoms associated with menopause
- Treatment of moderate to severe symptoms of vulvar and vaginal atrophy associated with menopause
- Prevention of postmenopausal osteoporosis

HRT should be restricted to achieving one or more of these goals. With the first two indications, duration of treatment is relatively short (typically 3 to 4 years), and hence the risk of harm is relatively low—except for women with established heart disease. In contrast, prevention of osteoporosis requires lifelong HRT, and hence the risk of harm is higher.

The only indication for long-term *progestin* therapy is protection against endometrial cancer, which could be caused by unopposed estrogen. Accordingly, use of EPT should be limited to women with an intact uterus. For women who have had a hysterectomy, estrogen alone should be used.

61.5.4.2.1 Treatment of Vasomotor Symptoms.

HRT is the most effective treatment for vasomotor symptoms (ie, hot flashes, night sweats), providing welcome relief for millions of women. Do the benefits of short-term therapy justify the risks? Probably, especially for women with severe symptoms and a favorable risk profile. To increase safety, the lowest effective dosage should be employed. Furthermore, because vasomotor symptoms subside over time, the need for continued HRT should be reassessed at regular intervals.

729

TABLE 60-3 Intravaginal Estrogens for Menopausal Hormone Replacement Therapy*

Generic Name	Trade Name	Usual Maintenance Dosage
Vaginal Creams		
Conjugated estrogens	Premarin	Apply 0.5–2 gm/day (625 mcg conjugated estrogens/gm) [†]
Estropipate	Ogen	Apply 2–4 gm/day (1.5 mg estropipate/gm) [†]
Estradiol	Estrace	Apply 1–2 gm 1–3 times/wk (100 mcg estradiol/gm)
Vaginal Rings		
Estradiol	Estring	This 2-mg ring releases 7.5 mcg/day for 90 days
Estradiol acetate	Femring	The 12.4-mg ring releases 50 mcg/day for 90 days* The 24.8-mg ring releases 100 mcg/day for 90 days*
Vaginal Tablets		
Estradiol hemihydrate	Vagifem	Insert 1 tablet (25 mcg) twice a week

* All intravaginal estrogens are used to treat urogenital atrophy. With one product—Femring—estradiol is absorbed in amounts sufficient to cause systemic effects, both beneficial (eg, suppression of vasomotor symptoms) and adverse (eg, increased risk of thrombosis).

† Administer cyclically (3 weeks on and 1 week off). For short-term use only.

Are there any alternatives to HRT for controlling vasomotor symptoms? Yes—but they are less effective than estrogen. Drugs shown to offer some benefit include selective serotonin reuptake inhibitors, or SSRIs (eg, fluoxetine [Prozac], sertraline [Zoloft]), and certain antiseizure drugs (eg, clonidine [Catapres], gabapentin [Neurontin]). By contrast, plant-derived estrogens (prepared from soy and black cohosh), which were previously believed to reduce symptoms, were proved ineffective in recent controlled trials.

61.5.4.2.2 Treatment of Symptoms of Vulvar and Vaginal Atrophy.

Estrogen is the most effective treatment for reducing symptoms of menopause-related vulvar and vaginal atrophy, characterized by dryness, irritation, itching and painful intercourse.

Because systemic estrogen carries significant risks, the FDA recommends that, if HRT is being used solely to manage vulvar and vaginal symptoms, a topical estrogen formulation should be considered. Options include vaginal creams, vaginal tablets, and vaginal rings ([Table 60-3](#)). Although long-term data are lacking, it seems likely that topical estrogen is safer than oral estrogen. Why? Because, with nearly all topical formulations, blood levels of estrogen remain low. The only exception is the Femring, which releases enough estrogen to cause significant systemic effects.

61.5.4.2.3 Prevention of Osteoporosis.

HRT reduces postmenopausal bone loss, and thereby decreases the risk of osteoporosis and related fractures. Unfortunately, when HRT stops, bone mass rapidly decreases by about 12%. Hence, to maintain bone health, HRT must continue lifelong. As a result, the risk of harm is high. Accordingly, alternative treatments are preferred. In fact, labeling of HRT products now must carry the following advice: *When this product is prescribed solely to prevent postmenopausal osteoporosis, approved nonestrogen treatments should be carefully considered. Furthermore, HRT should be considered only for women with significant risk of osteoporosis, and only when that risk outweighs the risks of HRT.* As discussed in [Chapter 74](#) (Drugs Affecting Calcium Levels and Bone Mineralization), effective alternatives to HRT include raloxifene [Evista], bisphosphonates (eg, alendronate [Fosamax]), calcitonin [Miacalcin], and teriparatide [Forteo]. Of course, all women (not to mention men) should practice primary prevention of bone loss. How? By ensuring adequate intake of calcium and vitamin D, performing regular weight-bearing exercise, and avoiding smoking and excessive alcohol use.

61.5.4.3 Inappropriate Uses: Attempted Prevention of Heart Disease and Dementia

61.5.4.3.1 Heart Disease.

As noted above under *Warnings*, HRT should *not* be prescribed for the express purpose of preventing heart disease. There is no evidence that either EPT or ET confers cardiovascular protection, whereas there *is* evidence that these regimens promote cardiovascular harm. Specifically, EPT increases the risk of MI, pulmonary embolism, DVT, and stroke, and ET increases the risk of DVT and stroke (but not the risk of MI or pulmonary embolism).

To reduce risk of cardiovascular events, postmenopausal women should be counseled about alternative ways to promote cardiovascular health. Among these are avoiding smoking,

performing regular aerobic exercise, decreasing intake of saturated fats, and taking prescribed drugs to treat hypertension, diabetes, and high cholesterol.

61.5.4.3.2 Alzheimer's Disease.

HRT should not be used to prevent Alzheimer's disease. There is no evidence that either EPT or ET can protect against dementia, whereas there *is* evidence that EPT can *cause* dementia, and that ET can increase the combined risk of dementia and mild cognitive impairment.

61.5.5 Discontinuing HRT

Because the risks of HRT are greater than previously appreciated, many women are discontinuing treatment. Unfortunately, discontinuation may cause vasomotor symptoms to return, typically within 4 days of the last HRT dose. Women who had severe symptoms before initiating HRT are at highest risk of developing intolerable symptoms when they stop.

What's the best way to quit? No one knows. There are two basic methods: immediate cessation and tapering slowly. However, there are no controlled studies to indicate which option might result in fewer symptoms. For women who choose to taper slowly, again there are two basic options, referred to as “dose tapering” and “day tapering.” With dose tapering, dosing is done every day, but the size of the daily dose is gradually reduced. If intense symptoms return following a dosage reduction, further reductions should be delayed until symptoms improve. With day tapering, the daily dose remains unchanged, but the number of days between doses is gradually increased—starting with dosing every other day, then every third day, and so on. Regardless of which method is used—dose tapering or day tapering—only the dosage of *estrogen* should be lowered; for women on EPT, the *progestin dosage should remain unchanged*. Why? Because lowering the progestin dosage might permit estrogen to stimulate endometrial growth, thereby posing a risk of endometrial hyperplasia.

730

731

61.5.6 Open Questions

Despite the valuable information provided by HERS and the WHI, women considering HRT could use even more information to guide their choice. Important questions that remain unanswered include the following:

- Are Prempro and Premarin (the preparations employed in the WHI and HERS) safer in lower doses? If so, are they effective in lower doses?

- Are other estrogens and progestins safer than the hormones in Prempro and Premarin? If so, are they also effective? Information would be especially welcome for recently approved estrogens.
- What are the risks of intravaginal estrogen compared with oral estrogens (when the objective is preventing vaginal atrophy)?
- When the HRT regimen contains a progestin, which dosing schedule is safer: continuous daily progestin or sequential progestin?
- How long should a woman remain on HRT?
- Are there genetic factors that significantly alter the risk/benefit ratio of HRT?
- Do the results of the WHI and HERS apply to perimenopausal women (in addition to postmenopausal women)?

When these questions have been answered, the risks and benefits of treatment options will be more clear, and hence women will be able to choose (or reject) HRT with greater confidence than is possible today.

61.5.7 Drug Products for HRT

61.5.7.1 Preparations

Preparations for HRT are listed in [Tables 60-3](#), [60-4](#), and [60-5](#). Administration may be oral, transdermal, or intravaginal. The oral estrogens employed most often are conjugated equine estrogens [Premarin] (prepared by extraction from *pregnant mares' urine*), estradiol [Estrace], estradiol acetate [Femtrace], and estropipate [Ogen]. For transdermal therapy, estradiol is the only estrogen employed, formulated in patches, gels, a spray, and an emulsion. Oral estrogen/progestin combinations include conjugated equine estrogens/medroxyprogesterone acetate [Prempro and Premphase] and estradiol/norethindrone acetate [Activella and Femhrt]. Combination estrogen/progestin patches include estradiol/norethindrone [Combipatch] and estradiol/levonorgestrel [ClimaraPro]. Intravaginal products—formulated as tablets, creams, and rings—are used primarily to manage symptoms of urogenital atrophy.

731

732

TABLE 60-4 Oral Drugs for Menopausal Hormone Replacement Therapy

Generic Name	Trade Name	Usual Dosage
Estrogens		
Conjugated estrogens, equine	Premarin	0.3–0.625 mg/day
Conjugated estrogens A, synthetic	Cenestin	0.3–1.25 mg/day
Conjugated estrogens B, synthetic	Enjuvia	0.3–1.25 mg/day
Estradiol, micronized	Estrace	0.5–2 mg/day
Estradiol acetate	Femtrace	0.45–1.8 mg/day
Estropipate	Ogen, Ortho-Est	0.625 mg/day
Esterified estrogens	Menest	0.3–1.25 mg/day
Ethinyl estradiol	Estinyl	0.02 mg/day
Progestins*		
Medroxyprogesterone acetate	Provera, Depo-subQ Provera 104	2.5–10 mg*
Megestrol acetate	Megace	20–40 mg*
Norethindrone	Micronor, Nor-QD	0.5 mg*
Norethindrone acetate	Aygestin	5 mg*
Norgestrel	Ovrette	0.075 mg*
Progesterone (micronized)	Prometrium	100–200 mg*
Estrogen/Progestin Combinations		
Conjugated estrogens/ medroxyprogesterone acetate	Prempro	0.3/1.5–0.625/2.5 mg daily
Conjugated estrogens/ medroxyprogesterone acetate	Premphase	Days 1–14: 0.625 mg estrogen (alone) daily Days 15–28: 0.625/5 mg estrogen/progesterone daily
Estradiol/norgestimate	Prefest	1 mg estradiol every day; 0.09 mg norgestimate in a repeating cycle of 3 days on and 3 days off
Estradiol/norethindrone	Activella	1 mg/0.5 mg daily

Ethinyl estradiol/norethindrone	Femhrt	5 mcg/1 mg daily
Estradiol/drospirenone	Angeliq	5 mcg/1 mg daily

* Progestins are used to counteract the effects of estrogen on the uterus. The progestin listed can be used when the regimen calls for taking estrogen and progestin separately, rather than using a combination product. In estrogen/progestin regimens, the estrogen is taken daily, and the progestin is taken daily or intermittently (eg, 14 days on, 14 days off).

TABLE 60-5 Transdermal Drugs for Menopausal Hormone Replacement Therapy

Generic Name	Trade Name	Strength (mcg absorbed/day)	Application
Estrogens			
Transdermal Patches			
Estradiol	Alora	25, 50, 75, 100	Twice weekly
	Climara	25, 37.5, 50, 60, 75, 100	Once weekly
	Esclim	25, 37.5, 50, 75, 100	Twice weekly
	Estraderm	50, 100	Twice weekly
	Menostar	14	Once weekly
	Vivelle	25, 37.5, 50, 75, 100	Twice weekly
	Vivelle-Dot	25, 37.5, 50, 75, 100	Twice weekly
Topical Emulsion			
Estradiol hemihydrate	Estrasorb	50	Once daily
Topical Gel			
Estradiol	EstroGel	0.75 mg is applied*	Once daily
	Elestrin	0.52–1.04 mg is applied*	Once daily
	Divigel	0.25–1 mg is applied*	Once daily
Spray Mist			
Estradiol	Evamist	1.53–4.59 mg is applied*	Once daily
Estrogen/Progestin Combinations			
Transdermal Patches			
Estradiol/norethindrone	CombiPatch	50/140, 50/250	Twice weekly
Estradiol/levonorgestrel	ClimaraPro	45/15	Once weekly

* Application produces blood levels of estrogen and estrone similar to those seen in the follicular phase of the ovulatory cycle.

61.5.7.2 Dosing Schedules

Every woman undergoing systemic HRT receives an estrogen, and every woman with a uterus also receives a progestin to counteract the stimulant effects of estrogen on the endometrium.

Several schedules of administration may be employed. In the WHI and HERS, both estrogen and progestin were administered *continuously*, thereby eliminating monthly bleeding. An alternative is to give estrogen continuously but give the progestin cyclically (eg, on calendar days 15 through 28). However, cyclic progestin has the disadvantage of promoting monthly bleeding, which may explain why most women use continuous dosing.

Vaginal estrogens can be given continuously for 1 to 2 weeks, followed by dosing 1 to 3 times per week, titrating the dosing schedule based on symptoms. Estring remains in the vagina for 3 months, after which it is removed and replaced with a new ring.

61.5.7.2.1

KEY POINTS	
<ul style="list-style-type: none">▪ Estradiol is the principal endogenous estrogen.▪ Progesterone is the principal endogenous progestational hormone.▪ The first half of the 28-day menstrual cycle is called the follicular phase. The second half is called the luteal phase.▪ During the follicular phase, estrogens produced by maturing ovarian follicles cause proliferation of the endometrium.▪ During the luteal phase, progesterone produced by the corpus luteum causes the endometrium to become more vascular and the endometrial glands to secrete glycogen.▪ Toward the end of the menstrual cycle, progesterone levels decline, causing breakdown of the endometrium, which results in menstrual bleeding.▪ In addition to their role in the menstrual cycle, estrogens are required for the growth and maturation of the uterus, vagina, fallopian tubes, and breasts. Estrogens also control pigmentation of the nipples and genitalia.	732
<ul style="list-style-type: none">▪ Estrogens suppress bone mineral resorption, and thereby have a positive effect on bone mass.▪ Estrogens raise levels of HDL cholesterol and reduce levels of LDL cholesterol. These actions partially explain the low incidence of coronary heart disease in premenopausal women.▪ Nausea is the most common adverse effect of exogenous oral estrogens.	733

- Prolonged use of estrogens alone is associated with an increased risk of endometrial hyperplasia and endometrial carcinoma. However, when estrogens are used in combination with a progestin, there is little or no risk of this cancer.
- When combined with a progestin, estrogens increase the risk of breast cancer in postmenopausal women. Recent data suggest that estrogen *alone* does not increase breast cancer risk.
- Estrogens are classified in FDA Pregnancy Category X—not because they are especially harmful, but because they have no legitimate use in pregnancy.
- Symptoms of menopause result from a decline in estrogen production by the ovaries.
- Two basic regimens are used for HRT: estrogen alone and estrogen combined with a progestin. The purpose of the estrogen is to compensate for estrogen that was lost because of menopause. The progestin is present to counteract the adverse effects that unopposed estrogen has on the endometrium. In women who no longer have a uterus, the progestin is omitted.
- The Women's Health Initiative (WHI) and the Heart and Estrogen/progestin Replacement Study (HERS)—two large, randomized, placebo-controlled trials—have given us the most statistically valid data to date on the benefits and risks of HRT.
- The principal benefits of HRT are suppression of vasomotor symptoms, prevention of urogenital atrophy, and prevention of bone loss and osteoporosis.
- HRT does not prevent cardiovascular disease, and should not be used for this purpose. To reduce cardiovascular risks, postmenopausal women should avoid smoking, perform regular exercise, decrease intake of saturated fats, and take drugs as indicated to treat hypertension, diabetes, and high cholesterol.
- The major risks of HRT are MI, pulmonary embolism, DVT, stroke, breast cancer, gallbladder disease, and dementia.
- The benefits of using HRT short term to reduce vasomotor symptoms generally outweigh the risks. To keep risk low, women should use the smallest effective dose for the shortest time needed.

- The benefits of using HRT short term to manage urogenital symptoms probably outweigh the risks. However, if this is the only reason for HRT use, a topical estrogen should be considered.
- For protection against osteoporosis, HRT must be taken long term. When HRT is discontinued, 12% of bone mass is lost. Because of the risks associated with prolonged HRT, alternative therapies are preferred. Among these are raloxifene, bisphosphonates, calcitonin, and teriparatide. To promote bone health, all women should perform regular weight-bearing exercise, ensure adequate intake of calcium and vitamin D, and avoid smoking and excessive alcohol.
- Premenstrual syndrome (PMS) consists of a constellation of psychologic and physical symptoms that develop in the luteal phase of the menstrual cycle and resolve with menses.
- The psychologic symptoms of PMS—including irritability, depression, mood lability, crying spells, and social withdrawal—are more disabling than the physical symptoms.
- To make a diagnosis of PMS, symptoms must be sufficiently intense, and must be absent between days 4 and 12 of the menstrual cycle.
- Fluoxetine [Prozac] and other SSRIs are the most effective drugs known for PMS. Reduction of psychologic symptoms is greater than reduction of physical symptoms (eg, breast tenderness, bloating, headache).

61.5.7.2.2

Summary of Major Nursing Implications*

61.5.7.2.2.1

ESTROGENS

Conjugated estrogens

Conjugated estrogens, synthetic

Estradiol

Estradiol acetate

	Estropipate	
	Ethinyl estradiol	
61.5.7.2.2....	Preadministration Assessment	
61.5.7.2.2....	Therapeutic Goal	
	Estrogens are used primarily for contraception (see Chapter 61) and for menopausal HRT, which has three approved indications: treatment of vasomotor symptoms, treatment of symptoms related to vulvar and vaginal atrophy, and prevention of osteoporosis. Indications unrelated to HRT are female hypogonadism, prostate cancer, and dysfunctional uterine bleeding.	
61.5.7.2.2....	Baseline Data	
	Assessment should include a breast examination, pelvic examination, lipid profile, mammography, and blood pressure measurement. If the indication for HRT is vasomotor symptoms, menopause should be verified by a serum FSH level.	
61.5.7.2.2....	Identifying High-Risk Patients	
	Estrogens are <i>contraindicated</i> for patients with estrogen-dependent cancers, undiagnosed abnormal vaginal bleeding, active thrombophlebitis or thromboembolic disorders, or a history of estrogen-associated thrombophlebitis, thrombosis, or thromboembolic disorders. In addition, estrogens are <i>contraindicated</i> during pregnancy—not because they are especially harmful, but because they offer no proven benefit.	733 734
61.5.7.2.2....	Implementation: Administration	
61.5.7.2.2....	Routes	
	Oral, IM, IV, transdermal, and intravaginal.	

61.5.7.2.2....

Administration

61.5.7.2.2....

Transdermal Patch

Give the patient the following instructions for using estradiol transdermal patches:

- Apply to an area of clean, dry, intact skin on the abdomen or some other region of the trunk (but not the breasts or waistline) by pressing the patch firmly in place for 10 seconds.
- If the patch falls off, reapply the same patch or, if necessary, apply a new patch.
- Remove the old patch and apply a new patch once or twice weekly according to the product specifications.
- Rotate the application site such that the same site is not used more than once each week.

61.5.7.2.2....

Transdermal Emulsion

Instruct the patient to apply the emulsion each morning to the top of both thighs and the back of both calves.

61.5.7.2.2....

Transdermal Gel

Instruct the patient to apply the gel once daily after showering to one arm, from the shoulder to the wrist.

61.5.7.2.2....

Transdermal Spray

Instruct the patient to apply 1, 2, or 3 sprays once daily to the inner forearm, and then let it dry at least 2 minutes before dressing and at least 30 minutes before washing.

61.5.7.2.2....

Intravaginal Cream

Instruct the patient to apply estrogen cream high into the vagina, usually at bedtime, using the applicator provided.

61.5.7.2.2....

Intravaginal Ring

Instruct the patient to insert the ring as deeply as possible into the vaginal vault, and to leave it in place for 3 months, after which it should be removed, and then replaced with a new ring if indicated.

61.5.7.2.2....

Dosing Schedules for HRT

Women with an intact uterus should receive estrogen plus progestin, whereas women who have had a hysterectomy should use estrogen alone. In both cases, dosing with oral estrogen is done *daily*. With estrogen plus progestin, the progestin component may be given *daily* or cyclically on 10 days per month.

61.5.7.2.2....

Ongoing Evaluation and Interventions

61.5.7.2.2....

Monitoring Summary

The patient should receive a yearly follow-up breast and pelvic exam.

61.5.7.2.2....

Minimizing Adverse Effects

61.5.7.2.2....

Nausea

Nausea is common early in treatment but diminishes with time. **Inform the patient that nausea can be reduced by taking estrogens with food and by dosing at night.**

61.5.7.2.2....

Endometrial Hyperplasia and Cancer

Therapy with estrogen alone during menopause increases the risk of endometrial carcinoma. Adding a progestin to the regimen lowers this risk to the pretreatment level. **Instruct the patient to notify the prescriber if persistent or recurrent vaginal bleeding develops, so that the possibility of endometrial carcinoma can be evaluated.**

61.5.7.2.2....

Breast Cancer

Estrogen, combined with a progestin, produces a small increase in the risk of breast cancer in postmenopausal women. **To minimize risk, advise patients to perform monthly breast self-exams, have yearly breast exams by a healthcare**

professional, and receive periodic mammograms. Estrogen alone does not seem to increase breast cancer risk.

61.5.7.2.2....

Ovarian Cancer

In postmenopausal women, giving estrogen alone—but not estrogen plus a progestin—increases the risk of ovarian cancer. **Advise women using estrogen alone to undergo periodic evaluation for ovarian cancer.**

61.5.7.2.2....

Cardiovascular Events

Therapy with estrogen plus a progestin increases the risk of MI, pulmonary embolism, DVT, and stroke. Estrogen alone increases the risk of DVT and stroke (but not MI and pulmonary embolism). **To reduce cardiovascular risk, advise women to avoid smoking, perform regular exercise, decrease intake of saturated fats, and take appropriate drugs to treat hypertension, diabetes, and high cholesterol.**

61.5.7.2.2....

Effects Resembling Those Caused by Oral Contraceptives

Use of estrogens for noncontraceptive purposes can produce adverse effects similar to those caused by oral contraceptives (eg, abnormal vaginal bleeding, hypertension, benign hepatic adenoma, reduced glucose tolerance). Nursing implications regarding these effects are summarized in [Chapter 61](#).

61.5.7.2.2....

Minimizing Adverse Interactions

The interactions of estrogens are probably similar to those seen with oral contraceptives. Implications regarding these interactions are summarized in [Chapter 61](#).

61.5.7.2.2.2

PROGESTINS

Levonorgestrel

Medroxyprogesterone acetate

Megestrol acetate

	<p>Norethindrone</p> <p>Norethindrone acetate</p> <p>Norgestimate</p> <p>Norgestrel</p> <p>Progesterone</p> <p>17-Hydroxyprogesterone caproate</p>	
61.5.7.2.2....	<p>Preadministration Assessment</p>	
61.5.7.2.2....	<p>Therapeutic Goal</p> <p>Progestins are used for contraception (see Chapter 61) and to counteract endometrial hyperplasia that could be caused by unopposed estrogen during HRT. Other uses include dysfunctional uterine bleeding, amenorrhea, endometriosis, and support of pregnancy in women with corpus luteum deficiency. Progestins are also used in IVF cycles and to prevent prematurity in women at high risk for preterm birth.</p>	<p>734</p> <p>735</p>
61.5.7.2.2....	<p>Baseline Data</p> <p>The physical examination should include breast and pelvic examinations.</p>	
61.5.7.2.2....	<p>Identifying High-Risk Patients</p> <p>Progestins are <i>contraindicated</i> in the presence of undiagnosed abnormal vaginal bleeding. <i>Relative contraindications</i> include active thrombophlebitis or a history of thromboembolic disorders, active liver disease, and carcinoma of the breast.</p>	
61.5.7.2.2....	<p>Implementation: Administration</p>	
61.5.7.2.2....	<p>Routes</p> <p>Oral, IM, transdermal, intravaginal.</p>	

61.5.7.2.2....

Administration

Advise patients to take oral progestins with food if GI upset occurs.

61.5.7.2.2....

Ongoing Evaluation and Interventions

61.5.7.2.2....

Minimizing Adverse Effects

61.5.7.2.2....

Gynecologic Effects

Inform patients about potential side effects (eg, breakthrough bleeding, spotting, and amenorrhea). Instruct patients to notify the prescriber if abnormal vaginal bleeding occurs.

61.5.7.2.2....

Teratogenic Effects

High-dose therapy during the first 4 months of pregnancy has been associated with an increased incidence of birth defects (limb reductions, heart defects, masculinization of the female fetus). Accordingly, use of progestins during early pregnancy is not recommended.

* Patient education information is highlighted as **blue text**.

⁶²CHAPTER 61 Birth Control

MARILYNN FREDERIKSEN

RICH LEHNE

Birth control can be accomplished by interfering with the reproductive process at any step from gametogenesis to nidation (implantation of a fertilized ovum). Pharmacologic methods of contraception include oral contraceptives, etonogestrel implants, injectable medroxyprogesterone acetate, intrauterine devices, vaginal rings, and transdermal patches. Nonpharmacologic methods include surgical sterilization (tubal ligation, vasectomy), mechanical devices (condom, diaphragm, cervical cap), and avoiding intercourse during periods of fertility (calendar method, temperature method, cervical mucus method).

Although we have birth control methods that are safe and effective, statistics show that unwanted pregnancy is common—suggesting that available methods are not used as widely or as effectively as they could be, and that alternatives to current methods are needed. In the United States, 49% of pregnancies are unplanned—which is no surprise given that 50% of women who are not planning a pregnancy fail to use contraception. Teenagers have the highest rate of unplanned pregnancies: Of all pregnancies that occur in this group, 82% are unplanned. Among women ages 20 to 24, the rate is somewhat lower: 58%. Of the unplanned pregnancies that occur every year, about 52% are carried to term, while 48% end in abortion.

Most of this chapter focuses on combination oral contraceptive pills—the most widely used *reversible* form of contraception. Sterilization is used more often, but is not reversible. In preparing to study these agents and other forms of contraception, you should review [Chapter 60](#), paying special attention to information on the menstrual cycle and the physiologic and pharmacologic effects of estrogens and progestins.

^{62.1}EFFECTIVENESS AND SAFETY OF BIRTH CONTROL METHODS**^{62.1.1} Effectiveness**

The effectiveness of a birth control method can be expressed as the percentage of unplanned pregnancies that occur while using the method. Employing this criterion, [Table 61-1](#) compares the effectiveness of the major birth control methods. As we can see, the most effective methods are Implanon, Depo-Provera, intrauterine devices (IUDs), and sterilization. Oral contraceptives (OCs) and the contraceptive ring and contraceptive patch are close behind. The least reliable methods include barrier methods, periodic abstinence, spermicides, and withdrawal.

Note that [Table 61-1](#) contains two columns of figures, one labeled *perfect use* and the other *typical use*. The *perfect use* figures represent pregnancy rates when a method of birth control is employed exactly as it should be (ie, consistently and with proper technique). The *typical use* figures represent pregnancy rates observed in actual practice. The higher pregnancy rates reported in the *typical use* column are largely an indication that methods of birth control are not always used when and as they should be.

62.1.2 Safety

Determining the relative safety of birth control measures is complex. Part of the difficulty lies with the fact that much of our information on the adverse effects of OCs was gathered when these agents were employed in doses higher than those employed today. Newer data show that OCs, as currently prescribed, are considerably safer than indicated by older studies. An additional complication stems from the fact that the risk of mortality associated with pregnancy and delivery is greater than the risk associated with any form of birth control. Hence, a birth control measure that is inherently more safe than others, but is also less effective, may become relatively less safe when the dangers associated with a greater pregnancy rate are factored in.

736

737

TABLE 61-1 Effectiveness of Birth Control Methods

Birth Control Method	Failure Rate* (%)	
	Perfect Use†	Typical Use‡
No method	85	85
Etonogestrel subdermal implant [Implanon]	0.05	0.05
Surgical sterilization		
<i>Female: tubal ligation</i>	0.2	0.4
<i>Male: vasectomy</i>	0.1	0.15
Intramuscular medroxyprogesterone acetate [Depo-Provera]	0.3	3
Intrauterine devices		
<i>Copper T 380A [ParaGard]</i>	0.8	<1
<i>Levonorgestrel T [Mirena]</i>	0.1	0.1
Oral contraceptives		
<i>Combination pills</i>	0.1	3
<i>Progestin-only pills</i>	0.5	3
Vaginal contraceptive ring [NuvaRing]	0.3	8
Contraceptive patch [Ortho Evra]	0.3	8
Condoms		
<i>Male</i>	2	15
<i>Female [Reality]</i>	5	21
Diaphragm with spermicide	6	20
Cervical cap	6	18
Contraceptive sponge [Today Sponge]		
<i>Parous</i>	20	32
<i>Nulliparous</i>	9	16
Spermicide alone	18	29
Periodic abstinence	2–10	25
Withdrawal	4	27

* Failure rate = percentage of women who have an unplanned pregnancy during first year of use.

† Perfect use = failure rate that would be expected if the birth control method were practiced exactly as it should be.

‡ Typical use = failure rate usually observed in actual practice.

Keeping the above provisos in mind, we can make the following observations on OC safety. Of the contraceptive methods available, OCs produce the broadest spectrum of adverse effects, ranging from nausea to menstrual irregularity to rare thromboembolic disorders. However, despite their wide variety of undesired actions, when used by healthy women, OCs produce no greater mortality than any other form of birth control. The lowest mortality rate is seen when barrier methods (diaphragm, condom, cervical cap) are used together with early abortion for contraceptive failure.

62.2 SELECTING A BIRTH CONTROL METHOD

[Figure 61-1](#) indicates the percentage of users who select a particular form of birth control. Perhaps surprisingly, the method chosen most frequently is sterilization: female sterilization (tubal ligation) plus male sterilization (vasectomy) are selected by over 36% of birth control users. OCs or male condoms are chosen by most of the remaining birth control users. Diaphragms, periodic abstinence, IUDs, and other techniques account for a small fraction of birth control use.

Several factors should be considered when choosing a method of birth control. Chief among these are *effectiveness*, *safety*, and *personal preference*. As indicated in [Table 61-1](#), the most effective methods are etonogestrel subdermal implants [Implanon], intramuscular medroxyprogesterone acetate [Depo-Provera], sterilization, and IUDs. Three other methods—OCs, the contraceptive ring [NuvaRing], and the contraceptive patch [Ortho Evra]—are close behind. The remaining methods—condoms, the sponge, diaphragm, cervical cap, spermicides, and periodic abstinence—must be used in a near-perfect fashion to afford any reasonable level of protection.

When factoring safety into the selection equation, several guidelines apply. Combination OCs should be avoided by women with certain cardiovascular disorders (see below), as well as by women over 35 years old who smoke. For women in these categories, an alternative method (eg, diaphragm, progestin-only pill, or IUD) is preferable. Although OCs are effective and relatively convenient, they can also cause many side effects. Accordingly, women who consider the benefit/risk ratio unfavorable should be ad

737

Figure 61-1 **Percentage use for birth control methods, United States, 2002.** *Note:* The segment labeled “other methods” refers to Norplant (no longer used), Lunelle, contraceptive patches, spermicides, cervical caps, female condoms, and other techniques.

Data from the Centers for Disease Control and Prevention.

vised about alternative contraceptive techniques. Women who are not in a mutually monogamous relationship, and hence are at risk for a sexually transmitted disease (STD), should not use an IUD.

Personal preference is a major factor in providing the motivation needed for consistent implementation of a birth control method. Because even the best form of contraception will be less effective if improperly practiced, the importance of personal preference cannot be overemphasized. Practitioners should take pains to educate patients about the contraceptive methods available so that selection and use can be based on understanding.
